TU-01. Characterisation of Antiferromagnets.

K. O'Grady[1] and G. Vallejo-Fernandez[1]
1. University of York, York, United Kingdom

The characterisation of antiferromagnets (AFs) for almost all applications is very challenging because intrinsically an AF gives little or no signal. Above the Néel temperature (TN) AF materials exhibit paramagnetic behaviour in a similar manner to a ferromagnet above its Curie point. This does allow for the determination of the Néel temperature but reveals little about the behaviour of the material once the AF order is established. Historically the structure of AFs was determined using techniques such as neutron scattering [1, 2] and more recently some studies have been undertaken using X-ray techniques such as XMCD [3]. However such techniques and particularly neutron scattering require large samples with dimensions of the order of millimetres. For all technological applications AF materials are used in thin film form and hence such techniques are not available for use due to the very long counting times that would be required. A second problem with AF materials is that their behaviour has not been well established until recently. For example Néel predicted the existence of AF domains but there are very few reports of their observation [4, 5]. Their behaviour is not well understood because conventional domain theory is based around the existence of magnetostatic energy in a conventional ferromagnet which is not present in an AF. Other critical factors associated with the structure of thin films are also poorly understood. Principal amongst these is that in polycrystalline films a granular structure will exist but the question then arises as to at what critical grain size will single domain behaviour be observed? In single crystal or large grain thin films where presumably AF domains will form, what is the nature and consequence of domain wall pinning? In this tutorial lecture the fundamental nature of antiferromagnets will be discussed addressing metals, alloys and oxides. However the focus will be on those materials which have, or are most likely to find application in spintronic devices. Techniques that allow the behaviour of AF thin films at least to be inferred will also be discussed. These are principally associated with the measurement of exchange bias systems where a ferromagnetic layer is used as an indicator of the structure of an underlying AF. However in exchange bias systems it is also the case that the exchange field from the ferromagnet causes a reaction and possibly a change of order in the AF. This concept is the basis of the so-called York Protocols which allow for the measurement of the behaviour of granular, generally sputtered, AF films. The underlying York Model of Exchange Bias developed in 2008 will then be discussed in detail as it allows for the full characterisation of granular films and in particular the determination of the anisotropy constant of AFs. This model has been used by all the major manufacturers of hard drive read heads to design improved AF layers in their stacks. For the case of large grain or single crystal thin films a brief review of complex large scale computer models of possible domain structures will be presented with the emphasis placed on a simple strong domain wall pinning model which has been found to replicate qualitatively the observed behaviour in such structures. Finally the effect of reduced dimensions on the behaviour of AFs will be presented as it is well established that small lithographically defined structures containing AF layers behave quite differently to bulk films.

TU-02. Making the Invisible Visible: Probing Antiferromagnetic Order in Novel Materials.

E. Arenholz[1,2]
1. Advanced Light Source, Lawrence Berkeley National Laboratory, Berkeley, CA, United States; 2. Material Sciences and Enegineering, University of California, Berkeley, CA, United States

In antiferromagnetic materials, the exchange interaction aligns adjacent atomic magnetic moments antiparallel to each other. As a result, antiferromagnets have no net spontaneous magnetization and their response to external magnetic fields is weak. Can we still determine their atomic magnetic moments and spin axis relative to the crystal lattice? Can we explore their nanoscale magnetic heterogeneity (domains, domain walls) and use this knowledge to develop new antiferromagnetic materials? Can we make the invisible antiferromagnetic spin order visible? Yes, we can! The absorption of polarized X-rays allows us to probe antiferromagnetic order with element-specificity, nanometer spatial resolution and ultrafast time resolution. Moreover, the magnetic moment of neutrons interacting with the periodic spin arrangement in antiferromagnets gives rise to neutron diffraction patterns that reflect the antiferromagnetic spin order, analogous to how X-ray diffraction is used as a fingerprint of atomic order in crystalline materials. In this talk, these sophisticated and powerful X-ray and neutron techniques which are accessible to every researcher (!) through collaborative research facilities, will be discussed in detail. The goal is that at the end of this talk, all researchers in the audience will be able to develop their research idea into an experimental plan in the exciting field of antiferromagnetic spintronics, which they could then propose and execute at a collaborative research facility.

Louis Néel pointed out in his Nobel lecture that while abundant and interesting from theoretical viewpoint, antiferromagnets did not seem to have any applications. Indeed, the alternating directions of magnetic moments on individual atoms and the resulting zero net magnetization make antiferromagnetic order hard to control by tools common in ferromagnets. Strong coupling would be achieved if the externally generated field had a sign alternating on the length-scale of a lattice constant at which moments alternate in antiferromagnets. However, generating such a field has been regarded unfeasible, hindering the research and applications of these abundant magnetic materials. We will discuss recent prediction and experimental confirmation that relativistic quantum mechanics can provide a staggered current induced field whose sign alternates within the magnetic unit cell of the antiferromagnet [1,2]. We demonstrate that this staggered spin-orbit field facilitates a reversible switching of an antiferromagnet CuMnAs deposited at low temperature on a structurally compatible Si or GaP substrate. Electrical readout is facilitated by anisotropic magnetoresistance. The complete write/store/read functionality has been realized in a USB demonstrator memory device with a multi-level bit-cell characteristics which enhances the storage capacity and allows to integrate memory with logic/neuromorphic functionality within a bit cell [3]. The absence of dipolar fields in the zero net moment antiferromagnets makes the memory invisible to magnetic probes and robust against external magnetic field perturbations. Moreover, antiferromagnets have ultra-fast, THz spin dynamics which allowed to demonstrate switching by pulse lengths scaled down to a picosecond [4].

AA-01. Compensated ferromagnetic Heusler compounds for antiferromagnetic spintronics.

C. Felser[1], G. Fecher[1], R. Stinshoff[1], A. Nayak[1] and M. Coey[2]
1. Solid State Chemistry, Max Planck Institute for Chemical Physics of Solids, Dresden, Germany; 2. Physics, Trinity College Dublin, Dublin, Ireland

Heusler compounds are a remarkable class of materials with more than 1,000 members and a wide range of extraordinary multifunctionalities including half-metallic high-temperature ferri- and ferromagnets, multiferroic shape memory alloys, and tunable topological insulators with a high potential for spintronics, energy technologies and magnetocaloric applications. Half Heusler and Heusler compounds can be designed antiferromagnetic, ferri- and ferromagnetic properties. Antiferromagnetic and compensated ferrimagnetic properties are interesting in the context of antiferromagnetic spintronics. Simple rules allows for a rational design of Heusler compounds [1]. Mn-rich Heusler compounds are a source for compensated ferrimagnets ranging from metals via bad metals to semiconductors [2-4]. Some of the cubic compensated ferrimagnets can be designed by simple electron counting rules [5-7] As stated by the famous Slater-Pauling rule, L21 Heusler compounds with 24 valence electrons never exhibit any spin magnetic moment. In the case of strongly localized magnetic moments at one of the atoms (here, Mn), they will exhibit a fully compensated half-metallic ferromagnetic state instead, in particular, when symmetry does not allow for antiferromagnetic order. With the aid of magnetic and anomalous Hall effect measurements, it is experimentally demonstrated that Mn1.5V0.5FeAl absolutely follows such a scenario. A small residual magnetization that arises owing to a slight mismatch of the magnetic moment in the different sublattices results in temperature dependence of the magnetic compensation, confirmed by observation of magnetic reversal and sign change of the anomalous Hall effect [6,7]. Tetragonal Heusler compounds with large magneto crystalline anisotropy can be easily designed by positioning the Fermi energy at the van Hove singularity in one of the spin channels. Because of the ferrimagnetic arrangement of the sublattice artificial antiferromagnets: compensated ferrimagnets, can be even easier designed in the hard magnetic tetragonal Mn2YZ Heusler compounds [8]. In the vicinity of the compensation composition in Mn–Pt–Ga, a giant exchange bias (EB) of more than 3 T and a large coercivity are found The large exchange anisotropy originates from the exchange interaction between the compensated host and the ferrimagnetic clusters that arise from intrinsic anti-site disorder. Our design approach is also demonstrated on a second material with a magnetic transition above room temperature, Mn–Fe–Ga, exemplifying the universality of the concept and the feasibility of room-temperature applications [8]. The compensation point in cubic as well as tetragonal Heusler compounds is confirmed by observation of magnetic reversal and sign change of the anomalous Hall effect.

AA-02. New functionality in half-metallic Mn_2Ru_xGa close to compensation.

Y. Lau[1,2]
1. Department of Physics, The Univeristy of Tokyo, Tokyo, Japan;
2. National Institute for Materials Science (NIMS), Tsukuba, Japan

Compensated half-metallic ferrimagnets (CFHMs) have a spin gap at the Fermi level and an electron occupancy that ensures compensation of two inequivalent antiparallel chemical sublattices at a specific composition and temperature, T_{comp}. The prototypical CFHM is Mn_2Ru_xGa (MRG), which we have investigated intensively ever since discovering it [1]. MRG crystallises in the cubic space group No. 216 with -43m point symmetry and Mn in 4*a* and 4*c* positions. MRG can exhibit perpendicular magnetic anisotropy (PMA) because of substrate-induced biaxial strain, and the point symmetry is then reduced to -4m2, with no inversion centre. The conduction electrons originate from predominantly one of the two Mn sublattices, giving rise to high spin polarization, large spontaneous Hall effect [2] and finite tunnel magnetoresistance [3] at T_{comp}, where the magnetisation is strictly zero, and the coercivity diverges. A strong Kerr signal that arises from the spin-polarised conduction band allows optical detection of resonance modes in sub-terahertz range and also offers a unique opportunity to study quasi-antiferromagnetic domains, domain walls and their motion using standard magneto-optical imaging techniques. The effective magnetic coupling of the MRG 4*c* sublattice moment to a perpendicularly-magnetized CoFeB layer via a thin Hf spacer leads to a robust pinned layer structure that exploits the high coercivity of MRG near the compensation [4]. This stack provides an alternative to the current synthetic antiferromagnetic multilayers but with a much simpler structure. Using the harmonic Hall technique [5,6], we have found evidence of current-induced spin-orbit effective fields at room temperature in MRG films. Systematic investigation of films of different Ru concentrations (hence with T_{comp} below or above room temperature) and of devices patterned along different crystallographic axes reveals several interesting features. First, the direction of the spin-orbit effective fields reverses upon reversing the current polarity *and* the MRG magnetization direction. The symmetry of the observed spin-orbit effective fields differs from that reported in single-layer MBE-grown NiMnSb [7], for which magnetization-independent terms are dominant. Second, the longitudinal effective field (parallel to the applied current) more than an order of magnitude greater than the transverse effective field, suggesting a dominant role of the diagonal terms in the response tensor. Third, the magnitude of the effective fields per unit current density reaches ~ 5 $mT/10^{10}$ A/m^2 near the compensation, nearly an order of magnitude higher than the values reported in conventional heavy metal/ferromagnet bilayers. The origin of spin-orbit effective fields in CFHMs, and potential generalization to other classes of magnetic materials will be discussed.

AA-03. Ultrafast spin dynamics in antiferromagnets.

O. Gomonay[1], T. Jungwirth[2] and J. Sinova[1,2]
1. Institute of physics, Johannes Gutenberg University, Mainz, Germany;
2. Institute of Physics ASCR, Praha, Czechia

Antiferromagnets are promising materials for spintronics because they show fast magnetic dynamics, low susceptibility to magnetic fields, and produce no stray fields. In addition, the antiferromagnetic dynamics can be efficiently manipulated by spin and charge currents. Here we discuss spin and/or charge current induced dynamics of the antiferromagnetic textures (domain walls, skyrmions) and nanoparticles. We consider and analyse four types of torques which (spin) current can generate in an antiferromagnet with two magnetic sublattices. These torques can be classified as the staggered/nonstaggered (S/NS) according to the effective spin accumulation at the magnetic sublattices and the field-like/antidamping-like (FL/ADL) according to the produced energy dissipation (Fig.1). The NS-FL torque is similar to the torque created by the magnetic field. The recently predicted [1] Néel spin orbit torque gives an example of the S-FL torque, while the spin transfer and antidamping Néel spin orbit torques [2,3] represent the NS-ADL case. The S-FL and NS-ADL torques can efficiently move the antiferromagnetic domain walls [4,5]. The symmetry matching between these torques and staggered magnetization provides high mobility compared to other torques. Due to the absence of the Walker breakdown, the velocity of the domain wall motion can reach 30 km/s at the reasonable values of currents. The NS-ADL is sensitive to the structure of the domain wall and pushes all the domain walls in the same direction, which is suitable for the race-track memory. On the contrary, the S-FL torque splits degeneracy of the domains, pushes the domain walls toward the unfavourable domain and thus is suitable for switching. Moreover, this torque is the only physical field which allows to distinguish domains with the opposite orientation of the Néel vector and to manipulate 180^0 domain walls in antiferromagnets. The dynamics of the Néel vector induced by the S-FL and NS-ADL torques is assisted by large internal torques of the exchange origin which allow to achieve an ultrafast (compared to ferromagnets) magnetic dynamics. In particular, NS-ADL torque induced by dc spin current induces stable autooscillations of the Néel vector with THz frequency. This paves a way to the antiferromagnetic-based devices fitting THz gap, e.g. emmiters and detectors of THz radiation, which couples to the magnetic dynamics via Néel spin orbit (S-FL) torque [6]. The S-ADL torque, whose effect up to our knowledge was not yet discussed in the literature, can induce fast and reliable 180^0 switching of the Néel vector, similar to the spin transfer torque in the ferromagnets. In contrast to NS-ADL which always competes with the internal damping and thus supports precession rather than switching of the Néel vector, the S-ADL torque can either compensate or enhance the internal damping depending on the geometry. The time-dependent S-ADL torque can also induce oscillations with THz frequency. However, the dynamics induced by this torque is not assisted by the internal exchange torques and thus is less efficient than S-FL and NS-ADL torques. From the symmetry point of view, the S-ADL torque can also compensate the Bloch damping which controls relative orientation of the magnetic sublattices and their length. Thus, this torque can play an important role in the vicinity of the Néel point. We also discuss the effects which different torques produce on an antiferromagnetic skyrmion. The field-like torques (both S-FL and NS-FL) influence the skyrmion stability. They allow to control uniaxial (via S-FL) and unidirectional (via NS-FL) anisotropy of the Néel vector. The NS-ADL torque creates a force which can induce linear motion of a skyrmion [7]. To summarise, (spin) current induced dynamics of antiferromagnets is much richer compared to ferromagnetic materials due to the variety of torques and magnetic degrees of freedom. By tuning and combining different types of torques is it possible to induce switching, precession, domain wall motion and other nontrivial dynamical regimes which give antiferromagnetic-based deivces new functionalities.

Ferromagnetic storage of binary information in hard disk drives (HDD) and magnetic random access memories (MRAMs) is based on uniaxial switching between two stable, energetically equivalent magnetic states of reversed magnetisation which are separated by a high anisotropy energy barrier in order to guarantee thermal stability. The electrical switching of the ferromagnetic bits is realised by current induced spin-transfer torques or by spin-orbit torques whereby giant or tunnelling magnetoresistance (GMR, TMR) effects are used for reading out the two collinear states. [1] In antiferromagents (AFs) such as CuMnAs or Mn_2Au, where the constituent magnetic sub-lattices form inversion partners, efficient and fast current induced switching between orthogonal Néel vector states was recently proposed [2-3] and experimentally realised [3-8]. In those experiments, the anisotropic magnetoresistance (AMR) was used to identify the biaxial switching between non-collinear magnetic states. However, reversible biaxial switching requires a complex (at least) four-terminal device architecture since writing currents have to be applied along two different axes. Moreover, the AF system needs to exhibit biaxial magnetic anisotropy to prevent relaxation between the non-collinear states. Uniaxial switching in AFs is in principle more favorable than biaxial switchinbg. Writing can be realised by simply changing the current polarity and only uniaxial magnetic anisotropy is required to ensure stable switching between collinear states. Theoretically, uniaxial switching driven by the current induced staggered Néel ordered spin-orbit field has been proposed by propagation of 180° antiferromagnetic domain walls [9] and by coherent spin rotation of the Néel ordered state. [10] Distinguishing between reversed antiferromagnetic states by electric measurements is not straightforward since macroscopic charge-currents in AFs are unpolarised. Nevertheless, antiferromagnetic GMR or TMR like spin-valves have been proposed which are based on subtle spin-coherent quantum interference phenomena that rely on perfectly epitaxial commensurate multilayers, and it is the relative orientation of the local spins on the last atomic planes of the two antiferromagnets facing each other across the non-magnetic spacer that determines the readout resistance signal. [11] The difficulty in observing these spin-valve effects experimentally and the even-in-magnetic moment dependency of the AMR has cast doubts on the ability to detect by practical means uniaxial switching in antiferromagnets. [12]. In my talk I will show that it is possible to separate macroscopic states of reversed Néel vectors by combining the even under Néel vector reversal AMR effect with the odd under Néel vector reversal staggered field like spin-orbit torque. The later appears in antiferromagnets where the crystal lattice lacks local inversion symmetry and where the antiferromagnetic sublattices form space-inversion partners [2,3]. Using this methode, reversible and stable uniaxial switching at room temperature in antiferromagenic CuMnAs, triggered by writing current pulses of opposite polarity will be shown. We detected the uniaxial switching by means of a homodyne detection method where an alternating probe current periodically perturbs the AF coupled moments by the staggered spin-orbit field so that a 2nd harmonics signal appears due to the periodically changing AMR. Since the 2nd harmonics signal changes sign under Néel vector reversal we can identify nonvolatile uniaxial switching between states of opposite Néel vectors. The reversed states show no decay over days. In contrast, we detected in the same devices by conventional AMR measurements biaxial switched states with relatively short retention times of 10′s of minutes.

Harnessing spin currents is a promising pathways towards low-power electronics [1]. Towards this end, it recently has been recognized that antiferromagnetic materials can play a more active role beyond their traditional use for providing a reference magnetization direction via exchange bias. Namely, antiferromagnets may be conduits for spin currents, as well as, actively enable spin current generation and detection. With respect to the later, we demonstrated spin current generation both via spin Hall effects in conducting antiferromagnets and spin Seebeck effects in insulating antiferromagnets. Using CuAu-I-type metallic antiferromagnets (PtMn, IrMn, PdMn, and FeMn) we showed by using spin pumping that these alloys have significant spin Hall effects, which in the case of PtMn become comparable to the ubiquitously used Pt [2]. The spin Hall angles increase for the alloys with heavier element; a behavior that is well reproduced by first-principle calculations of the spin Hall conductivities based on intrinsic spin Hall effects. Furthermore, the calculations suggest pronounced anisotropies of the spin Hall conductivities, which we tested using spin transfer torque ferromagnetic resonance measurements using epitaxially grown antiferromagnetic films [3]. We observe that indeed the spin Hall conductivity is maximized for different growth orientations (a-axis for PtMn and PdMn, and c-axis for IrMn) in accordance with the first principle calculations. In addition using spin pumping measurements with permalloy/FeMn/W trilayers, we observe that there are two distinct mechanism for transporting a spin current in the metallic antiferromagnet, which we associate with electronic and magnonic spin transport, respectively [4]. This work was supported by the U.S. DOE, Office of Science, Materials Sciences and Engineering Division and DFG.

AA-06. Spin Transport in Speromagnets: Disordered Spintronic Materials with Antiferromagnetic Correlations.

B.L. Zink[1]
1. Physics & Astronomy, University of Denver, Denver, CO, United States

Recent efforts in spintronics research have shown that first ferromagnetic (FM), and now antiferromagnetic (AF) insulators support spin transport. This is particularly exciting since the lack of charge transport in these magnetically ordered insulating materials removes the scattering and dissipation that leads to heat losses that currently limit silicon nanoelectronics. These systems are crystalline or otherwise structurally ordered in addition to their magnetic order, and spin transport effects are usually interpreted in terms of collective excitations such as magnons. Some of the most promising materials, such as the ferrimagnetic insulator yytrium iron garnet (YIG), are also quite complicated crystals. This presents challenges in integrating these materials in silicon or other nanoelectronics elements for potential future use as spintronic memory or logic elements. We have recently added a dramatic twist to the study of spin transport in insulators, as we have demonstrated long-distance spin transport in disordered magnetic insulators. This talk describes our work that follows on recent electrical generation and detection of spin transport through the crystalline ferrimagnetic insulator yttrium iron garnet (YIG). These non-local transport experiments use charge currents to excite spin dynamics in the YIG via the spin Hall effect (SHE), and subsequently detect a spin current some distance away using the inverse spin Hall effect (ISHE). As shown schematically in Fig. 1, we have carried out similar experiments on amorphous YIG (*a*-YIG), a material showing no long- or medium-range order (either structural or magnetic). *a*-YIG, sometimes historically classified as a speromagnet, where spins are fixed in random directions due to the randomness of the magnetic anisotropy, typically shows a spin freezing near 50 K, and above this temperature follows the Curie-Weiss law with parameters suggesting very strong antiferromagnetic correlations in an essentially paramagnetic state. Our results, as shown in Fig. 2, show surprisingly long length-scale spin transport with easily measurable signals even for distances greater than 100 microns at temperatures near and above 300 K [1]. Experiments performed on a-YIG supported both on a bulk substrate and on suspended Si-N membrane thermal platforms show that spin injection and transport does not require thermal gradients, but the presence of in-plane thermal gradients enhances spin transport and reveals a large non-equilibrium spin thermal conductance. Among other intriguing aspects of this unexpected spin transport, we clarify that the effects are large not in the low-temperature spin-glass state, but at higher temperatures where only antiferromagnetic spin correlations are present. We will also show similar effects in a second disordered magnetic material, present data directly comparing use of Pt strips that cause spin transport via the SHE and Cu strips that show no spin transport as expected, and argue that the role of correlations is a more general feature that could dominate even in spin transport through more structurally ordered systems. This work is supported by the US National Science Foundation (DMR-1709646 and EECS-1610904).

AB-01. Electronic states and magnetic properties around the grain boundary in Nd-Fe-B sintered magnets studied by first-principles calculations.

Y. Tatetsu[1] and Y. Gohda[1]
1. Department of Materials Science and Engineering, Tokyo Institute of Technology, Yokohama, Japan

Nd-Fe-B sintered magnets, known as the strongest magnets, are used in various kinds of applications, for example, vehicles, turbines, etc., since they have the largest $(BH)_{max}$ among permanent magnets. However, the mechanism of the thermal instability in the coercivity of Nd-Fe-B magnets is not clear because there are numerous unknown factors that reduce the coercivity. These unknown factors are strongly related to the complicated grain boundary structures in Nd-Fe-B magnets. In general, understanding of grain boundaries in materials is very important from the aspect of controlling physical properties, and this can be also applicable to Nd-Fe-B magnets. In fact, several experimental studies have been clarifying important relationships between the coercivity and the grain boundaries which are constructed by $Nd_2Fe_{14}B$ main grains and subphases [1]. There are some experimental approaches to improve the coercivity of Nd-Fe-B magnets by adding a small number of elements, for example, Cu, Ga, etc., instead of Dy which is expensive, but even so it is mostly used in commercial magnets to keep high coercivity at high temperatures [1-4]. According to atom prove measurements, added Cu covers the $Nd_2Fe_{14}B$ main grains, and this might be one of the reasons for the coercivity improvement. Despite these efforts, what reduces the coercivity of Nd-Fe-B magnets is still unclear. This is because it is hard to observe and understand the nanoscale physics around grain boundaries only from experiments. First-principles electronic-structure calculations, based on density functional theory, are a powerful tool to investigate nanoscale physics in not only bulk systems but also grain-boundary systems, and can be applicable to analyze the atomic position and electronic states. We performed first-principles calculations for Cu-added Nd-Fe-B magnets [1-3] by using the OpenMX code [5] within density functional theory in order to understand the magnetic properties, especially the magnetic anisotropy around the interface which is strongly related to the coercivity [6, 7]. In addition, we analyzed where added Cu atoms should exist around the grain boundary by comparing the formation energies of five model systems labeled I~V. As a subphase, we chose $NdO_{0.25}$ which has been confirmed the presence around the triple junction in Nd-Fe-B magnets in experiments. The cutoff energy is 500 Ry and a k-point mesh is $3 \times 3 \times 2$. From our analysis, Cu prefers being around the interface (II and III in figure 1) to being the inner region of subphases and the main phase (IV and V). Furthermore, Fe at the interface of the $Nd_2Fe_{14}B$ main phase can be replaced by Cu because the formation energy is lower in the system (III) with Cu at Fe sites than the system (I) without Cu. This replacement improves the magnetic anisotropy of Nd atoms at the interface. Interestingly, the anisotropy improvement in Nd near Cu is about 40% from the non-Cu-doped system. Because the magnetic interaction between the 5d electrons in Nd and valence electrons in added Cu is weak. As a result, the 5d electrons tend to spread in the [001] direction, and the large total-angular momentum of 4f electrons in Nd is toward the [001] direction. This is one of the reasons for the coercivity improvement. The coercivity in Ga-doped Nd-Fe-B magnets is enhanced about 80 % recovering from the non-Ga-doped sintered magnets after annealing processes. From experimental analyses, Ga is the key to the wettability improvement of the Nd-rich phase [4], and the coercivity increases due to $Nd_6Fe_{13}Ga$ present at triple junctions. In order to examine the reason why the coercivity is improved by $Nd_6Fe_{13}Ga$, we performed first-principles calculations for $Nd_2Fe_{14}B/Nd_6Fe_{13}Ga$ grain-boundary model structures. Practically, large-scale simulations are necessary for understanding the coercivity improvement in Nd-Fe-B magnets from nanoscale. For example, figure 2 shows a large-scale $Nd_2Fe_{14}B/Nd_6Fe_{13}Ga$ grain-boundary-model system containing about 3000 atoms in a unit cell, in which the lattice mismatch between the $Nd_2Fe_{14}B$ main phase and $Nd_6Fe_{13}Ga$ subphase is less than 0.5 %. In this study, however, we chose smaller unit cells to seek the termination layer of $Nd_6Fe_{13}Ga$ at the interstitial regions of Nd-Fe-B magnets for large grain-boundary model systems. All atomic positions and cell parameters were optimized. After the structural optimization, the atomic positions of the inner region of the main phase and subphase are barely changed. On the other hand, the interface structures are complicated. In the $Nd_2Fe_{14}B$ surface system, K_1 of Nd at the surface shows strong in-plane anisotropy that can cause the coercivity decrease of Nd-Fe-B magnets [8]. In our grain-boundary model systems, K_1 of Nd is improved compared with that of the surface system thanks to $Nd_6Fe_{13}Ga$ present at the interface. This is due to Nd 5d electrons distributing in the longitudinal direction around interstitial regions, which improves K_1 of Nd. In conclusion, Ga doping works effectively in terms of improving K_1 of Nd at the interface.

A novel approach of substitution of Ce for Nd in preparing $R_2Fe_{14}B$ nanocrystalline magnets with high coercivity Liang Zha[1]; Zhou Liu[1]; Guang Tian[1]; Kun Li[1]; Mingzhu Xue[1]; Zhuyin Shao[1];Hui Zhao[1]; Yinfeng Zhang[1]; Wenyun Yang[1]; Youfang Lai[1]; Guanyi Qiao[1]; Xin Li[1]; Shilei Ding[1]; Shunquan Liu[1]; Honglin Du[1]; Changsheng Wang[1]; Jinzhi Han[1]; Yingchang Yang[1]; Jinbo Yang[1,2,3] [1] State Key Laboratory for Mesoscopic Physics, School of Physics, Peking University, Beijing 100871, P. R. China. [2] Collaborative Innovation Center of Quantum Matter, Beijing, 100871, P.R. China [3] Beijing Key Laboratory for Magnetoeletric Materials and Devices,Beijing 100871, P. R. China ABSTRACT The Ce substituted $(Nd_{1-x}Ce_x)_{12.2}Fe_{81.6}B_{6.2}$ ribbons were prepared by annealing amorphous ribbons from melt spinning. It was found that all annealed ribbons consist of α-Fe, Nd(Ce)-rich phases, and $R_2Fe_{14}B$ phase. The coercivity of the $Nd_{12.2}Fe_{81.6}B_{6.2}$ ribbons with multiphase can reach a value of about 11.34 kOe, and the coercivity decreases slightly with the increasing of the Ce content. The coercivity still shows a value of 7.46 kOe when the Ce substitution of Nd was over 60% (x= 0.6). The Mr/Ms ratios of the ribbon are above 75% with the Ce content increasing from 0.2 to 0.6. It is expected that these results could provide a novel approach for preparing high coercivity Ce-substituted Nd-Fe-B materials. Key word: Nd–Fe–B alloy; Ce substitution; Coercivity INTRODUCTION The substitution for Nd by abundant rare earth element such as Ce is a practical approach for the comprehensive utilization of rare earth resources in permanent magnets, which can not only reduce costs but also provide a feasible way for integrated and effective utilization of rare earth resource [1,2,3]. The coercivity mechanism has been systematically studied for developing Ce-containing Nd-Fe-B permanent magnetic materials. Researchers[4,5,6,7] have found that the microstructure and grain boundary as well as the composition may play a pivotal role in the magnetic properties and coercivity mechanisms. Yang et al. found that the coercivity increased when 20% Nd was replaced by Ce in $(Nd_{1-x}Ce_x)_{14}Fe_{79.5}B_{6.5}$ melt-spun ribbons, and pointed out that scattering lattice parameters is the direct reason for the abnormal increase [8]. Shen et al. obtained $Nd_{12}Fe_{82}B_6$ ribbon with a coercivity of 10.93 kOe by melt spinning directly [9]. While M. Grigoras et al. made a comparison between the magnetic properties and microstructure of $Ce_{10+x}Fe_{78-x}B_6$ (x = 0, 2, 4, 6) nanocrystalline ribbons, prepared directly by melt spinning from the melt, and the ones obtained after annealing of amorphous precursors, whose corresponding coercivities are 4.7kOe ($Ce_{14}Fe_{80}B_6$) and 6.21kOe ($Ce_{16}Fe_{78}B_6$), respectively. It was found that the best preparation method was annealing the amorphous strip appropriately [10]. Obviously, the coercivity mechanisms of Ce-containing permanent alloys depend both on compositions and preparation processes. Consequently, it is significant to design proper composition and structure, optimize processing, and analyze the mechanisms in depth for this kind of magnet. Therefore, in this work, the $(Nd_{1-x}Ce_x)_{12.2}Fe_{81.6}B_{6.2}$ ribbon with the main phase of $Re_2Fe_{14}B$ was obtained by melt spinning following by annealing appropriately. The relationship between coercivity and Ce content was studied. Fig.1 XRD patterns of the $(Nd_{0.8}Ce_{0.2})_{12.2}Fe_{81.6}B_{6.2}$ (A) Crystallized ribbons, (B) Amorphous ribbons and (C) Raw material Fig.1 shows the XRD patterns of the $(Nd_{0.8}Ce_{0.2})_{12.2}Fe_{81.6}B_{6.2}$ alloy prior to and after annealing at 700 ° C for 15 min. As is evidently shown in Fig.1, the as-spun $(Nd_{0.8}Ce_{0.2})_{12.2}Fe_{81.6}B_{6.2}$ ribbon exhibits features of an amorphous structure, of which magnetic softness expectedly provides further verification. The x-ray diffraction of the tetragonal $Nd_2Fe_{14}B$, Nd-rich phase and α-Fe emerge after annealing compared with raw material. Fig.2 Hysteresis loop of samples of $(Nd_{1-x}Ce_x)_{12.2}Fe_{81.6}B_{6.2}$ (Ce=0.0, 0.2, 0.4, 0.6) Figure 2 shows the room temperature hysteresis loop of the ribbons annealed at 700 ° C for 15 minutes. It is interest to note that the coercivity of the $Nd_{12.2}Fe_{81.6}B_{6.2}$ ribbons can reach a value of about 11.34 kOe under the multiphases condition, and the coercivity decreases slightly with the increasing of the Ce content. The $(Nd_{1-x}Ce_x)_{12.2}Fe_{81.6}B_{6.2}$ shows a coercivity value of 7.46 kOe for x=0.6, which is abnormally high for the Ce-substituted magnets[9]. The Mr/Ms ratios of the ribbon are all above 75% with the Ce content increasing from 0.2 to 0.6. It can be seen from the inset that at x = 0, there was a small kink on the hysteresis loop, further suggesting that $Re_2Fe_{14}B$ coexists with α-Fe. As the Ce atomic percentage increases, the coercivity decreases on account of the introduction of Ce decreasing the magnetocrystalline anisotropy, which is consisted with the conclusion of Shen et al. [9]. However, the squareness of the loop does not deteriorate significantly with the increase of Ce. The double annealing process that maintains high coercivity at high Ce substitution provides a practical approach to comprehensive utilization of rare earth resources.

AB-03. Magnetic performance change of multi-main-phase Nd-Ce-Fe-B magnets by diffusing (Nd, Pr)H_x.

W. Zhang[1], T. Ma[1], B. Peng[1] and M. Yan[1]
1. School of Materials Science and Engineering, Zhejiang University, Hangzhou, China

Grain boundary diffusion process (GBDP) is effective to enhance coercivity of the single-main-phase (SMP) $RE_2Fe_{14}B$ (RE, rare earth) magnets through forming magnetic hardening shells surrounding the hard grain cores. Here GBDP was applied to the multi-main-phase (MMP) (Nd, Pr)$_{22.3}$Ce$_{8.24}$Fe$_{bal}$ M$_{1.0}$B$_{1.0}$ (wt.%) magnets prepared by sintering the mixture of Ce-free and Ce-containing 2:14:1 powders, which have shown superior magnetic properties, especially coercivity, to the SMP ones at the same average composition. The remanence of the (Nd, Pr)H_x diffused magnets increases gradually with the increase of diffusion temperature from 480 to 880 °C, the coercivity however slightly decreases. The highest $(BH)_{max}$ of 350.1 kJ/m^3 is achieved when diffusing at 680 °C, which is 9.2 % higher than 320.7 kJ/m^3 for the as-prepared magnet. The remanence increment is due to the diffusion of Nd/Pr into the 2:14:1 phase grains, enlarging the intrinsic saturation magnetic polarization. The slight coercivity reduction is due to the gradual homogenization of RE distribution within the 2:14:1 grains of the undiffused parts, i.e. approaching the ‘‘close to equilibrium (or SMP)’’ state, which offsets the positive contributions from the enrichment of Nd/Pr in the Ce-rich 2:14:1 phase and the formation of continuous RE-rich intergranular phase. These findings suggest that the GBDP effect on coercivity of the MMP Nd-Ce-Fe-B magnets is distinctly different from the SMP ones, which suggests that the chemical heterogeneity should be carefully controlled to improve the magnetic performance of such high cost-performance permanent magnets.

NdFeB-based permanent magnets have been widely applied in various fields. The critical rare earth (RE) elements, such as Pr, Nd, Dy or Tb, have been overused by large amount of consuming RE for making RE-Fe-B magnets. As the most abundant rare earth element on earth and the byproduct of Nd and Pr extraction processes, Cerium (Ce), however, is overstock. The development of the Ce-based magnets is a feasibly economic way for using the rare earth resources effectively. In this paper, we have investigated the Ce-Fe-B magnets prepared by spark plasma sintered (SPSed) technique and so called dual alloy method with different ratio of alloys of Ce-Fe-B and Pr-Nd-Fe-B. As expected, the remanent magnetization J_r, coercivity H_{ci} and maximum energy product $(BH)_{max}$ of SPSed magnets increase obviously with increasing weight percentage of Pr-Nd-Fe-B alloy. The magnetic properties of J_r = 0.71 T, H_{ci} = 915 kA/m, $(BH)_{max}$ = 72 kJ/m^3 are obtained for the SPSed magnets with 20 wt.% of the Ce-Fe-B alloy. The temperature coefficients of remanence (α) and coercivity (β) of the magnets are better off from -0.46 %/K, -0.60 %/K to -0.23 %/K, -0.53 %/K in the temperature range of 300-400 K. Fig.1 shows a typical M-T curve and dM/dT for the Ce-containing magnets with Pr-Nd-Fe-B alloy produced by dual alloy method. Three Curie temperatures are exhibited in dual-alloy magnets. The existence of three Curie temperatures may indicate three types of hard magnetic main phases with different compositions. The first Curie temperature T_{c1} = 441 K is close to that of the Pr-Nd-Fe-B-free magnet. It is the Curie temperature of Ce-Fe-B-based main phase. The third Curie temperature T_{c3} = 580 K is that of the Pr-Nd-Fe-B-based main phase. The second Curie temperature T_{c2} = 493 K is between T_{c1} and T_{c3}. It appears to be the Curie temperature of Pr-Nd-Ce-Fe-B magnetic phase. In addition, with increasing Pr-Nd-Fe-B content, there is no obvious change for T_{c1} and T_{c3}, but T_{c2} increases from 493 K to 516 K depending on the content of Pr-Nd-Fe-B alloy. It was confirmed that Ce tends to get into grain boundary while Nd is more likely to get into main phase[1]. The changing Curie temperature may result from the main phase grains with different Ce concentrations. Element diffusion and immigration lead to form a new magnetic phase and therefore T_{c2} appears. Thus, a nano-crystalline multi-main-phase Ce-containing sintered magnet was fabricated by SPS technique. Fig. 2 gives a BSE image and corresponding EDX elemental mappings of Ce-based magnet with 20% Pr-Nd-Fe-B alloy addition. The Ce mapping exhibits non-uniform contrasts in different areas. For example, area 1 and area 2 marked in BSE image are Ce-lean while area 3 and area 4 marked in BSE image are Ce-rich. The results of elemental weight percentage analysis shows that the ratio of Ce/(Ce+Nd+Pr) is almost equal to 1 for area 3 and area 4. The ratio of Ce/(Ce+Nd+Pr), however, is about 0.52-0.55 for area 1 and area 2. Therefore, Pr-Nd-Ce-Fe-B main phase is formed because of element diffusion and immigration. According to the weight percentage of Ce, Pr, Nd in the compositions, the theoretical Curie temperature of Pr-Nd-Ce-Fe-B phase is calculated to be in the range of 503-507 K, being closer to the measured Curie temperature T_{c2}. The EDX result demonstrates the inhomogeneous distribution of Ce, which consists with the M-T result. The present research may offer potential references on further research and development for the practical applications of this type high abundant rare earth permanent magnetic material. AB-05. Nd-Fe-B films with perpendicular magnetic anisotropy and extremely large room temperature coercivity.

C. Ma[1], S. Wang[1], A. Morisako[1], S. Piramanayagam[2] and X. Liu[1]
1. Faculty of Engineering, Shinshu University, Nagano, Japan; 2. School of Physical and Mathematical Sciences, Nanyang Technological University, Singapore, Singapore

Nd-Fe-B thin films have potential applications in high sensitive magnetic sensors and high density magnetic recording media due to its large magneto-crystalline anisotropy and high saturation magnetization[1-3]. They are also being investigated for energy harvesting. For all those applications, controlling the magnetic anisotropy to prepare films with perpendicular magnetic anisotropy are important[4]. In this digest, we present a novel process to prepare Nd-Fe-B thin films with perpendicular magnetic anisotropy. Substitution of various elements such as Tb, Dy and Sm were carried out. Of particular interest is that a 1 at% addition of Tb, Dy, or Sm can strongly enhance the perpendicular magnetic anisotropy of the Nd-Fe-B films. Films with additions of Tb show coercivity larger than 30 kOe. A clear correlation between perpendicular magnetic anisotropy of annealed state and the domain formation in the as-deposited state were noticed[5,6]. In this experiment, Nd-Fe-B films were deposited by a facing targets sputtering system. The films were deposited onto thermally oxidized silicon wafer. The substrate temperature was ranging from 100 ^{o}C to 400 ^{o}C. It was confirmed by X-ray diffractometry (XRD) that all the deposited films are amorphous. The films were then subjected to a flash annealing process. Crystallized, magnetically hard films were obtained by annealing the samples at 650 ^{o}C for 5 minutes[7,8]. All the as-deposited amorphous films showed soft magnetic properties with coercivities less than 100 Oe in both perpendicular and in-plane direction. Fig. 1 shows magnetic force microscopy (MFM) images of as-deposited films without Tb addition (a) and with 1 at% Tb addition (b). We could not find any particular domain configuration in films deposited without Tb addition. However, well defined stripe domains with period of around 110 nm were present in the as-deposited films with Tb addition. The stripes were found to be aligned in the same direction as the stray magnetic field direction of facing targets sputtering system. Well aligned stripe domains are originating from the induced in-plane anisotropy field and perpendicular magnetic field as indicated by micromagnetic simulations. Further investigation of the perpendicular magnetic anisotropy from the saturation magnetization and domain period showed that the films have perpendicular magnetic anisotropy of around 5.0×10^{4} J/m^{3}. Films became magnetically hard and crystallized after annealing at 650 ^{o}C. Fig. 2 shows hysteresis loops of films deposited without Tb addition (a) and with Tb addition (b). According to Fig. 2 (a). films deposited without Tb addition show almost identical perpendicular and in-plane hysteresis loops. However, as shown in Fig. 2(b), films deposited with addition of Tb show excellent perpendicular magnetic anisotropy with large perpendicular remanence but very low in-plane remanence. It should be noted that the films have very large coercivity that a maximum applied field of 24 kOe could not even reverse the magnetization. Films show almost zero coercivity at in-plane direction further confirms the excellent perpendicular magnetic anisotropy. XRD results shows c-axis normal to the film plane crystallographic properties for films with Tb addition, which further confirmed the perpendicular magnetic properties in those films. Our results show clear magnetic correlations between as-deposited amorphous films and annealed crystallized films. Our research provides a simple way to evaluate crystallographic and magnetic properties of Nd-Fe-B films even without annealing the films. Addition of Tb, Dy, and Sm were found can enhance the perpendicular magnetic anisotropy in the Nd-Fe-B films.

AB-06. Development of non-rare earth grain boundary diffusion process for Nd-Fe-B permanent magnets.

Z. Liu[1], Q. Zhou[1], H. Zeng[1], H. Yu[1], X. Zhong[1] and X. Che[1]
1. School of Materials Science and Engineering, South China University of Technology, Guangzhou, China

Nd-Fe-B based rare earth permanent magnets are essential for a variety of devices. The performances of the magnetic materials are directly related to their microstructure. Recent researches have shown that the magnetic properties are very much dependent on the grain boundary structure. As a result, grain boundary diffusion (GBD) process has become an effective approach for improving the coercivity and reducing the heavy RE content of Nd-Fe-B magnets since the beginning of this century. In this paper, the development of GBD process has been introduced. Aiming to continuously reduce the material cost, GBD process has undergone three stages, as shown in Fig.1. In the early stage, heavy rare earth elements Dy or Tb and their compounds like Dy_2O_3, Dy-H, Dy-F were employed as the diffusion media. The magnetic properties, especially coercivity, of sintered NdFeB magnets and melt spun Nd-Fe-B powders were significantly enhanced. In the second stage, eutectic compounds RE-TM (RE=Nd, Pr, etc.; TM=Cu, Ni, etc.) were used for GBD. These compounds do not contain expensive rare earth elements Dy and Tb, and thus further reduced the material cost. The coercivities of both sintered magnets and hot deformed magnets have been greatly improved. Recently, we reported the enhancements of the magnetic properties and corrosion resistance of Nd-Fe-B magnets by a non-RE compound diffusion process[1], which can be regarded as the third stage of GBD. The details of non-RE GBD process and our very recent work will be presented in this paper. For the details, metal oxides were firstly employed as the diffusion media. The Tb, Dy-free sintered Nd-Fe-B magnets were coated with an oxide layer by magnetron sputtering, followed by solid diffusion heat treatment. With the successful diffusion of oxide into the magnet, the coercivity of the magnets has increased significantly and the maximum energy product was also enhanced without a significant decrease in remanence. The underlying mechanisms for these enhancements have been analyzed. The microstructural investigations show that the oxide entered mainly into the intergranular regions and modified the composition and structure of the grain boundary phase. The intergranular oxide phases observed in the oxide diffused magnet also contribute to the improved temperature stability and corrosion resistance of the magnet. Two types of oxides including MgO and ZnO have been discussed in this paper and both are effective in improving the coercivity of sintered Nd-Fe-B magnet. One example is shown in Fig.2. Our further studies indicate that not only oxides but also the low melting point alloys can work as the grain boundary diffusion medium for improving the coercivity of RE-lean Nd-Fe-B magnets. This novel GBD approach may overcome the limitations of conventional grain boundary diffusion, which requires heavy rare earth or rare earth compound, and has significance in further minimizing the use of rare earth resources.

Abstract: We have synthesized high coercivity $Nd_2Fe_{10.5}Co_2Cr_{1.5}B$ magnetic nanoparticles through a green and low cost mechanochemical method. The coercivity (H_C) of isolated $Nd_2(Fe_{10.5}Co_2Cr_{1.5})B$ nanoparticles and nanoparticles embedded in a CaO matrix was found to be 11.3 kOe and 9 kOe, respectively. The thermal coefficient of remanence (α (*Mr*)) and coercivity (β (H_C)) of these nanoparticles after removal of CaO, measured from room temperature to 400 K, was found to be -0.0015 and -0.0065, respectively. These nanoparticles exhibit the spin reorientation transition temperature (T_{SR}) of ~ 89 K, which is ~46 K less than that of bulk $Nd_2Fe_{14}B$ magnets, hence, more attractive for cryogenic applications. *Introduction:* NdFeB magnets are the strongest permanent magnets and are extensively used in energy generation and conversion systems. The magnetic properties can be tuned by modifying their microstructure or grain boundaries. Sintering, melt spinning, alloying, infiltration and diffusion based techniques are commonly used for this purpose. Nanostructuring of NdFeB materials is of high current interest[1-4]. Hence, we synthesized Cr alloyed NdFeCoB hard magnetic nanoparticles using green and cost effective mechanochemical processing. The process involves grinding of starting oxide materials to nanoscale powders, unlike the processes of elemental melting or production from solutions at high temperatures. Corrosion is a limitation of current NdFeB magnets, our Cr alloyed NdFeCoB magnets exhibit better corrosion resistance compared to alloys without Cr. *Experimental details:* $Nd_2Fe_{10.5}Co_2Cr_{1.5}B$ nanoparticles were prepared through processing a mixture of Nd_2O_3 (99.9 %, Alfa Aesar), Fe_2O_3 (99.9 %, Sigma Aldrich), CoO (99.9%, Alfa Aesar), B_2O_3 (99.9%, Alfa Aesar) and Cr_2O_3 (99.9 %, Sigma Aldrich) powders and Ca granules (99.9%, Sigma Aldrich) using a mechanochemical process. The content of each precursor first selected to produce $Nd_2Fe_{10.5}Co_2Cr_{1.5}B$. Excess amount of Nd_2O_3 and Ca granules was then added to compensate potential loss and ensure full reduction during processing, respectively. All precursors were milled using a Fritch Pulverisette-7 planetary ball mill at 500 rpm for 6 h under Ar. The milled powder samples were collected in a glove box filled with Ar. These nanoparticles were cold pressed, and heat treated in a vacuum furnace (~10^{-5} torr) at 850 °C for 90 min. NH_4Cl/methanol solution was used to remove the by-product, i.e., CaO. For structural, compositional, morphology and magnetic property measurements, several characterization techniques, e.g., XRD, SEM, EDX, TEM, PPMS were used. *Results and discussion:* Figure 1a shows the room temperature M–H hysteresis curves of mechanochemically processed $Nd_2(Fe_{10.5}Co_2Cr_{1.5})B$ nanoparticles before and after removal of CaO from the samples. The room temperature coercivity (H_C) decreases from 11.4 kOe to 9 kOe, while remanent magnetization (*Mr*) increases from 7.3 emu/g to 38.3 emu/g after removal CaO from the samples. The decrease in H_C is attributed to diffusion of hydrogen in the tetragonal structure of $Nd_2(Fe_{10.5}Co_2Cr_{1.5})B$ during CaO removal by NH_4Cl/methanol or the percolation effect due to strong particle-particle interactions when particles are not in the CaO matrix. Figure 1(b) shows the temperature dependent demagnetization curve for $Nd_2(Fe_{10.5}Co_2Cr_{1.5})B$ nanoparticles in the temperature range from 150 K to 400 K. Fig 2 shows the change of H_C and *Mr* with temperature, these values are a maximum at 150 K. H_C and *Mr* are lower at low temperatures due to spin reorientation arising from the interplay between the magneto-crystalline anisotropies of the different magnetically ordered sub-lattices. The easy axis of magnetization changes at the spin reorientation temperature (T_{SR}). The T_{SR} for bulk/single crystal Nd-Fe-B magnet is 135 K. The T_{SR} was determined by the derivative of the magnetization versus temperature (*dM/dT*) curve for our Cr alloyed Nd-Fe-Co-B nanoparticles at low applied field of 100 Oe, which was found to be 89 K. We have measured the thermal coefficient of remanence (α) and coercivity (β) in different temperature windows e.g., from 300 K to 400 K (α= -0.0015, β= -0.0065), from 150 K to 400 K (α= -0.0024, β= -0.0080) and from 250 K to 350 K (α= -0.0012, β= -0.0041). The thermal stability of our nanoparticles up to 350 K is comparable to those of commercial NdFeB magnets. *Conclusion:* We present the structural and magnetic properties of low cost, high performance and heavy rare earth free $Nd_2(Fe_{10.5}Co_2Cr_{1.5})B$ nanoparticles synthesized by a mechanochemical process which uses low cost oxide powders. Low spin reorientation transition temperature and high coercivity values of our Nd-Fe-Co-Cr-B magnets make them useful for low temperature corrosive environments.

Abstract: A novel route to prepare Nd-Fe-B magnetic particles by utilizing both spray drying and reduction-diffusion (R-D) processes was investigated in this study. Precursors were prepared by spray drying method using the aqueous solutions containing Nd salt, Fe salt and boric acid with stoichiometric ratios. Nd-Fe-B particles with the uniform size of 1 micrometer were obtained by R-D with reducing agent of CaH_2 followed by additional washing with wet ball milling. Especially, these two step washing process contributed to the excellent magnetic properties with high remanence and coercivity. $Nd_2Fe_{14}B$ particles were synthesized after washing and vacuum drying with the maximum energy product above 20.0 MGOe. Experimental methods: In order to prepare $Nd_2Fe_{14}B$ powders, $NdCl_3{\cdot}6H_2O$, $FeCl_3{\cdot}6H_2O$ and H_3BO_3 were weighted considering stoichiometry of compositions and dissolved in deionized (DI) water. Spray drying was performed under the condition of hot air of 250 ^oC, and feed rate of aqueous solution of 20 ml/min. Subsequently, the spray dried powders were desalted at 800 ^oC for 2 hours in air, followed by ball milling for 2 hours. The powders after ball milling were mixed with CaH_2 and then they were compressed into compacts. R-D of the compacts was carried out at 1000 ^oC for 3 hours in Argon (Ar) atmosphere. For the effective washing, the compacts were pulverized to coarse powders and the powders were washed with DI water and wet ball milling. Results and Discussion: After R-D process, $Nd_2Fe_{14}B$ clusters were embedded in CaO matrix uniformly, and bright contrasts in SEM images identified as Nd-rich phase appeared in the clusters. The corresponding EDX spectra showed atomic ratio of Fe/Nd was 4.89 that is close to the Fe/Nd ratio of 5.1 for the nominal constituent $Nd_{15}Fe_{77.5}B_{7.5}$. The atomic ratio of Ca/O approaches to 1, implying that the $Nd_2Fe_{14}B$ phase has not been oxidized. After one-step of washing, just the matrix CaO was removed, but the oxygen content was as high as 3.12 wt%. After two-step washing including wet ball milling, no obviously different contrast was observed and the atomic ratio of Fe/Nd was increased to 5.3 which meant the process lost the part of Nd-rich phase. Compared to the one-step washed powders, the weight of oxygen was increased from 3.12% to 4.37%. TEM image showed well dispersed magnetic phase of $Nd_2Fe_{14}B$ with particle size below 1 micrometer and displayed a shape of bacilliform, and the insert is the SADP pattern of the nanocrystalline $Nd_2Fe_{14}B$. HRTEM image showed an assembly of $Nd_2Fe_{14}B$ particles. It can be seen that the nanoscale domains adopt different structural orientations. The lattice fringes within each crystal domain have an interfringe nanocrystalline $Nd_2Fe_{14}B$ spacing of 3.14Å, which is close to the interplane distance of 3.11Å between the (220) planes in tetragonal structure of $Nd_2Fe_{14}B$. From M-H demagnetization curves at room temperature, magnetic properties for the powders after R-D were coercivity value of 10.6 kOe, but low remanence (Mr) and saturation magnetization (Ms). The coercivity of powders after two-step washing proposed in this work was decreased to 5.1 kOe, while Mr increased drastically. A (BH)max value as high as 22.1 MGOe was obtained. Conclusion: $Nd_2Fe_{14}B$ particles from the precursors obtained by spray drying were successfully synthesized. A high coercivity of 10.6 kOe of the Nd-Fe-B particles was attained before washing, which is attributed to isolation of nonmagnetic phase CaO and Nd-rich phase between $Nd_2Fe_{14}B$ particles. Finally, the particles with high (BH)max more than 20 MGOe by the control of washing step in R-D process were obtained. It was revealed that the ratio of CaH_2/the oxide powders and efficient washing system were important factors affecting magnetic property of final products.

AB-09. Coercivity enhancement of hot-pressed magnet prepared by HDDR Nd–Fe–B powders using Pr-Cu eutectic alloys diffusion.

T. Song[1], X. Tang[1], W. Yin[1], R. Chen[1] and A. Yan[1]
1. Ningbo Institute of Industrial Technology, Chinese Academy of Sciences, Ningbo, China

Hydrogenation-disproportionation-desorption-recombination (HDDR) has been developed as a well-known method synthesizing $R_2Fe_{14}B$ (R=Nd, Pr) magnetic powders with ultrafine-grained microstructure [1]. The $Nd_2Fe_{14}B$ phase disproportionates into neodymium hydride, Ferro boron, iron during a heat treatment in hydrogen up to temperatures higher than 650 °C. During evacuation of system, hydrogen desorbs and the dispropertionated mixture of Nd, Fe_2B, and Fe recombines forming submicrom grains of $Nd_2Fe_{14}B$ with an average grain size of about 0.3 μm. It may be a promising way preparing R-Fe-B powders with high coercivity and remanence [2-3]. However, the coercivity of the magnets prepared by HDDR powders are far below the expected value [4]. Grain boundary diffusion of Nd–Cu or Pr–Cu alloy was employed to enhance the coercivity of HDDR ternary Nd–Fe–B powders recently. Therefore, the grain boundary diffusion process, an effective method to prepare magnets with high coercivity [5], is also applied in this study. The ingot with the nominal composition of $Nd_{30}Co_{5.28}Al_{0.6}Zr_{0.14}Ga_{0.54}Fe_{bal.}B_{1.05}$ (wt. %) crushed into powders and followed by Hydrogenation-disproportionation process. The low melting-point $Pr_{82}Cu_{18}$ (wt. %) melt-spun powders was mixed with the Hydrogenation-Disproportionation powders and followed by Desorption-Recombination was defined as S1. The low melting-point $Pr_{82}Cu_{18}$ (wt. %) melt-spun powders was mixed with the HDDR powders was defined as S2. The powders was hot pressed at 750 °C. Demagnetization curves of hot-pressed magnets with Pr-Cu eutectic alloys addition as shown in Fig.1. Compared to the reference sample, the coercivity of S2 is improved drastically to 15.2 kOe, however, the coercivity of S1 was decreased to 10.6 kOe. L-TEM Fresnel images of S2 observed in zero magnetic field was shown in Fig. 2a-c. There are no obvious lines at just-focus state (Fig. 2a). However, when the sample is investigated at under-focus and over-focus states, dark and white lines can be observed (Fig. 2b and c). Moreover, the dark line at under-focus state turns into the white line at over-focus state while the white line at under-focus state turns into the dark line at over-focus state. It is clear that the magnetic domains are continuous across the grain boundary. The continuous magnetic domain walls suggest short-range exchange coupling between adjacent grains. Note that the magnetic domains are interrupted by the thick grain boundary phases indicating the magnetic decoupling of the adjacent grains. The present work further reveals that magnetic isolation between adjacent grains is essential to obtain a higher coercivity. The present work further reveals that magnetic isolation between adjacent grains is essential to obtain a higher coercivity. In addition, we strongly believe that the diffusion process will be also beneficial for preparation of hot-deformed HDDR magnets due to the existence of R-rich phases in adjacent grains.

AB-10. Corrosion of Co,Al-alloyed NdFeB magnetic nanostructures processed by microwave synthesis.

H. Parmar[1], X. Tan[1], Y. Zhong[1], V. Chaudhary[1], D. Peng[1], Y. Huang[1] and R.V. Ramanujan[1]
1. Nanyang Technological University, Singapore, Singapore

Abstract NdFeB based alloys were synthesized by microwave combustion followed by reduction diffusion process. The corrosion resistance were improved in nanostructured Co-NdFeB alloyed by minimal substitution of Al and Nd, which is comparable to sintered NdFeB magnets. The corrosion potential and current density of Al and Nd substitution of Fe improved corrosion resistance to -0.87V, -0.74V and 329 μA/cm^2, 144 μA/cm^2 respectively, and Ni-plating of appropriate thickness provided a high degree of protection against corrosion. Introduction Sintered NdFeB (neodymium–iron–boron) permanent magnets exhibit excellent magnetic properties[1]. Magnets been used for many extreme applications in various fields like electrical machines, electronics, acoustics, communications, automation, magnetic resonance imaging and biomedical applications. The low corrosion resistance of these magnets in humid environments has limited its wide applications [2]. Alloy additions and surface metal coatings[3-5] have been used to improve the corrosion resistance. The aim of the present paper is to study the effect of Al and Nd content in nanostructured NdFeB alloys on corrosion and to determine the influence of thickness of electroplated nickel coatings on improving the corrosion resistance of Co,Al-NdFeB magnets. Experiments Three alloy compositions, i.e., $Nd_{15}Fe_{62}Co_{15}B_8$, $Nd_{15}Fe_{59}Co_{15}Al_3B_8$ and $Nd_{20}Fe_{54}Co_{15}Al_3B_8$ named as a ND15, ND15Al3 and ND20Al3 respectively were prepared by microwave combustion followed by reduction diffusion process. The synthesis process was described earlier[6]. Cold pressed bulk sample was used for further corrosion and coating experiments. Corrosion study of the bulk sample was performed by measuring its electrochemical polarization curve in 3.5wt% NaCl solution at room temperature (25 ± 1 °C). A typical 3 electrode potentiostatic system from AUTOLAB PGSTAT 302N was used, with the sample as a working electrode, a platinum foil : counter electrode and an Ag/AgCl : reference electrode in the electrochemical cell. An external electric potential was applied between the reference electrode and the working electrode, current flow between these 2 electrodes are continuously monitored. A current vs. potential curve or a potentiostatic curve was then observed to analyse corrosion behaviour. Ni electroplating of 2μm and 10μm was conducted for ND15Al3 and ND20Al3 compositions. Results and Discussion $Nd_{15}Fe_{62}Co_{15}B_8$ composition considered as a parent samples and 3% of Fe was replaced Al to form the 2nd composition $Nd_{15}Fe_{59}Co_{15}Al_3B_8$ and 5% Fe was replaced by Nd in the 2nd composition to form the 3rd composition $Nd_{20}Fe_{54}Co_{15}Al_3B_8$. XRD pattern of ND15Al3 and ND20Al3 composition before corrosion study and after corrosion study (Fig 1(a) & (b). ND 15Al3 and ND20Al3 samples XRD pattern confirms the tetragonal phase formation. However, ND20Al3 samples consist of two phases one was Nd-rich phase marked by asterisk and the other was $Nd_2(FeCoAl)_{14}B$ tetragonal phase. The coercivity was increased for the ND20Al3 sample (Fig 1(d)), while the saturation magnetization and remanence magnetization decreased due to Fe replacement by Nd. The polarization curves for ND15, ND15Al3 and ND20Al3 are shown in figure 1(c). The replacement of Fe by 3% Al has improved corrosion resistance. The corrosion potential (Ecorr) and current density (Jcorr) observed for ND15 and ND15Al3 were -1.02V, 557 μA/cm^2 and -0.94V to 848 μA/cm^{2}respectively. When Fe was replaced by Nd for ND20Al3 composition, Nd-rich phase appeared which improved Ecorr. The Ecorr and Jcorr for ND20Al3 composition were -0.82 V and 349 μA/cm^2. The observed Ecorr for ND20Al3 composition was better than commercial sintered magnet[5]. The detailed study of ND15Al3 and ND20Al3 corroded samples were carried out by XRD and SEM EDS. All peaks of ND15Al3 samples were broadened after corrosion, while for ND20Al3 samples the Nd-rich phase peaks disappeared, which indicates that the Nd-rich phase actively dissolves[7](Fig 1(a) & (b). SEM and EDS results supported the XRD results. The corrosion study indicates the improvement in corrosion resistance of ND15Al3 and ND20Al3 sample compared to ND15 samples, hence Ni-plating was carried out for both these compositions. 2μm thickness Ni-plating was done by electroplating process for both compositions, while 10μm thickness plating was also performed for ND20Al3 composition. After Ni-plating corrosion resistance improved for both the compositions, Ecorr and Jcorr for ND15Al3 and ND20Al3 compositions were -0.87V, -0.74V and 329 μA/cm^2, 144 μA/cm^2 respectively. Further increase in Ni-plating to 10μm improved corrosion potential and current density to -0.66V and 45 μA/cm^2 for ND20 compositions. Conclusion $Nd_2(FeCo)_{14}B$ corrosion resistance was improved by substituting 3% Al and further improved by replacing Fe by 5% Nd. Fe replacement by Nd leads to a multiphase system. A Nd-rich phase dissolves and protects the tetragonal phase from corrosion. Ni-plating on both Al and Nd substituted substrate improved protection. Moreover, 10μm thickness of Ni-plating on Nd substituted composition has the best corrosion potential of -0.66V and current density of 45μA/cm^2.

Powder & Ceramics Division, Korea Institute of Materials Science, Changwon, The Republic of Korea; 3. Department of Chemistry, Sogang University, Seoul, The Republic of Korea

Abstract: Magnetic properties of Nd-Fe-B can be enhanced with the substitution of RE (RE = Pr, Tb, and Dy). Magnetic particles of $Nd_{13.5}RE_{4.5}Fe_{77.5}B_{7.5}$ were prepared by co-precipitation followed by reduction diffusion. After substitution, Pr is ferromagnetic but Tb and Dy are anti-ferromagnetic to the Fe in the Nd-Fe-B crystal lattice. The magnetic moment was increased after substitution of Pr into Nd-Fe-B, but decreased after substitution of Tb and Dy. The calculated magnetic moment for Nd-Fe-B, Nd-Pr-Fe-B, Nd-Tb-Fe-B and Nd-Dy-Fe-B were 25.50, 26.32, 21.03, and 21.01 μB, respectively. Pr substitution decreases the magneto crystalline energy, while Tb and Dy substitution increases it. Enhancement in the anisotropy energy increased the domain wall width and consequently, the coercivity was increased. Introduction: Improvement of the magnetic properties of Nd-Fe-B has been an important goal of researchers. Significant improvement in the properties of Nd-Fe-B magnets has been observed when Ce, La, Pr, Dy, and Tb were substituted for Nd [1-2]. Dy and Tb are thought to be the best choices to increase coercivity; however, Gd is very useful for increasing the thermal stability of Nd-Fe-B. Higher coercivity can also be achieved by reducing grain size, and many researchers are trying to improve the magnetic properties by refining the microstructure [3-5]. Not only coercivity, but also remanence can be improved by substitution with RE [6]. Experimental Process: Chloride compounds of Nd, Fe, and RE (where RE = Pr, Tb and Dy) were dissolved in DI water and then 3.5 M NaOH solution was added drop-by-drop to raise the pH of the solution to 13 to convert the metal chlorides to metal hydroxide. These hydroxides were washed twice with DI water and ethanol, and dried overnight at 80 °C. Product obtained was annealed at 700 °C for 30 minutes to convert all hydroxides to oxides while air was flowing in the furnace. Mixture of oxides obtained was mixed with boric acid and CaH_2 in a glove box and then pressed into pellet form. The pellet was reduced in a tube furnace by heating at 1000 °C for 3 h. The product was washed with water again and again to remove CaO completely, then washed twice with acetone and stored in inert environment. Structure analysis: XRD patterns confirmed the formation of RE-Fe-B, although patterns have a few Nd peaks. The presence of this Nd was further confirmed by SEM and TEM analysis. The shape of the particles produced was irregular and size ranged from 0.6 to 10 μm. The particles produced were single crystals, however some particles fused during the reductive annealing at 1000 °C. SEM and TEM confirmed the homogenous distribution of Nd, RE, and Fe in all the Nd-RE-Fe-B particles produced. Magnetic properties analysis: Magnetic properties on atomic level originate from the coupling of the unpaired electrons in the valance shell of the atoms. Properties enhance/decreases further, after the exchange coupling between these atoms in the crystal lattice. In Nd-Fe-B, coupling of Nd, and Fe decides the total magnetic moment of the crystal. If an atom substitutes Nd in Nd-Fe-B, it can be ferromagnetic or antiferromagnetic to the neighboring Fe atoms. In Nd-Fe-B lattice, Nd is ferromagnetic to the Fe, and when Pr is substituted for Nd it is also ferromagnetic to the Fe. Pr substitution should increase the total magnetic moment, and this was also found in our experiment. When Tb and Dy replace Nd, they are antiferromagnetic to the Fe. This anti-ferromagnetic coupling reduces the overall magnetic moment of a RE-Fe-B crystal. The products below are arranged in descending order of magnetic moment. Nd-Pr-Fe-B > Nd-Fe-B > Nd-Tb-Fe-B > Nd-Dy-Fe-B The experimental values of the magnetic moment for Nd-Fe-B, Nd-Pr-Fe-B, Nd-Tb-Fe-B, and Nd-Dy-Fe-B from our experiment were 25.50, 26.32, 21.03, and 21.01 μB, respectively. Magnetic moment is inversely proportional to the anisotropic energy. The magneto crystalline anisotropy energy was increased from 0.2284 MJ/m^3 to 0.3910 and 0.3924 MJ/m^3 after the substitution of Tb and Dy respectively in Nd-Fe-B. However, the magneto crystalline anisotropy energy decreased to 0.2050 MJ/m^3 after the substitution of Pr. Below, our products are arranged in ascending order of anisotropic energy. Nd-Pr-Fe-B < Nd-Fe-B < Nd-Tb-Fe-B < Nd-Dy-Fe-B Domain wall energy is directly proportional to the magneto crystalline energy, hence substitution of Tb and Dy increases the domain wall energy that ultimately increases the domain wall width and coercivity.[7] Nd-Fe-B at 4.7 kOe and Nd-Pr-Fe-B around 4.0 kOe were demagnetized. Coercivity for Nd-Tb-Fe-B and Nd-Dy-Fe-B was around 9.6 kOe.

Since Sagawa reported in [1] on the excellent hard magnetic properties of NdFeB permanent magnets, the utilization of anisotropic sintered NdFeB magnets in large motor and generator applications has grown spectacularly. Such hard magnetic material consists of a major tetragonal intermetallic compound ($Nd_2Fe_{14}B$), with excellent intrinsic hard magnetic properties, and a minor Nd-rich phase. Obviously, the magnetic behavior depends strongly on the microstructure of the magnet material, which in turn is determined by the production process. Microstructural factors affecting the hard magnetic character include the mean and the standard deviation of the grain size distribution, the orientation degree of the grains, the distribution of the Nd-rich phase, and the presence of a residual amount of other secondary phases (e.g. α-Fe, $NdFe_4B_4$, and other borides). All kind of defects in the microstructure, especially soft magnetic phases, can easily deteriorate the hard magnetic properties. It has been reported a slope change in the curve of magnetization as a function of temperature at around 150 K due to a spin reorientation transition (SRT) [2]. Such effect has been carefully analyzed for sintered magnets, since it is essential for the design of sensors, magnetic apparatus or magnetomechanical devices for cryogenic applications [3]. Alternative production routes of NdFeB magnets result in new microstructures whose impact on magnetic properties has to be carefully studied. Inert gas atomization is one of the novel processes under evaluation to produce NdFeB powders [4]. This technique consists on breaking a liquid metal stream into droplets by means of a high velocity inert gas flow. These droplets become spherical particles after solidification. The small size of the droplets, typically in the microns range, and the high velocity of the gas enable a fast heat transfer between both, resulting in high cooling rates and fine microstructures. Using this technique, we have produced several NdFeB alloys. After splitting the as-atomized powders in different size fractions by sieving, their microstructure and magnetic properties have been studied. In this work, we report the magnetic properties as a function of temperature, between 1.8 and 400 K, and of particle size. Fig. 1 shows the characteristic microstructure of a single gas atomized NdFeB particle, whose main constituents are $Nd_2Fe_{14}B$ grains of a few microns in size. The Inverse Pole Figure (IPF) demonstrates the random crystallographic texture of the material. The cooling rate of gas atomized particles increases when the particle size is reduced. As a result, larger particles exhibit higher microsegregation and, hence, the precipitation of soft magnetic α-Fe phase. On the other hand, smaller particles display finer microstructures. As for the coercive field, it was observed that it increases significantly when the particle size is reduced, reflecting a higher difficulty for reverse domain nucleation (less surface defects, finer grain size, lower volume fraction of secondary soft magnetic phases, etc.). Fig. 2 shows the temperature dependency of the saturation magnetization, $M_s(T)$. The anomaly, i.e. a slope change of the $M_s(T)$ curve, observed around 150 K could be ascribed to the spin-reorentation transition (SRT) mentioned before, which has been reported to occur in the same temperature range when the magnetic field is applied parallel and perpendicularly to the sample direction [2]. In contrast with the measurements performed in single crystals and anisotropic sintered magnets, isotropic gas atomized powders exhibit an increment of saturation magnetization below the split tilt temperature of the SRT. This work has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 720838 (NEOHIRE project).

AC-01. Quantitative magnetic measurement by electron magnetic chiral dichroism with high spatial resolution in the transmission electron microscope. ***(Invited)***

J. Zhu[1] and D. Song[1]
1. Tsinghua University, Beijing, China

Electron magnetic chiral dichroism (EMCD) is a newly developed technique that allows the local spin and orbital magnetic moment of materials to be quantitatively measured with close-to-atomic spatial resolution, element specificity, spin specificity and site specificity in the transmission electron microscope (TEM). In the talk, three parts will be involved: (1) a general way for quantitative EMCD measurement of magnetic parameters [1-3]; (2) high spatial resolution EMCD for magnetic measurement down to 1 nm or even atomic-plane scale [4-5]; (3) three-dimensional magnetic measurement by EMCD [6]. In the first part, a general way to experimentally achieve the quantitative measurement of magnetic parameters are presented, assisted with our theoretical simulations of dynamical diffraction effects. We will use three typical cases to demonstrate the procedure and results of quantitative EMCD technique, namely spinel $NiFe_2O_4$, garnet $Y_3Fe_5O_{12}$ (YIG) and perovskite $La_{0.7}Sr_{0.3}MnO_3$, which are with different crystallographic, magnetic structures and specific applications. The basic and intrinsic magnetic parameters, spin and orbital magnetic moment with element specificity, spin specificity and site specificity, are resolved as shown in Table 1 (take the example of YIG), many of which can not be obtained by other magnetic characterization techniques. These comprehensive information might provide a deep insight of their intrinsic magnetic properties. In the second part, we develop the method of high spatial resolution EMCD to get the magnetic information at nanometer scale. By combining the converged beam electron diffraction with EMCD technique, the magnetic measurement with ~ 1nm spatial resolution is applied the $Y_3Fe_5O_{12}$-Pt interface,which is a typical system to study the transport efficiency of pure spin current. Along with the analysis of atomic structure, electron structure and chemical composition by some other advanced techniques in the TEM, the origin of disorder layer at the interface is revealed and the decreased efficiency of spin current transport is attributed to the deteriorated magnetic properties. Our results provide the knowledge to control and manipulate the interfacial structure and properties in order to obtain higher spin transport efficiency. Also, recently we have proposed a new approach to probe local magnetic information with atomic-plane-scale spatial resolution by combining EMCD with chromatic-aberration-corrected transmission electron microscopy. At last, in-plane EMCD technique is developed, as the traditional EMCD technique has been restricted to measurements of magnetic signal in the electron beam direction. We introduce an approach that allows both in-plane and out-of-plane magnetic signals to be measured using EMCD in the Lorentz TEM, taking the example of Co nanoplate. Therefore, three-dimensional magnetic measurement by EMCD is possible. Meanwhile, the magnetic signals can be detected by applying the out-of-plane magnetic field, achieving the in-situ study of magnetic behaviors.

Table 1 Magnetic parameters of YIG

Magnetic parameters	EMCD (present work)	XMCD	Neutron diffraction	First principle calculation	Macro measurement (SQUID, present work)
m_L/m_S (oct)	0.06±0.02				
m_L/m_S (tet)	0.08±0.02				
m_L (oct)	0.28±0.03				
m_L (tet)	0.31±0.03				
m_S (oct)	4.5±0.2				
m_S (tet)	3.9±0.2				
M_{oct}	4.8±0.2			4.12[34]	
M_{tet}	4.2±0.3			4.20[34]	
M_{total}(unit cell)	3.0±0.7		3.1[33]	4.36[34]	3.3

Note: m_L/m_S refers to the ratio of orbital and spin magnetic moment (m_L is the orbital magnetic moment and m_S is the spin magnetic moment). M_{oct} and M_{tet} are the total atomic magnetic moments (including the orbital and spin magnetic moment) of oct and tet Fe in the units of μ_B per atom. M_{total} is the total magnetic moments for $Y_3Fe_5O_{12}$ in a unit cell.

Table 2 magnetic moment of Fe at YIG/Pt interface

Position / $M \times K$ (μ_B)[a]	Bulk	~3 nm distance from interface	~2 nm distance from interface
With disorder layer	1.43±0.10 (5 μ_B)	1.04±0.11 (3.6 μ_B)	0.76±0.10 (2.7 μ_B)
Without disorder layer	1.57±0.15 (5 μ_B)	-	1.55±0.12 (4.9 μ_B)

[a]Note: *M* is the magnetic moment of Fe element; *K* is the dynamical coefficient as shown in equation (1). The magnetic value in the brackets is normalized with magnetic moment Fe^{3+} in YIG bulk, which is estimated to be 5 μ_B according to Hund laws.

Stable confinement of elemental magnetic nanostructures, such as a single magnetic domain, is fundamental in modern magnetic recording technology [1]. It is well known that various magnetic textures can be stabilized by geometrical confinement using artificial nanostructures. The magnetic skyrmion [2,3], novel spin texture promising for future memory devices because of its topological protection and dimensions at the nanometer lengthscale, is no exception. So far, skyrmion confinement techniques using large-scale boundaries with limited geometries such as isolated disks and stripes prepared by conventional microfabrication techniques have been used. Here we demonstrate an alternative technique confining skyrmions to artificial nanostructures (corrals) built from surface pits fabricated by a focused electron beam. Using aberration-corrected differential phase contrast scanning transmission electron microscopy (DPC STEM) [4-6], we directly visualize stable skyrmion states confined at a room temperature to corrals made of artificial surface pits on a thin plate of bulk β-Mn-type chiral magnet $Co_8Zn_8Mn_4$ (Curie temperature; Tc ~300 K) [7,8]. DPC STEM images (Figure 1) clearly demonstrate a stable single skyrmion state located at the center of a 800 nm equilateral triangular corral at a room temperature (295 K) under the perpendicular magnetic field of 59.9 mT. Under the residual field of the objective lens (~20 mT), the single-skyrmion state turned into a triple-skyrmion state. The transition from the single-skyrmion state to the triple-skyrmion state occurred in a very narrow range of perpendicular magnetic field (40.0±1.0 mT). Intriguingly, a two skyrmion state was not evident during the transition. Moreover, no helical magnetic state was observed inside the triangular corral under the residual field of objective lens. On the other hand, a single-skyrmion state becomes unstable under an increasing magnetic field and vanishes above 77 mT. To understand the present results, it is important to characterize the nature of the defects fabricated by a focused electron beam. By using plan-view TEM/STEM and STEM energy dispersive X-ray (EDX) analysis techniques, we confirmed that the linear surface defects are built of a sequence of separated tiny surface pits with no preferential sputtering of specific atomic species. Their diameters and the separation depend on the conditions of fabrication, such as probe size and exposure time, and also on the thickness of the thin plate at the irradiated region, but their typical diameter is 5 nm and they are typically separated by 10 nm as shown in Figure 2a. To characterize the nature of the defects more in detail, we observed cross-sectional views of the surface pits. It should be noted, however, the thin plate specimen shown here is not exactly the same as the one used to demonstrate the stable skyrmion states as shown in Figure 1. We usually use standard ion thinning method to prepare thin plate specimens to observe skyrmions in order to minimize surface damage and ensure surface quality, but it is extremely difficult to prepare a cross-sectional specimen from such a thin plate by the ion thinning method. We therefore fabricated the cross-sectional specimen by using a focused ion beam (FIB) technique. We fabricated four linear surface pits (indicated as A–D in the plan-view in Figure 2b). The linear surface pits indicated as A were fabricated using the same beam condition used when we created the 800 nm triangular corral as shown in Figure 1. We confirmed that the defect on the top (beam entrance) crystalline surface (indicated by A) is actually a pit with a diameter and depth of 5 nm, while the defect on the bottom (beam exit) damage layer (indicated by A') is larger than that on the top surface (Figure 2c,d). After all, it proved that the defects are a pair of surface defects, one on the top surface of the thin plate and the other on the bottom surface of the thin plate. In conclusion, we have demonstrated stable skyrmion states at a room temperature in a thin plate of $Co_8Zn_8Mn_4$ confined to artificial corrals built from the periodic array of top and bottom surface pits fabricated by a focused electron beam. Artificial control of skyrmion states with the present technique [9] should be a powerful way to realize future non-volatile memory devices using skyrmions.

Thin film structures exhibiting perpendicular magnetic anisotropy (PMA) are of technological importance and promising candidates for spintronic nano-devices in the context of ultrahigh density magnetic storage, fast memory applications and nano-sensors. At favourable atomic ordering, ultra-thin alloys of Co with Pd or Pt and sandwiches display PMA. In Co based multilayer (ML) systems, the effective anisotropy originates from the interplay between the interface and volume contribution of anisotropy. Comparable values of these two anisotropies help the system to break into multiple domains. The characteristic features of magnetic domains in such systems can be controlled by the growth condition [1], thickness of the constituent layers as well as with external stimuli *viz.,* magnetic field, heat-treatment [2], laser [3] and ion-beam irradiation [4]. Ion-beam irradiation is a viable technique to tune magnetic properties, associated with locally induced structural imperfection or intermixing, relevant in the context of magnetic ML [5]. The irradiation energy and fluence can be separately adjusted to control the depth and the lateral extent of the damaged region, which leads to the modification of magnetic properties. The ions lose energy during their passage through the material, which is either spent in displacing target atoms by elastic collision (nuclear stopping) or exciting the atoms by inelastic collisions (electronic stopping) [6]. In this study, we are going to show the modification of magnetic domains in Co/Pd ML by ion-beam irradiation. There are a variety of studies of ion-beam modifications in magnetic ML either in the context of patterning [7] or depth resolved structural modifications [8]. The focus in this work will be on the modification of nano-scale magnetic domains and their modelling along with the investigation of integral magnetic properties and structural changes. ML films with the composition (Si (substrate) / Ta (30) / Pd (30) / [Co (3) / Pd (8)] $_{50}$ / Pd (12) Å) have been deposited by ultra-high vacuum DC magnetron sputtering with Ar pressure of 2×10^{-3} mbar. The ion-beam irradiation was performed with Ar^+ ions having three different energies of 50, 100 and 150 keV along with six different fluences ranging from 10^{14} to 10^{16} ions/cm^2. Simultaneous atomic and magnetic force microscopy (AFM/MFM) was carried out for the pristine and irradiated films to observe the topography and magnetic domains. Magnetization measurement has been performed with vibrating sample magnetometer (VSM) with applied field along in-plane (IP) and out-of-plane (OOP) direction of the film surface. Cross-sectional transmission electron microscopy (XTEM) was carried out for selected samples employing high voltage (1250 kV) electron microscopy. The pristine ML film displays a nano-scale maze-like domain pattern in as-deposited condition as shown in Fig. 1(a). The two opposite contrasts designate the presence of oppositely magnetized domains with high magnetic phase difference. The average dimension of the domains turned out to be 464 (±12) nm, estimated from the power spectral density curve associated with the 2D Fourier transform of the domain image. The hysteresis loop in Fig. 1(b) clearly shows the predominant OOP magnetization of the film with a square hysteresis loop. The coercivity along the OOP and IP direction is estimated to be 880 (±5) and 440 (±5) kG respectively. The OOP saturation field is around 5 kG, whereas the IP loop cannot be brought up to saturation within the limited field of the VSM. Figure 1(c) displays the overall cross-section view of the film. The high resolution TEM image of the selected area clearly depicts the presence of ultra-thin layer stacking for the pristine film (Fig. 1(d)). However, the selected area electron diffraction pattern in Fig. 1(e) shows the polycrystalline nature of the film, in agreement with similarly prepared ML systems. Ion beam irradiation was performed at three different energies *viz.,* 50, 100 and 150 keV of Ar^+ ions. Calculation shows that the ions completely penetrate the ML and stop on average deep inside the Si substrate. The fluence was varied by varying the time of irradiation. The magnetic domains (before exposing to external magnetic field) of the irradiated samples have been shown in Fig. 2(a) and (b) for ion energies 50 and 100 keV respectively for the fluences of 10^{14}, $10^{15}$and 10^{16} ions/cm^2. Irradiation with the lowest energy and fluence shows the presence of periodic domain structure with alternating contrast. The average domain size decreases to 117 (±7) nm and the periodic domain pattern no longer exists at higher fluences. The reduced domain size and contrast with increasing ion energy and fluence designates the decrease in PMA. The feather-like domains with cross-tie domain walls are observed in MFM images with fluences $>10^{14}$ ions/cm^2 according to Fig. 2(a). For 100 keV ion energy, the MFM image is largely influenced by topographic features with higher roughness. Magnetization measurements also support the spin re-orientation from OOP to IP of the film surface with increasing ion-energy and fluence.

Spin structures including domain walls and magnetic vortices have attracted enormous interests not only due to their fascinating topological textures but also their potentials in a wealth of technological applications such as high efficient storage and memory devices. In the research of those spin structures, synchrotron-based microscopes have been playing key roles by direct imaging of static and dynamic behaviors of spin structures and therefore providing a powerful insight into the underlying physics of nanospin phenomena and an essential knowledge for their applications in advanced nanotechnologies [1, 2]. In our work, we employed a full-field soft X-ray microscope (XM-1) at Advanced Light Source (ALS) to directly observe non-trivially distorted vortex cores consisting of asymmetric Bloch walls and their dynamics. Fig. 1 shows the deformed vortex core observed in an asymmetric permalloy (Py, $Ni_{80}Fe_{20}$) disk with a height of h = 100 nm, a diameter of D = 500 nm, and an asymmetric ratio of $r = 0.3D$ (a) together with simulated vortex core and the out-of-plane (OOP) magnetic component (m_z) larger than 0.7 (b). The distorted vortex core was found to be vortex cores placing non-coaxially on top and bottom surface of the disk, which are connected by an asymmetric Bloch wall creating flux closer domain. Such core structure is significantly distinguished from common circular vortex cores characterized by a single vortex core (polarity, p) aligned on both surfaces of a magnetic element pointing either up or down and a circular in-plane domain (circularity, c) rotating either clockwise or counter-clockwise [3,4]. Interestingly, the nontrivially shaped vortex core shows an abnormal dynamic behavior. Unlike the traditional gyrotropic motions of circular vortex cores, sloshing motion was observed in the distorted core although micromagnetic simulations demonstrated that vortex cores on top and bottom surfaces still have gyrotropic motions. The unique dynamic motion of the deformed vortex core is likely due to the asymmetric Bloch wall restricting the motions of vortex cores on surfaces [5]. This research was also supported by Leading Foreign Research Institute Recruitment Program through NRF (2012K1A4A3053565) and by the DGIST R&D program of the Ministry of Science, ICT and future Planning (17-BT-02. Work at the ALS was supported by the U.S. Department of Energy (DE-AC02-05CH11231).

Magnetic force microscopy (MFM) is used to detect and visualise the stray magnetic fields that emanate from the surface of magnetic materials [1]. With typical resolution limits of ≈30 nm MFM can be used to image the magnetisation configuration of a vast range of materials and magnetic phenomena in a laboratory-based environment. Typically, MFM is used only in a qualitative capacity to gain physical insight into the morphology of magnetic domains, however, there are established calibration methods that can be employed to make quantitative measurements. These involve precise determination of the probes magnetic properties and subsequent contribution to the measured image. Two such methods include image deconvolution in the frequency domain, the so called real space tip transfer (RSTTF) approach [2], and probe calibration using current carrying microstructures, which are used to generate a well-defined field profile [3,4]. In this work we explore the use of current-carrying coils of micro-metric, in particular, we focus on the crucial role of electrostatic compensation on the measured values of the effective monopole and dipole contributions of the magnetic probe. In order to generate the measurable MFM signal with an appropriate signal-to-noise ratio, a current of a reasonable magnitude should be driven through the coil. Hence, the potential difference becomes non-negligible and appreciable parasitic electrostatic fields can arise. The gradients of the electrostatic force are superimposed with those originating from magnetic interactions, making accurate quantitative analysis impossible. It is therefore of extreme importance to measure the magnitude of these electrostatic force gradients and develop an effective way of their full compensation. The electrical compensation is achieved through the application of an a.c. signal between the probe and sample, which introduces an additional force observed as side bands to the fundamental mode of the cantilever. An additional lock-in is used to measure these bands and a feedback loop is employed to keep the magnitude of these side bands to zero by applying a d.c. voltage equivalent to the error signal. This signal is then applied during the second lifted pass where the MFM response is recorded. The experimental setup displaying the typical coil topography and the electrical ground configurations is shown in Fig. 1a. The effect of electrostatic compensation switched off and on is shown in Fig. 1b and c, respectively. Without the use of compensation, there is a clear electrostatic influence on the measured MFM signal, which is mainly observed at the coil edges as well as charging effects on the surrounding SiO_2 substrate. Conversely, the addition of electrostatic compensations is shown to significantly reduce these parasitic effects (Fig. 1c phase). The electrostatic nulling signal (i.e. the d.c. voltage required to reduce the measured scanning Kelvin probe microscopy (SKPM) signal to zero) is shown in Fig. 1c SKPM. Finally, average line profiles of the MFM signals with/without electrostatic compensation are presented in Fig. 1d. Even qualitatively these line profiles vary significantly, which dramatically impacts on quantitative solutions, making the measurements taken without compensation not trustworthy. Finally, we investigate the effects of electrostatic compensation on calibrated measurements and compare the extracted magnetic properties of an MFM probe. This work builds upon the existing framework [3,4] where current carrying coils are used in generating known magnetic fields for calibrated MFM measurements. We extend the robustness and accuracy of this technique to include considerations of the effect of the electrostatic field. Furthermore, we use the combined MFM-SKPM method to eliminate unwanted artifacts. This is of high importance for research areas where nanoscale quantification of the stray magnetic field is required. One emerging example is the quantitative measurement of the field emanating from magnetic skyrmions, which can be used to gain insight to the local spin structure. This will provide a better understanding of fundamental properties of these novel nanostructures, paving the way for future technologies [5].

Electromagnetic properties are one of the keys for understanding and mastering nano systems used in many applications, as in medical treatment, optics, microelectronic or data storage. Various methods exist to map magnetic fields. Some are based on near field microscopy, like magnetic force microscopy, other on X-ray set-ups, like photoemission electron microscopy. Electron holography (EH), a powerful transmission electron microscopy method, is another appropriate tool which combines high sensitivity with a high spatial resolution. EH allow the quantitative measurement of both internal and external fields in individual nano-objects instead of assemblies of nanoobjects. This interferometric method can also be used for performing in situ/in operando experiments. We thus developed and applied EH on very different systems, from the single nanoparticles to the thin layer and the complex magnetic device, for studying their magnetic properties. In this presentation, we will present our investigations on a single Fe nanocube and an FeRh thin layer. - Nanomagnets recently attracted considerable interest due to their possible application as building blocks for hard drive disks and permanent magnets or as nanobiological vectors for drug delivery and hyperthermia. Despite theoretical studies, the size-dependence of spin arrangements in single nanomagnets has not yet been evidenced experimentally due to sensitivity limitations of the investigation tools. The single domain limit, corresponding to the critical nanomagnet size separating vortex/single domain configurations, has never been observed although it will dictate the optimized size for applications. In such small nano-objects, micromagnetic simulations show that the magnetic internal structure changes from single domain (SD) to vortex states as the cube size increases (Fig. 1). Some years ago, we reported symmetrical vortices, i.e. vortex of <001> axis, in isolated 30 nm single crystal Fe cubes with a 14 nm vortex core size [2]. Next, we showed that vortices can also be stabilized in the presence of dipolar interactions thanks to holes in the cubes inducing a pinning of the vortex core [3]. Here we will present the spin configuration phase diagram in size-controlled single Fe nanocubes combining EH experiments and micromagnetic simulations [4]. High sensitivity imaging explicitly reveals how three different spin arrangements can be stabilized within a 3 nm window, evidencing the key importance of nanometric size control of magnetic nanoparticles. Moreover, it gives a deeper understanding of the single domain limit, which is more complex than expected with the appearance of a previously unreported <111> vortex state. Such a measurement opens the door to fine magnetic control of nano-objects. - In situ heating/cooling EH has been used to quantitatively map the magnetization of a cross-sectional FeRh thin film through its magnetic transition [5]. This alloy presents a remarkable and unusual magnetic transition from a low temperature antiferromagnetic state (AFM) to a high temperature ferromagnetic state (FM) close to 370K accompanied by a 1% volume expansion.[6-8] The transition is obtained for a narrow composition range 0.48<x<0.56 in the B2-ordered a' crystal phase of Fe1-xRhx. These remarkable features make FeRh particularly well suited for advanced magnetic devices for instance in heatassisted or even electrically –assisted magnetic recording [9-10] and magnetic random access memories based on AFM spintronics [11], or for magnetocaloric materials [12]. Further developments of reliable devices including thin FeRh films or others materials presenting a magnetic transition require a full control of the magnetic state within the film, a perfect knowledge of the mechanisms involved in the transition and a deep understanding of the influence of interfaces and low dimensionality. However, the mechanisms involved in the transition are still under debate. EH experiments provide a direct observation of an inhomogeneous spatial distribution of the transition temperature along the growth direction. Most interestingly, a regular spacing of the ferromagnetic domains nucleated upon monitoring of the transition is also evidenced. Beyond these findings on the fundamental transition mechanisms, EH also brings insights for in operando analysis of magnetic devices and a very promising approach to investigate the mechanisms of phase transitions in various magnetic systems (as MnAs [13]) at all pertinent scales.

Our study demonstrates a breakthrough in the ability to provide direct real-space insight into atomic-plane resolved magnetic circular dichroism in materials. This information is important on a fundamental level in physics, materials science and nanotechnology, as well as for applications such as new designs of energy-efficient spintronic devices. Our approach combines the latest developments in chromatic aberration corrected electron microscopy with electron energy-loss magnetic chiral dichroism(EMCD). We study the double perovskite Sr_2FeMoO_6 and quantitatively measure the ratio of orbital to spin magnetic moment atomic plane by atomic plane.[2,3] The spatial resolution of atomic-plane resolved EMCD method goes beyond that of any currently available technique, including XMCD and neutron diffraction. It is applicable to studies of spin configurations, atomic structure and chemical bonding at different magnetically coupled interfaces, including magnetic spring effects at interfaces between hard and soft magnets, magnetoelectric coupling between ferromagnetic and ferroelectric materials and exchange bias between antiferromagnetic and ferromagnetic materials.

The CoMnSi compound has aroused much interest because it shows a metamagnetic transition and useful magnetic properties [1–5]. Annealing was often used to improve its properties. However, the underlying mechanism is not well understood. In this work, we investigated the effect of annealing on the structure and magnetic properties of an as-cast sample of CoMnSi. As shown in Fig. 1, the annealing increases magnetic moments at ferromagnetic state but decreases magnetic moments at antiferromagnetic state. As a result, the annealing brings about a doubling of the maximum magnetic entropy change. Synchrotron radiation X-ray diffraction revealed that the annealing does not change the crystal structure but brings about different changes of two nearest Mn-Mn distances. As displayed in Fig. 2, the X-ray absorption near edge structure (XANES) experiments unveiled that the local environment around the Mn atoms are changed slightly by annealing but that the local environment around the Co atoms are changed significantly. When compared with the as-cast sample, the intensity corresponding to the electronic transition from 1s to 3d of the annealed sample reduces, while the intensity corresponding to the electronic transition from 1s to 4p increases. The Fourier transforms analysis of the extended X-ray absorption fine structure (EXAFS) showed that the Co-Si bond length of the annealed sample is shorter than that of the as-cast sample, but he Co-Mn bond length of the annealed sample is same as that of the as-cast sample. Such observations suggested that the annealing promotes the p-d hybridization between Co and Si atoms, causing a sharper metamagnetic transition.

High storage density magnetic devices rely on the precise, reliable and ultrafast switching times of the magnetic states. Optical control of magnetization using femtosecond laser without applying any external magnetic field offers the advantage of switching magnetic states at ultrashort time scales, which has attracted a significant attention. Recently, it has been reported and demonstrated the, *so-called*, all-optical helicity-dependent switching (AO-HDS) in which a circularly polarized femtosecond laser pulse switches the magnetization of a ferromagnetic thin film as function of laser helicity [1]. Afterward, in more recent studies, it has been reported that AO-HDS is a general phenomenon existing in magnetic materials ranging from rare earth – transition metals ferrimagnetic (e.g. alloys, multilayers and hetero-structures system) to even ferromagnetic thin films. Among numerous studies in the literature which are discussing the microscopic origin of AO-HDS in ferromagnets or ferrimagnetic alloys, the most renowned concepts are momentum transfer via Inverse Faraday Effect (IFE) [1-3] and the concept of preferential thermal demagnetization for one magnetization direction by heating close to Tc (Curie temperature) in the presence of magnetic circular dichroism (MCD)[4-6]. In this study, we investigate all-optical magnetic switching using a stationary femtosecond laser spot (3–5 μm) in TbFe alloys via photoemission electron microscopy (PEEM) and x-ray magnetic circular dichroism (XMCD) with a spatial resolution of approximately 30 nm. We spatially characterize the effect of laser heating and local temperature profile created across the laser spot on AO-HDS in TbFe thin films. We find that AO-HDS occurs only in a 'ring' shaped region surrounding the thermally demagnetized region formed by the laser spot and the formation of switched domains relies further on thermally induced domain wall motion. Our temperature dependent measurements highlight the importance of attaining Tc, local temperature and temperature gradients for helicity-dependent switching. In addition, by investigating a series of samples with different Tb concentrations and film thicknesses, we demonstrate that the switching direction for a given laser helicity, inverts at a threshold film thickness [7]. We show that our results can be explained in the presence of one orientation MCD. Magnetic domains are heated preferentially and consequently, demagnetized in the region close to Tc, leading to an asymmetrical response with respect to the incoming laser helicity. These new findings shed light on a robust and reliable switching process, which paves the way for further understanding of the AO-HDS and its microscopic origin.

AC-10. A Magnetic Field Camera for Real-Time Subsurface Imaging Applications.

A.B. Suksmono[1,2], D. Danudirdjo[1], R.P. Prastio[1], A.D. Setiawan[3] and D. Rahmawati[1]
1. School of Electrical Engineering and Informatics, Institut Teknologi Bandung, Bandung, Indonesia; 2. ITB Research Center on ICT (PPTIK-ITB), Institut Teknologi Bandung, Bandung, Indonesia; 3. School of Electrical Engineering, Telkom University, Bandung, Indonesia

We have constructed an imaging device that can show spatio-temporal distribution of magnetic field in real-time. The device employs 16 units of AMR (anisotropic magneto resistance) 3-axis magnetometers, which are arranged into a 4×4 size sensor-array. All of the magnetic field values measured by the array are collected by a microcontroller, which then preprocess and send the data to a smartphone or a PC using a USB or wireless (bluetooth) channel. An interpolation and display software in the smartphone/PC have also been built to present the field as a larger video on a screen; hence, the device serves as a magnetic field camera. In the experiments, we show that the magnetic-field distorted by objects buried under a surface can be imaged by the proposed device; therefore, we can use it for a real-time subsurface imaging or NDT (non-destructive testing) applications. Camera is an image capturing device. A distinctive feature of a camera is that the entire image (or sequence of images/video) are captured simultaneously, instead of elements-by-elements or pixel-by-pixel. In the latter case, the device will be called a scanner. In the digital camera, usually the captured image is displayed instantly; therefore, we refer the generic name "camera" to refer to a device capable to capture and display the image instantly. Previously, we have constructed a magnetic imaging system utilizing the built-in magnetometer of a smart-phone [1]. To obtain an image representing the distribution of magnetic field intensity, one has to scan the area of interest and then run a reconstruction program to obtain the field values. Therefore, this device is categorized as a (magnetic field) scanner, which will be referred as B-Scanner. The "B" in the names follows the notation of magnetic flux density, which is denoted as B. In this paper, we present a design and realization of a magnetic field camera or the B-Camera. The B-Camera has the capability to capture and display magnetic field distribution of a region instantly. Instead of sequential scanning of a gridded area done in the B-Scanner, we employ an array of magnetometers that measure the field values on a regular grid of the area simultaneously. Then, a reconstruction software will interpolate entire values of in the domain and display the result on the screen instantly. Block diagram and implementation of the device is displayed in Fig.1. The magnetic field camera (MFC) blocks consist of sensor-array part, display, and communication between sensor and the display. In principle, the camera works like the magnetic field scanner, unless the sensors position are fixed at regular grid points/array. The MFC (Magnetic Field Camera) is divided into the following functional blocks: (a) sensor array and multiplexer, (b) microcontroller, (c) communication-1: sensor-array side, (d) communication-2: smartphone side, and (e) computing/interpolator and display. Fig.2 shows the block diagram of the camera and the obtained results. In (a), a coin (made of nickel) is located at the center of the camera array. The display unit, which in this case is a smartphone, shows magnetic field distribution as an image. From the menu, a user can select either the x, y, z, components of the field or its magnitude. The (b) part of the figure shows the image of field distribution when the coin is located at the corner of the array. Both of (a) and (b) consistently shows the magnetic field distribution at the correct place, considering that the user will direct the array downward when performing the imaging.

K. K. Meng*,Y. Jiang* *kkmeng@ustb.edu.cn *yjiang@ustb.edu.cn Spin orbit coupling (SOC) has attracted considerable attention as it is central to the rich phenomena observed in heavy metal (HM)/ferromagnetic metal (FM) heterostructures, such as spin orbit torque (SOT), spin Hall magnetoresistance (SMR), spin Seebeck effect and magnetic skyrmions[1-2]. Especially, the charge current passing through the HM film with strong SOC produces transveral pure spin current due to the spin Hall effect (SHE), which exerts torques on the magnetization of the FM film, and the sign and magnitude of SOT are essentially determined by the spin Hall angle (SHA) of HM. According to the physical origin, enhancing the effective SHA and spin accumulation at HM/FM interfaces has been the central method for improving the switching efficiency in SOT-active devices. Because SHA is hard to be intrinsically controlled, many extrinsic ways to control it have been proposed. Qiu et al.[3] utilized the large spin absorption at Ru/FM interface to decrease the spin memory loss and effectively enhance SHA. In our study, we will modulate the spin accumulation and the efficiency of SOT by nonequilibrium proximity effect *[accepted by Appl. Phys. Lett.]*. According to the geometric relation between the flow of electrons and accumulated spins in the multilayers of Pt/Co/Pt/SiO_2 and Pt/Co/Pt/YIG illustrated in Figure 1(a) and (b), respectively. The charge current J_e applied in the Pt layer is converted into spin current J_s due to SHE, which travels perpendicular to the film plane with the spin polarization parallel to the plane. A part of the spin current at Pt/Co/Pt/YIG multilayers, compared with Pt/Co/Pt/SiO_2 multilayers, will be absorbed by the magnetization M of YIG through spin transfer torque when J_e is parallel to M. In this case, we expect that the reduction of J_s^{back} in Pt/Co/Pt/YIG will enhance the SHA of Pt closing to YIG. According to the magnetic field H dependence of the out-of-plane magnetization M and the anomalous hall resistance R_H at room temperature for the two multilayers shown in Fig. 1 (c) and (d), which indicating that the saturation magnetizations M_s and the coercivities H_c are almost the same in the two multilayers, however, the critical switching current in Pt/Co/Pt/YIG is only half of that in Pt/Co/Pt/SiO_2 as shown in Fig. 2(a) and (b), indicating the enhancement of effective SHA in the former structure. To quantitatively determine the strength of the spin orbit effective fields in the two samples, the non-adiabatic harmonic Hall voltage measurements with sweeping magnetic field parallel or perpendicular to the current direction were carried out at room temperature. The harmonic measurements by applying a sinusoidal AC current with the amplitude of 10×10^6A/cm^2 at 300 K are taken as an example as shown in Fig. 2 (c), in which the results were measured with the out-of-plane magnetization component $M_Z > 0$ and $M_Z < 0$ respectively. According to the calculated H_D values plotted with respect to the applied current in Fig. 2 (d), the SHA in Pt/Co/Pt/SiO_2 is calculated to be 0.049 while the value is 0.071 in Pt/Co/Pt/YIG. The harmonic measurements demonstrated that the effective SHA has been enhanced in Pt/Co/Pt/YIG/GGG. In conclusion, we have studied the SOT-induced magnetization switching in the two multilayers of Pt/Co/Pt/SiO_2 and Pt/Co/Pt/YIG. The critical current in Pt/Co/Pt/YIG is effectively reduced compared to that in Pt/Co/Pt/SiO_2. We propose that the nonequilibrium proximity effect at the Pt/YIG interface suppresses the spin current reflection and enhances the effective spin accumulation at the Co/Pt interface. The harmonic measurements demonstrated that the effective SHA has been enhanced in Pt/Co/Pt/YIG/GGG. Our method provides an efficient way to modulate SOT.

Spin Hall effect (SHE) that converts charge currents into spin currents in a heavy metal (HM) with strong spin-orbit coupling (SOC) has attracted much interest due to its practical use in technological applications. When a HM comes in contact with a ferromagnet, the spin currents that diffuse into the FM will modify the spin dependent transport properties such as anomalous Hall effect (AHE). On the other hand, the spin currents will also exert torque on the magnetization, which is similar to spin transfer torque. The investigation and clarification of these intriguing issues are of fundamental importance for better understanding the underlying physics. In HM/FM heterostructures with perpendicular magnetic anisotropy (PMA), the generated pure spin current can also exert torques on the magnetization, which is referred as to spin orbit torques (SOT). On the other hand, spin accumulation can take place at the FM/HM interface via the Rashba effect, which has also generated significant effective torques and caused current-induced domain nucleation and fast domain wall motion. Both mechanisms can result in the exertion of dampinglike torques and fieldlike torques on the FM, which can be characterized by equivalent dampinglike effective field H_D and fieldlike effective field H_F respectively. It should be noted that, quite generally, the SOT induced magnetization switching has been mostly investigated in HM/FM multilayers with the interfacial induced PMA, in which the HM layer modifies the interfacial orbital angular momentum of the FM layer and enhances its SOC. From a practical viewpoint, however, the interfacial PMA is not thermally stable in nanoscale magnetic devices. Recently, we have systematically investigated the SOT in MnGa/HM and MnAl/HM films with intrinsic PMA, which seems to be ideal for the current induced magnetization switching[1-4]. However, the switching current density (~10^7 A/cm^2) in MnX/HM bilayers as shown FIG. 1 is similar with those in interface induced PMA multilayers, which is unsatisfactory for practical low-power spintronic devices. In the magnetic systems that lack inversion symmetry (whether due to underlying crystal structure or interfaces), SOC can combine with the exchange interaction to generate an anisotropic exchange interaction that favors a chiral arrangement of the magnetization. This is known as the Dzyaloshinskii-Moriya interaction (DMI), which has a form $D_{12}\bullet(S_1\times S_2)$. The vector D_{12} depends on the details of electron wave functions and lies parallel or perpendicular to the line connecting the two spins, depending on the symmetry. Contrary to the Heisenberg exchange interaction, which leads to collinear alignment of lattice spins, the form of DMI is therefore very often to cant the spins by a small angle. If DMI is sufficiently strong enough to compete with the Heisenberg exchange interaction and the magnetic anisotropy, it can stabilize long-range non-collinear spin textures. Therefore, if the presence of strong SOC introduces a strong interfacial DMI in the MnX/HM films, the non-collinear spin textures such as Néel-type skyrmion could be driven and a much smaller switching current density (~10^2 A/cm^2) should be realized. On the other hand, when a conduction electron passes through a non-collinear magnetic structure, the spin of the conduction electron adiabatically couples to the local spin and experience a fictitious magnetic field (Berry curvature) in real space, which deflects the conduction electrons perpendicular to the current direction. Therefore, it will cause an additional contribution to the observed Hall signals that has been termed topological Hall effect (THE) as shown in FIG. 2. THE can be described by the same theoretical scheme as the intrinsic AHE, which has been clarified to be a Berry phase in momentum space. In the presence of a non-collinear magnetic structure, the total Hall resistivity can usually be expressed as the sum of various contributions: $\rho_H=R_0H+\rho_A+\rho_T$, where is the normal Hall coefficient, the anomalous Hall resistivity, and the topological Hall resistivity[5]. Based on our previous works of SOT, the results will open the route to engineer non-collinear spin textures for SOT devices, in which a much smaller switching current density is expected if the chiral DW, such as Néel-type skyrmion, can be confirmed.

Spin current, flow of spin angular momentum, is at the heart of spintronics. Since it is closely related to device application, the effective generation and detection of spin current have been intensively studied so far in this field. Spin Hall effect (SHE) and its inverse (ISHE) are typical phenomena to generate and detect the spin current. Recently, it has been revealed that the SHE and ISHE are affected by spin fluctuations in magnetic systems such as weak ferromagnetic metals near Curie temperatures [1] and spin-glass metals [2]. The latter is well-known as one of the magnetic ordering states with complex spin structures. It appears when magnetic impurities are randomly distributed in a nonmagnetic noble metal. The interaction between the localized magnetic moments is mediated by conduction electron spins, which is referred to as the Ruderman-Kittel-Kasuya-Yosida (RKKY) interaction. Depending on the distance between the two magnetic impurities, the exchange coupling is either ferromagnetic or antiferromagnetic. As a result of the RKKY interaction, spin glasses exhibit a cusp anomaly in the magnetic susceptibility as a function of temperature T. It is commonly believed that most of the magnetic moments are randomly frozen below the cusp temperature, so-called spin glass temperature T_g. However, according to recent SHE measurements in CuMn spin-glass metals [2], the SHE signal started to decrease at a temperature labeled as T^*, which is 4 times higher temperature than T_g. This result indicates that the spin current can detect magnetic fluctuations of the localized moments in a much more sensitive manner compared to the conventional magnetic susceptibility measurements. On the other hand, in order to deeply understand the relation between the spin current and magnetic fluctuations, further experiments are highly desirable. Here we have performed SHE measurements in $Cu_{99.5-x}Mn_xBi_{0.5}$ alloys with much higher Mn concentrations (x = 4.2, 10.6) than the previous work [2]. With increasing the Mn concentration x, T_g monotonically increases. This enables us to investigate the effect of spin fluctuations on the SHE in spin glasses at much lower temperatures than T_g. A small concentration of Bi (0.5%) has been added to induce large SHEs in CuMn spin-glass metals [2, 3]. The inset of Fig. 1 shows a typical spin Hall device used in the present work. The device is based on the lateral spin valve with a strong spin orbit material in the middle, which allows us to induce a spin current in the Cu channel and to inject it into the CuMnBi wire [4]. The measured ISHE resistance ΔR_{ISHE} (the detected Hall voltage divided by the injection current illustrated in the inset of Fig. 1) for different Mn concentrations $Cu_{99.5-x}Mn_xBi_{0.5}$ (x = 1.5, 4.2, 10.6) is plotted as a function of temperature T in Fig. 1. With decreasing T, ΔR_{ISHE} increases because the spin diffusion length of the Cu channel becomes longer with T. For $T < T^*$, however, ΔR_{ISHE} starts to decrease and becomes almost zero for higher concentrations (x = 4.2 and 10.6) at low temperatures. Such a large suppression of ISHE has never been seen for lower Mn concentrations [2]. The result shown in Fig. 1 can be explained by the following scenario: at high enough temperatures, the Mn moments fluctuate with high frequencies and the conduction electron spins cannot follow this fast motion. Thus, the ISHE signal is simply determined by skew scattering at the Bi impurity sites [2,3]. With decreasing T, the fluctuation of the Mn moments is getting slower. The conduction electron spins can feel the fluctuation and the directions of conduction electron spins are randomized. Since the Mn moments are randomly frozen for $T < T_g$, the directions of conduction electron spins become completely random and thus the ISHE signal disappears well below T_g. The relations of T_g and T^* with the Mn concentration x are summarized in Fig. 2. For all the investigated x region, T^* is always a few higher than T_g. From the present SHE measurements, we are able to shine a new light on the spin fluctuation regime ($T_g < T < T^*$, indicated by blue shade in Fig. 2) where conduction electron spins are affected by the motions (or interaction) of localized magnetic moments, which has never been detected with other experimental methods.

Magnetization manipulation by spin-orbit torques (SOTs) has advanced to an active research field over the past few years. Most work so far has focused on material systems with conventional ferromagnets deposited on heavy metal layers where the space inversion symmetry is broken at the interface [1-4]. However, space inversion symmetry is intrinsically broken in non-centrosymmetric crystals and thereby could give rise to SOTs even in single-layer materials [5,6]. Moreover, materials with inversion-asymmetric point groups promise a variety of novel SOT symmetries [6] compared to the well-known field-like and damping-like SOTs. While novel SOT symmetries have been reported for bilayer systems [7] or ferromagnetic semiconductors [8,9], their investigation in metallic ferromagnetic materials with inversion-asymmetry has only been recently addressed in NiMnSb [5]. Here, we present the first observation of intrinsic SOTs in single layers of PtMnSb, which is a magnetic half-Heusler alloy. For this, we prepared PtMnSb single crystal thin films by co-sputter deposition on MgO(111) substrates [10]. It crystallizes in the C1b crystal structure as schematically shown in Fig. 1. Similar to NiMnSb, its inversion asymmetry allows for a local spin-polarization upon current-injection that persists even when integrating over the whole unit cell. To perform electrical transport measurements, the full sheet samples were patterned into Hall bar structures with dimensions 80x10 um by means of electron beam lithography. Magnetotransport measurements were carried out using the Harmonic Hall resistance technique [1] where the first harmonic Hall resistance gives access to the magnetoresistance characteristics due to the equilibrium orientation of magnetization and the second harmonic Hall resistance carries information about any current-induced effects such as current-induced effective fields. In our study, we simultaneously record the first and second harmonic Hall resistance while rotating the externally applied magnetic field in the sample plane (xy angle scans) and subsequently apply different external magnetic fields in the range from 50 to 2000 mT. From the first harmonic Hall resistance, we deduce magnetic anisotropy parameters such as an effective demagnetization field and fourfold in-plane anisotropy. The latter was found in the crystallographically similar material (Ga,Mn)As [11]. We perform macrospin simulations for xy angle scans to quantify the anisotropy in our system by fitting it to our data. We find a dominating in-plane fourfold anisotropy with corresponding anisotropy fields in the range of few mT and a less dominant uniaxial anisotropy that is one order of magnitude smaller. This information is used to evaluate the second harmonic Hall resistance where all effective fields have to be taken into account to correctly interpret the lineshape of the second harmonic Hall resistance. An example data set for the second harmonic Hall resistance is shown in Fig. 2 obtained for a 10 nm thick single layer PtMnSb Hall bar. Here a current density of $5x10^6$ A/cm^2 is applied. One can clearly see that its amplitude within a xy angle scan decreases when increasing the field as indicated by the black arrow. This behavior is characteristic for current-induced effective fields that are more and more suppressed when increasing the external field. We can assign the effective fields to SOTs that are linked to the crystal structure. Using crystallographic symmetry arguments, we can separate the observed the SOTs in odd and even components with respect to magnetization inversion. For both the even and odd SOTs, we reveal corresponding effective fields that scale up to the 2nd and 3rd power of the magnetization components and have a distinct symmetry compared to the well-known field-like and damping-like SOTs reported in ferromagnetic/heavy metal bilayers. Finally, we characterize the SOTs as a function of PtMnSb thickness and discuss the possibility of using PtMnSb for magnetic switching applications.

Films with ultra-high magnetic anisotropy fields hold great promise for future telecommunications as they possess magnetic resonance frequencies in the THz range [1-3]. In the context of spin-transfer driven nano-oscillators (STNOs), which work on the principle of angular momentum transfer from a spin-polarised current to a small magnetic element [4,5], stabilising auto-oscillations, certain Heusler alloys represent a suitable choice for achieving communication beyond 5G [6]. The recently discovered half-metallic compensated ferrimagnet, Mn_2Ru_xGa, is such a Heusler alloy. It has been shown experimentally [7] and confirmed by DFT calculations [8] to possess a spin-gap at the Fermi level. Here, the transport properties of MRG are investigated in applied magnetic fields up to 58 T and analysed in the context of a molecular field model to determine the anisotropy and exchange energies. Large out-of-plane magnetic anisotropy is observed, with a Hall resistivity of 5 μOhm.cm, shown in figure 1 (a). Between 135 K and 165 K the coercivity is larger than 6.5 T and the sign of ρ_{xy} reverses. The change in sign indicates a reversal of the spin-polarisation with respect to the applied magnetic field, consistent with reaching the compensation temperature, T_{comp} ≈ 155 K. Hall loops obtained in pulsed magnetic fields, shown in figure 1 (b), follow the same trend as that in figure 1 (a) and at 150 K the coercivity is in excess of 9 T. At fields larger than the coercivity, MRG also exhibits a temperature dependent spin-flop transition, μ_0H_{sf}, where the antiferromagnetic alignment of the two Mn sub-lattices is broken. The temperature dependence of μ_0H_c, figure 1 (c), shows a clear divergence around T_{comp} indicated by the shaded region. This behaviour is expected: as the net magnetisation vanishes, the magnetic anisotropy field will tend to infinity and with it the coercivity. The temperature dependence of μ_0H_{sf} is also plotted in figure 1 (c). Temperature dependent scans of ρ_{xy} in zero applied field across T_{comp} show that, despite having a vanishing net magnetic moment, the Hall resistivity is finite and does not change sign (figure 1 (d)). In normal ferromagnets and non-half-metallic ferrimagnets, the anomalous Hall effect is proportional to the component of the net magnetisation along the surface normal, z [9]. In MRG, the Hall signal is due to the magnetic moment on the Mn 4c sub-lattice only. The Mn 4a sub-lattice states form the spin-gap. Unlike rare-earth - transition-metal alloys, such as TbFe and GdCo [10], the only magnetic element in MRG is Mn, and therefore the retention of ρ_{xy} over T_{comp} is not due to differing contributions to the Hall signal from the two magnetic sub-lattices. Molecular field modelling [11] is used to determine the intra and inter-lattice exchange constants from the Curie temperature and the compensation temperature, reproduced in figure 2 (a). Figure 2 (b) shows clearly that the Hall conductivity, σ_{xy}, follows the magnetisation of the 4c sub-lattice and not the net magnetisation. The response of the net magnetisation can be obtained by subtracting the value of the Hall conductivity at the compensation temperature, $\sigma_{xy\text{-}comp}$, from the raw data, $\sigma_{xy}(T)$. $\sigma_{xy}(T) - \sigma_{xy\text{-}comp}$ follows the net magnetisation from the molecular field model (Figure 2 (b)). From the field dependent data in high magnetic fields, we calculate the sub-lattice anisotropy energy, K_{4c}, from the spin-flop field $H_{sf} = (2\, H_{k\text{-}4c}\, H^{i}_{4c})^{1/2}$ where $H_{k\text{-}4c}$ is the 4c sub-lattice anisotropy field and H^{i}_{4c} is the molecular field on the 4c sub-lattice. A comparison of the z-component of the Mn 4c sub-lattice from the model and the experimental data, as a function of both the in-plane, μ_0H_x, and out-of-plane field μ_0H_z at 220 K, is shown in figure 2 (c). Despite slight discrepancies, the molecular field model reproduces the experimental data. Furthermore, knowing the molecular field experienced by the Mn 4c sub-lattice, $\mu_0H^{i}_{4c}$, and the sub-lattice anisotropy energy, K_{4c}, magnetic resonance frequencies of 0.700 THz and 0.145 THz are predicted. As such, MRG behaves magnetically as an antiferromagnet and electrically as a fully spin-polarised ferromagnet. It is also capable of operating in the THz regime. The immediate technological relevance is that any spin-transfer torque effects will also be dominated by the properties of the 4c sub-lattice. Part of this work was carried out under the EU Project TRANSPIRE - DLV-737038. We acknowledge the support of the HLD at HZDR, a member of the European Magnetic Field Laboratory (EMFL).

AD-06. A Comparative Study on Spin-Orbit Torque Efficiencies from W/ferromagntic and W/ferrimagnetic Heterostructures.

T. Wang[1], C. Pai[1], H. Yen[1], T. Chen[1] and C. Wu[1]
1. Material Science and Engineering, National Taiwan University, New Taipei City, Taiwan

It has been shown that W in its resistive form possesses the largest spin-Hall ratio among all heavy transition metals, which makes it a good candidate for generating efficient dampinglike spin-orbit torque (DL-SOT) acting upon adjacent ferromagnetic or ferrimagnetic (FM) layer. Here we provide a systematic study on the spin transport properties of W/FM magnetic heterostructures with the FM layer being ferromagnetic $Co_{20}Fe_{60}B_{20}$ or ferrimagnetic $Co_{63}Tb_{37}$ with perpendicular magnetic anisotropy. The DL-SOT efficiency $|\xi_{DL}|$, which is characterized by a current-induced hysteresis loop shift method, is found to be correlated to the microstructure of W buffer layer in both $W/Co_{20}Fe_{60}B_{20}$ and $W/Co_{63}Tb_{37}$ systems. Maximum values of $|\xi_{DL}|\approx0.144$ and $|\xi_{DL}|\approx0.1$ are achieved when the W layer is partially amorphous in the $W/Co_{20}Fe_{60}B_{20}$ and $W/Co_{63}Tb_{37}$ heterostructures, respectively. Our results suggest that the spin Hall effect from resistive phase of W can be utilized to effectively control both ferromagnetic and ferrimagnetic layers through a DL-SOT mechanism.

AD-07. All-Optical Measurements of Spin Hall Angles in Tungsten and Tantalum.

S. Mondal[1], S. Choudhury[1], J. Sinha[1] and A. Barman[1]
1. S. N. Bose National Centre for Basic Sciences, Kolkata, India

The quest to find an energy efficient alternative to charge-current based magnetic memory devices has led the scientific community to exploit spin current driven phenomena. The generation and manipulation of pure current is a hot topic and spin Hall effect (SHE) is one of the most efficient means to achieve this. Various methods have been developed to determine the conversion efficiency from charge current to spin current, the so-called spin Hall angle (SHA) but there remain large discrepancies between the values of SHA determined by those methods even for a well studied heavy metal (HM), Pt. Recently we developed a novel all-optical method to determine the SHA in HM and demonstrated a large value of about 0.11 in Pt [1]. Here, we have extended this method to determine the SHA for two important HMs, namely, Tungsten (W) and Tantalum (Ta) [1, 2]. In this method, the spin current (J_s) generated by the change current in a HM layer exerts a damping-like spin torque in an adjacent ferromagnetic (FM) layer in HM/FM/Oxide heterostructure. Using an all-optical time resolved magneto optical Kerr effect (TR-MOKE) technique, we measure the modulation of Gilbert damping (MOD) of the FM layer (see fig.1 (a)). Here, we first investigate the thickness (t) dependence of SHA in tungsten (W) in sputter deposited Substrate/W(t)/CoFeB(3nm)/SiO_2(2nm) heterostructures (t = 2, 3, 4, 5, 6, 7 nm) by applying charge current through chromium/gold contact electrodes. The ultrafast magnetization dynamics is measured in polar Kerr geometry using pump pulse (λ = 400 nm, pulsewidth = 100 fs, spot diameter ~ 800 nm) with 10 mJ/cm^2 fluence and probe pulse (λ = 800 nm, pulsewidth = 80 fs, spot diameter ~1μm) with 2 mJ/cm^2 fluence. The time dependent magneto-optical Kerr rotation was measured in presence of a constant bias field and with varying charge current. We observe a linear variation of effective damping (up to ±15%) with applied charge current density (J_c) from which the SHA is derived [2]. A nonmonotonic variation of SHA with W layer thickness is observed which shows sudden reduction to a very low value for t < 3 nm and t > 5 nm. SHA attains maximum value of 0.40 ± 0.04 at t = 3 nm as shown in fig. 1 (b), which is one of the highest reported values to date. A transition from β-phase to α-phase of W and the corresponding change in resistivity is found to be responsible for the variation of SHA [3] with thickness for 3 nm ≤ t ≤ 7 nm, while for t = 2 nm the W layer is below its spin diffusion length, which may cause backflow of the spin current to the W layer and underestimation of MOD and SHA. Next, we have performed a comparative study between the SHA of W and Ta by varying the thickness of Ta (t = 3 nm to 20 nm). Within β phase of Ta, SHA is found to be almost constant around 0.13 ± 0.03, which is much lower than the highest SHA observed in W [4]. Simultaneously, we observe substantial redshift in the precessioanl frequency with J_c for all the heterostructures which is attributed to the contribution from Joule heating and field-like torque [1, 2]. Our findings can promote heavy metal based magnetic heterostructures to be suitable candidate for future spintronics devices. At the same time, the study of modulation of damping in CoFeB layer having important for development of MTJ-based magnetic switching devices. AD-08. Demonstration of unidirectional spin Hall magnetoresistance by using naturally oxidized Cu.

G. Okano[1] and Y. Nozaki[1,2]
1. Department of Physics, Keio University, Yokohama, Japan; 2. Center for Spintronics Research Network, Keio University, Yokohama, Japan

Bilayer systems consisting of a ferromagnet (FM) and a heavy metal (HM) have been widely used to investigate a variety of spin-dependent transport phenomena. Recently, the unidirectional spin Hall magnetoresistance (USMR) was reported in NiFe/Pt and Co/Pt bilayer systems [1,2]. As schematically shown in Fig. 1, the USMR shows a unidirectional change in the electrical resistance with respect to an angle θ between an electrical current and a magnetization of FM, although a uniaxial variation was observed in the ordinary SMR. In the ordinary SMR, both the spin Hall effect (SHE) and the inverse spin Hall effect (ISHE) in HM are essential. When an electric current is applied to the FM/HM bilayer, a spin accumulation appears at the interface between FM and HM which produces a spin current (SC) in the bilayer. It is noted that, as schematically shown in Fig. 1(a), the amount of the backflow of the SC depends on a relative orientation of spin angular momentum of the SC with respect to the magnetization of FM which leads to the uniaxial change in electrical resistance. On the contrary, it is theoretically suggested that the USMR is attributable to a spin polarization dependence of both an electron mobility and a density of electrons in the FM [3]. The latter can be modulated by a spin accumulation and causes the change of the electrical resistance of the FM. Thus, unlike the ordinary SMR [4], the ISHE in HM does not contribute to the USMR. In this study, we demonstrated the USMR without using HMs, such as Pt, Ta or W, which is significant to verify that the mechanism of USMR is totally different from the ordinary SMR. Recently, it was experimentally reported that a naturally oxidized Cu can generate a SC similarly to HMs with large SOI [5]. Hence, the SC generated by the naturally oxidized Cu enables us to exclude not only the effect of the ISHE but also other effects owing to large SOI of HMs. Figure 2(a) shows the experimental setup with the SEM image of the sample. Four bilayers were prepared, Sample 1: Pt(10)/NiFe(5)/Sub., Sample 2: NiFe(5)/Pt(10)/Sub., Sample 3: Cu(10)/NiFe(5)/Sub. and Sample 4: NiFe(5)/Cu(10)/Sub. (All thicknesses are in nm.) All bilayers were patterned into 8 μm wide and 20 μm long rectangles. On each bilayer, electrodes with 8 terminals composed of Au(20)/Ti(3) were fabricated to measure 1st and 2nd harmonic components of the resistances (R^{1f} and R^{2f}) of the bilayers, which enables us to evaluate the AMR and USMR, respectively. It is also noted that a coplanar waveguide (CPW) composed of Au(100)/Ti(3) was deposited on the rectangle with insulating SiO_2(120) to demonstrate the spin pumping (SP) and successive ISHE detection. A continuous alternating current with a frequency of 137 Hz was applied to the bilayers and both R^{1f} and R^{2f} were measured using a lock-in amplifier. An external magnetic field in the range from 300 to −300 mT was applied along θ direction from the long axis of the rectangle. It is noted that the values of R^{2f}/R^{1f} were averaged in the field range from –300 to –200 mT for the evaluation of the USMR. Figure 2(b) shows the θ dependence of the USMR. The USMR in Sample 1 and 2 show sinθ dependence although the sign of USMR is opposite because SCs with opposite spin polarization were injected into the NiFe layer. The signs and amplitudes of the USMR (approximately 0.3×10^{-5}) were similar to those reported previously [1]. In Sample 4, the USMR signal was not observed similarly reported for Co/Cu/Sub. in Ref. [2]. Namely, the USMR does not appear when the nonmagnetic metal adjacent to FM has weak SOI. In Sample 3 which also consist of NiFe and Cu with weak SOI but the stacking order is different from Sample 4, the USMR shows clear sinθ dependence and the sign is always positive. The result is similar to Ref.[5] which shows that SCs generated in a naturally oxidized Cu has same polarization with those generated in Pt. The electric current J dependence of the USMR was also measured as shown in Fig. 2(c) and the absolute values of the USMR linearly increase with J in all samples except Sample 4. It is noted that Figs. 2(b) and 2(c) which show that the amount of the USMR is proportional to $J\sin\theta$ are the clear evidences that the USMR appears in Cu(10)/NiFe(5)/Sub. Furthermore, from the spin pumping and successive ISHE experiment, we also confirmed that the naturally oxidized Cu in Sample 3 does not convert SCs into charge currents. Namely the ISHE does not occur in the naturally oxidized Cu. The result suggests that the SC generation in the naturally oxidized Cu is not attributed to the SHE. In summary, we have demonstrated that, unlike the ordinary SMR, the USMR does not require SHE nor ISHE because Cu/NiFe/Sub. bilayer which does not consist of a strong SOI material shows the clear USMR although further experiment must be required to clarify the physical origin for the SC generation in the naturally oxidized Cu.

AD-09. Dzyaloshinskii-Moriya interaction and spin-orbit torques for controlling skyrmions in Co-based trilayers.

J. Hanke[1,2], F. Freimuth[2], S. Bluegel[2] and Y. Mokrousov[2]
1. Institut fur Physik, Johannes Gutenberg University, Mainz, Germany;
2. Peter Grunberg Institut and Institute for Advanced Simulation, Forschungszentrum Julich, Juelich, Germany

Originating from the interplay of spin-orbit coupling and broken spatial inversion symmetry, the antisymmetric exchange interaction, also known as Dzyaloshinskii-Moriya interaction (DMI), attracts ever-growing attention as it mediates the formation of fascinating chiral spin textures that are perceived to be of great technological relevance, *e.g.*, for future memory devices. Recently, the interfacial DMI was shown to be tunable in magnetic heterostructures of Co sandwiched between different heavy transition metals such as Pt and Ir, heralding bright prospects for the observation of small magnetic skyrmions at room temperature [1-3]. In this context, the phenomenon of current-induced spin-orbit torques (SOTs) can be envisaged to provide a particularly efficient means for controlling and manipulating the dynamical properties of such chiral nano-scale objects. Remarkably, electrically driven switching of the magnetization due to SOTs in inversion-asymmetric crystals has been demonstrated in single ferromagnetic layers [4] and even in antiferromagnets [5]. In *ab initio* calculations of the electronic structure, the antisymmetric exchange interaction stabilizing chiral skyrmions is typically obtained either from demanding computational frameworks associated with non-collinear spin spirals, or by adopting restrictive approximations for the magnitude of the spin-orbit interaction. In sharp contrast, we present here an advanced Wannier interpolation scheme [6] that enables us to evaluate the DMI in its efficient Berry phase theory [7] based on the ferromagnetic state including the full spin-orbit interaction self-consistently. Applying this technique to the ferromagnetic trilayers $Ir_{\delta}Pt_{1-\delta}$/Co/Pt and $Au_{\gamma}Pt_{1-\gamma}$/Co/Pt, we correlate the microscopic origin of the DMI and the intimately related SOTs with the first-principles electronic structure [6]. Strikingly, we find that the DMI changes sign when we tune the composition ratio in the heterostructures, which promotes the corresponding systems as promising candidates for detailed experimental studies of the antisymmetric exchange interaction. While the DMI is nearly isotropic with respect to the orientation of the ferromagnetic Co moments, the current-induced antidamping torques in clean Ir/Co/Pt reveal a particularly pronounced dependence on the magnetization direction according to our density functional theory calculations. Finally, we elucidate how the obtained anisotropy of fieldlike and antidamping SOTs imprints on the general control and manipulation of the dynamical properties of chiral nano-scale skyrmions in Co-based trilayers. We gratefully acknowledge funding from the German Research Foundation (DFG) under Grant No. MO 1731/5-1 as well as from the EU Horizon 2020 research and innovation programme under grant agreement number 665095 (FET-Open project MAGicSky).

AD-10. Spin-orbit effective fields in CoTb single layer.

L. Liu[1], J. Deng[1], J. Yu[1], C. Zhou[1] and J. Chen[1]
1. Materials Science and Engineering, National University of Singapore, Singapore

Recently current-induced spin-orbit torque (SOT) has been widely investigated in nonmagnet /ferromagnet (NM/FM) bilayer structures in order to achieve lower power consumption in scalable memory devices. The SOT exerted on the FM layer was considered to arise from the spin Hall effect (SHE) in the NM and/or the Rashba effect at the interfaces. For the former case, the critical switching current density (J_c) increases with increasing thickness (t_{FM}) of the FM layer, while for the later case, an ultra-thin FM layer is necessary to maintain the structure inversion asymmetry (SIA). SOT was also studied in magnetic single layers[1, 2] where there is non-centrosymmetric space group (bulk inversion asymmetry, BIA) or non-centrosymmetric site point group (local structure inversion asymmetry) in their crystal structure[3]. Because the SOT induced effective fields are uniformly distributed in magnetic layer, the switching current density is assumed to be independent of the thickness. More importantly, because the carrier spins are exchange coupled to the local magnetic moments which produces a direct SOT without involving any spin transfer, the SOT efficiency should be higher than that in the NM/FM bilayer structures. Until now, the observed SOT in single magnetic layer is focusing on magnetic semiconductors[1] or antiferromagnetic metals[2] with in-plane magnetic anisotropy. The SOT in magnetic single layer with perpendicular anisotropy has not been observed. In our study, we grow 20 nm CoTb thin films with bulk perpendicular magnetic anisotropy (PMA) and observe very large spin-orbit effecitve fields from Harmonic Hall measurement. Since there is no extra heavy metal layer to act as spin Hall source and the thickness of CoTb single layer is thick enough to eliminate the Rashba effect from the interfaces, we suggest these effective fields originate from the bulk especially from Tb, which is evidenced by recent report that rare-earth thin films can generate spin Hall torque[5]. The spin torque efficencies 100 Oe/(10^7 A/cm^2) and 140 Oe/ (10^7 A/cm^2) for 20 nm $Co_{89}Tb_{11}$ and 20 nm $Co_{81}Tb_{19}$ single layers are serveral time larger than that of NM/FM bilyer structures. In order to verify our observation, we develope a “pulsed AHE“ technique to esitimate the out-of-plane (OOP) effective field (H_z) of 20 nm $Co_{89}Tb_{11}$ thin film. By measuring the anomalous Hall effect under different in-plane electrical current pulse with certain pulse widths, we eliminate the Joule heating and obtain the spin torque efficiency of OOP effective filed (H_z/J_e) to be 105 Oe/(10^7 A/cm^2), which is close to in-plane spin torque efficiency calculated from Harmonics Hall measurement. The large spin orbit torque observed in CoTb single layer may open a way to explore the rich spin orbit physics in metallic alloy with bulk PMA. The direct coupling between the carrier spin and local magnetic moments in CoTb alloy may makes it possible to manupinate the magenetization by electrical current. Although the mechnism is still unclear, its potential in appliation is promising.

AD-11. Chiral magnetization switching induced by spin orbit torque in Pt/Co/Ta structure.

S. Li[1] and W. Lew[1]
1. School of Physics and Physical Science, Nanyang Technological University, Singapore, Singapore

Spin-orbit torque (SOT) has attracted extensive attention as an efficient method of controlling the magnetization of multilayered magnetic structures[1]. To realize SOT-induced magnetization switching in the structure with perpendicular magnetic anisotropy (PMA), an external in-plane magnetic field is required to break the symmetry along the current direction[2]. The chiral magnetization switching behavior as a result of opposite applied field direction when the applied field is sufficiently large has been widely reported[2-5]. However, the SOT switching behavior under a small applied field is remained unclear. In this work, we investigated the SOT-induced magnetization switching behaviors in Pt/Co/Ta structure under the influence of external magnetic fields. The structure consisting of a thin Co layer sandwiched by Pt and Ta has an enhanced SOT, due to the opposite sign of spin Hall angle in Pt and Ta[6]. The characterized effective fields were found to be ~ 162 Oe per 10^{11} A/m^2 for the damping-like term and ~ 108 Oe per 10^{11} A/m^2 for the field-like term. SOT-induced magnetization switching was detected by measuring the Hall resistance using a sweeping DC current with a fixed longitudinal field H_x. The measurements were performed with up and down initial magnetized states under both positive and negative H_x, respectively. For each configuration, the measurement was repeated using different current sweeping directions, from -10 mA to +10 mA to -10 mA and from +10 mA to -10 mA to +10 mA. It is found that SOT-induced switching can be achieved under a field $H_x \geq 500$ Oe. The switching behaviors are influenced by all the directions of the field, the initial magnetization and the current sweeping when $H_x = 500$ Oe. When $H_x > 1$ kOe, the switching behavior is only dependent on the field direction. Figure 1 shows the experimental results under $H_x = \pm 500$ Oe. For $H_x = +500$ Oe, the down initial magnetization and current sweeping from +10 mA to -10 mA to +10 mA configuration result in different switching behavior. For $H_x = -500$ Oe, a different switching behavior happened in the configuration of up initial magnetization and current sweeping from +10 mA to -10 mA to +10 mA. When the applied H_x increased to 1 kOe, the same switching behaviors were obtained for $H_x = +1$ kOe and $H_x = -1$ kOe, respectively. As shown in Fig. 2, the opposite switching loops were obtained due to the direction of the applied fields.

Spin-torque nano-oscillators (STNO) have strong potential for applications such as rf communications, microwave generation, field sensing, and neuro-inspired computing. An important aspect involves phase-locking [1] and modulation [2] due to external signals, which have been studied extensively in vortex-based systems. However, the role of vortex core reversal [3] in this context has remained largely ignored. Indeed, in nanocontact-based systems, core reversal can give rise to more complex states such as chaos [4]. Because of the sensitivity to initial conditions, chaos is potentially useful for information processing as a large number of patterns can be generated rapidly [5]. We have conducted experiments to probe how nanocontact vortex oscillators can be modulated in the chaotic state by an external signal. Such states are obtained by sweeping the applied dc electrical current or magnetic field, where transitions between different oscillation regimes can be seen as jumps in the central frequency and changes in the number of modulation sidebands, as shown in Figure 1. These different regimes correspond to how the periodicity of the vortex core reversal relates to the frequency of core gyration around the nanocontact [4]; a commensurate phase appears when the reversal rate is an integer fraction of the gyration frequency, while a chaotic state appears when this ratio is irrational. An example of the effect of external modulation is shown in Figure 2, where the power spectral density exhibits rich features due to the modulation between the external source frequency, gyration frequency, and core reversal frequency. We can explain these features with first- or second-order modulation between the three frequencies. Phase-locking is also visible between the external source frequency and internal vortex modes. We explored the phase-locking properties in both the commensurate and chaotic regimes, where chaos appears to impede phase-locking while a more standard behavior is seen in the commensurate phase. We have also conducted micromagnetics simulations with the MuMax code [5], where most of the salient features are reproduced. We also explored larger coupling strengths between the external signal and the NCVO, where different fractional regimes can be identified in Arnold tongue diagrams [6]. This allows us to quantify the role of the coupling strength on synchronization and transitions to chaos. This work was partially supported by the Agence Nationale de la Recherche (France) under Contract No. ANR-17-CE24-0008 (CHIPMuNCS).

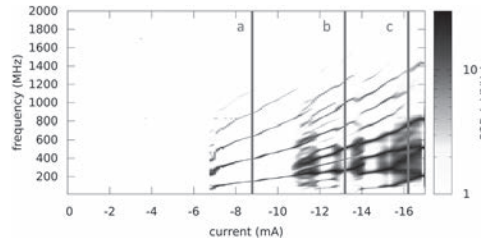

Fig. 1. Frequency vs current map of the power spectral density. On this figure is given the natural output power of the vortex according to the sent DC current. Different dynamical regimes are observed. No oscillations are observed below 6.8 mA. (a) Steady state gyration, where harmonics indicate elliptical trajectories. (b) Commensurate state, where periodic core reversal modulates the vortex gyration. (c) Chaotic state, where gyration and core reversal frequencies are incommensurate.

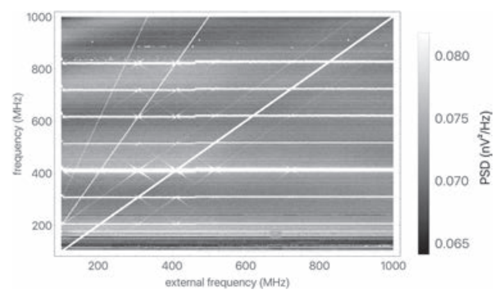

Fig. 2. Power spectral density map as a function of external frequency for an NCVO in the commensurate state. Phase-locking occurs when the external frequency is equal to gyration frequency, 3:4 and 4:3 synchronization orders. Phase-locking between core reversal and external frequencies are also visible. Crossing frequencies near synchronization regions are due to modulation between external, gyration, and core reversal frequencies. Amplitudes are qualitatively higher if signals involve gyration or external frequencies, close to a synchronization region, and for increasing external frequency sweeps.

Institute for Physics of Solids, TU Dresden, Dresden, Germany

The fundamental oscillation mode of magnetic vortices in thin-film elements has recently been proposed for designing spin-torque-driven nano-oscillators [1]. Commercial applications require tuning of the output frequency by external parameters, such as applied fields or spin-polarised currents. However, the tunability of vortex-based devices is limited, since the gyrotropic frequency is specific to the individual sample design. Indeed, the fundamental frequency is known to be determined by the saturation magnetisation,M_s, as well as the geometrical confinement of the magnetisation, i.e. the diameter and height of the magnetic disk [2, 3]. Micromagnetic simulations [4] have shown that if regions with different saturation magnetisation can be induced in a magnetic disk, multiple precession frequencies can be generated. We show that ion implantation [5] is a novel route to fabricate such devices. Permalloy (Py) disks of various diameters and thicknesses were prepared using electron beam lithography followed by electron beam evaporation. Individual disks were contacted by gold leads to study the interaction of spin-polarized current with the magnetic vortex. The presence of a vortex is verified by magneto optic Kerr effect (MOKE), X-ray magnetic circular dichroism (XMCD) and magnetotransport measurements. The magnetic field dependence of the vortex position can be tuned by the disk size as shown by XMCD (Figure 1 (a)). Higher magnetic stability due to larger annihilation fields can be achieved by smaller disk diameters, whereas larger field sensitivity is present in larger disks (Figure 1 (b)). Magnetotransport measurements on electrically contacted disks show the presence of anisotropic magnetoresistance (AMR) in different disks with varying thickness (Figure 1 (c)). Using a conventional lock-in technique, the resonance frequencies are measured for disks with different radii as shown in Figure 2 (a), with the inset showing the scanning electron microscope image of an electrically contacted disk. In order to modify the magnetisation within a single disk and to achieve two different oscillation frequencies, we implant chromium in different regions of the disk (inner and outer). Cr-implantation leads to a decrease in the Curie temperature and thus a reduction in the magnetic moment [6]. The reduction of M_s as a function of Cr fluence was optimised on extended Py films using a vibrating sample magnetometer – superconducting quantum interference device (VSM-SQUID), see figure 2 (b). A clear drop in M_s with increasing the chromium ion fluence is observed. Concentric donut-like structures were then implanted with Cr and the modification of dynamics as a function of magnetic field was investigated. An example of Cr-implantation in a 3 μm radius disk at 30 keV with a fluence of $1.2 * 10^{16}$ ions/ cm^2 is shown in Figure 2 (c). The vortex core is shifted between the two different magnetisation regions by applying an external in-plane field. The vortex nucleates in the irradiated region at – 2.281 mT, leading to a resonance frequency of 30.2 MHz (shown in orange in Figure 2 (c)). Further increasing the external field pushes the vortex core to the non-irradiated region where the resonance frequency is 42.3 MHz (shown in green), corresponding to a field of + 1.597 mT. The results show that ion implantation is a novel way to obtain multiple frequencies from a single disk. AE-03. Stability and manipulation of magnetic skyrmions.

G. Finocchio[1]
1. University of Messina, Messina, Italy

Magnetic skyrmions are topological protected solitons with a chirality that can be stabilized by the Dzyaloshinskii-Moriya interaction (DMI). Understanding the physical properties of magnetic skyrmions is important for fundamental research with the aim to develop new spintronic device paradigms where both logic and memory can be integrated at the same level or for unconventional computing. We have recently studied different mechanism of stabilization of skyrmions in confined devices, one of them needs a large DMI to introduce in the energy landscape an energetic minimum associated with a metastable skyrmion state and one that gives a skyrmion state which size depends on a trade off among magnetostatic, exchange and DMI energies. Here, we firstly show a universal model based on the micromagnetic formalism combining a proper ansatz and scaling relationships and a specific Q-d phase space (quality factor Q vs. reduced DMI d) that can be used to study skyrmion stability as a function of magnetic field and temperature. We consider ultrathin, circular ferromagnetic magnetic dots. Our results show that magnetic skyrmions with a small radius—compared to the dot radius—are always metastable, while large radius skyrmions form a stable ground state. The change of energy profile determines the weak (strong) size dependence of the metastable (stable) skyrmion as a function of temperature and/or field. We also show as this fundamental results can be used for specific application. Fig. 1 shows a racetrack memory device where the skyrmions in the track are metastable and therefore small—giving a high storage density. The skyrmions are detected under a magnetic tunnel junction (green square) with a polarized layer with a magnetization pointing along the out-of-plane direction which generates a dipolar field parallel to the skyrmion core magnetization. This field can modify the stability properties of the skyrmion in the region below the contact, moving it through the Q-d phase space. By shifting the skyrmions across the line of stability, their radius will expand significantly making it much easier to detect from the tunnel magnetoresistance signal. After leaving the detection regions, the skyrmions will return to their small size in the metastable region. The spin-Hall effect(SHE)-driven skyrmion motion is characterized by an in-plane angle, i.e. the skyrmion Hall angle (SHA)[1]. Finally, we micromagnetically report, for the first time, the SHE-driven dynamics of a breathing skyrmion. In particular, we can excite the breathing mode by applying an ac perpendicular-polarized current and we can control the SHA by an in-plane external field Hy. Our results show that the SHA depends on the SHE current only under the simultaneous presence of Hy and breathing mode[2]. Our achievements can be important for understanding the origin of the SHA current dependence when the field-like torque comes from the SHE and the breathing mode is due to temperature and/or disordered parameters[3]. These results can open a path toward the design of optimal materials for skyrmion based devices. Acknowledges The author thanks R. Tomasello, K. Y. Guslienko, A. Giordano, O. Fesenko, J. Baker, S. Chiral magnets may host skyrmion lattices, that can be equivalently described as a superposition of plane waves or lattice of particle-like topological defects. In the skyrmion hosting crystal $Fe_{0.5}Co_{0.5}Si$ we use Lorentz transmission electron microscopy (L-TEM) to investigate the energetics associated with the topological decay of magnetic skyrmions far from equilibrium. We record Field-Cooled (FC) and Zero-Field-Cooled (ZFC) phase diagrams of thinned $Fe_{0.5}Co_{0.5}Si$ single crystals using cryo L-TEM. Measurements are performed using thin $Fe_{0.5}Co_{0.5}Si$ platelets with a thickness of d =250 nm. The [110]-direction is aligned parallel to the sample normal and to the externally applied magnetic field direction. Phase diagrams are established by taking series of images as a function of magnetic field and temperature. An example phase diagram and the measurement protocol for the decay into the helical phase in zero magnetic field is shown in Fig. 1 with exemplary L-TEM images and corresponding Fourier transform data. When lowering the temperature through the skyrmion pocket for the FC case a metastable skyrmion phase extending to temperatures much below the skyrmion pocket can be achieved. Note that at low temperatures a novel skyrmion cluster phase in a conical background is found. From the metastable phase we investigate the decay time of the skyrmion lattice when increasing or decreasing the externally applied magnetic field. We observe that the life time of the skyrmions depends exponentially on temperature. The prefactor of the Arrhenius law describing the skyrmion decay changes by about 30 orders of magnitude for small changes of magnetic field reflecting a substantial reduction of the life time of skyrmions by entropic effects and thus an extreme case of enthalpy-entropy compensation. Such compensation effects, being well-known across many different scientific disciplines, affect topological transitions and thus topological protection on an unprecedented level [1].

Max Planck Institute for Intelligent Systems, Stuttgart, Germany

Frustration is of great general interest as it gives rise to new physical phenomena, such as magnetic monopoles [1]. Frustration arises when competing interactions cannot be all satisfied at the same time [2]. We combine this research field with magnetic vortices that can be described as magnonic crystals when arranged periodically. Geometrical frustration is observed in vortex crystals that are positioned analogous to the nanoislands in artificial spin ice. The crystal properties of magnonic vortex crystals can be manipulated dynamically on the timescale of milliseconds [3]. In contrast to artificial spin ice systems, the frustration in the vortex crystals can be tuned and turned on and off at will [4]. The magnetic vortex state forms in ferromagnetic nanodisks of suitable geometry and features an in-plane curling magnetization with an out-of-plane component in the center region, the vortex core [5]. The vortex is described by two state parameters: the polarization of the core pointing either up or down and the circularity, the sense of the in-plane magnetization curling either clockwise or counter-clockwise. We study two-dimensional magnonic vortex crystals that are arranged analogous to the nanoislands in artificial kagome spin-ice (see Fig. 1(a)). Scanning transmission x-ray microscopy (STXM) measurements at the MAXYMUS microscope of the BESSY II synchrotron in Berlin, Germany and at the PolLux endstation at the SLS in Villigen, Switzerland are used to observe the vortex core motions temporally and spatially resolved. Artificial spin ice systems consist of nanoislands that are in a single domain state. The spins in the junctions of the nanoislands follow the so called ice-rule [6]. In the hexagonal kagome spin ice, a junction consists of three nanoislands. The ice rules are obeyed if all spins do not point towards or away from the junction. Since the overall spin has always a finite value, the system is frustrated. In our system, two vortices with alternating polarization are analogous to one nanoislands (Fig. 1 (b)). Thus, the hexagons consist of twelve vortices. The vortices in the pairs are in close proximity and are strongly coupled. Vortices in triple junctions at the connections of the hexagons are weaker coupled. If each vortex in the triple junction prefers an alternating polarization with each neighbor, frustration arises. For the comparison with a nanoisland in artificial spin ice, a vortex pair with alternating polarization is represented by a blue arrow pointing from a polarization of p=-1 (black dots in Fig. 1) to the vortex with a polarization of p=+1 (white dots in Fig. 1). The eight possible configurations of arrows in a junction are shown in Fig. 1(b). If the ice rule is obeyed, two arrows point into the center and one points out of it, or vice-versa. If all three arrows point in or out of the center, the ice rule is broken. An adiabatically decreasing high frequency magnetic field is used to tune the polarization configuration in the crystal. Depending on the frequency of this state formation signal, different ground states can be tuned [7]. In Fig. 2 the polarization patterns determined by the STXM measurements are shown for the whole vortex crystal. For a state formation frequency of 234 MHz (Fig. 2(a)) the strongly coupled vortex pairs always have alternating polarizations. In this situation, a vortex pair can be compared to a nanoisland of artificial spin ice systems with a certain alignment of the magnetization. The ice rule violations are marked in orange in Fig. 2(a). As in spin ice systems there is no long-range order perceptible. That means that even though a highly symmetric state might be the lowest-energy state, it is not necessarily adjusted to the crystal. The data suggest that the vortices favor an alternating polarization configuration with each of their neighbors during the state formation with a frequency of 234 MHz. As this is not possible for three vortices in a triple junction, the polarization state formation process is frustrated. It is also possible to tune a non-frustrated polarization state to the system. For a state formation frequency of 261 MHz (Fig. 2(b)) an almost complete homogeneous polarization configuration is tuned. The strongly coupled vortex pairs always have equal polarizations. There are few defects that occur at the weaker coupled triple junctions. Compared to the frustrated state a long-range order is observed. It is thus possible to change the polarization configuration from a frustrated state to a non-frustrated state and vice-versa. In the present experiments, the frustration is turned on and off within milliseconds but this can be accelerated to the nanosecond regime. This allows future studies to compare the frustrated and the non-frustrated state of an otherwise identical system to gain deeper insight into the geometrical frustration itself.

AE-06. Static and dynamic behavior of Interlayer exchange coupled $Ni_{80}Fe_{20}$/Ru Continuous Films and Nanowires.

L. Xiong[1] and A. Adeyeye[1]
1. National University of Singapore, Singapore

INTRODUCTION Spin valve structures where two ferromagnetic (FM) thin film layers are separated by a non-magnetic (NM) spacer layer have attracted tremendous interest due to their potential applications in giant magnetoresistance (GMR)[1] based read sensors[2] and magnetic random access memory (MRAM)[3]. The magnetization of the FM layers in such a trilayer structure are coupled to each other by the interlayer exchange coupling[4] (IEC), which is strongly dependent on the thickness and material of the spacer. As the thickness of the spacer layer is varied, the IEC oscillates in sign and magnitude, known as the Ruderman-Kittel-Kasuya-Yosida (RKKY)[5] interaction, leading to either FM or antiferromagnetic (AFM) ordering of the magnetic layers. Varied coupling types and strength lead to significantly different magnetization reversal processes and dynamic responses when the structure is subjected to a microwave power excitation. It provides an interesting way to engineer the spin wave propagation and thus the ferromagnetic resonance (FMR). However, most of the works reported in the literature only focus on the trilayer structures, with little work reported on the IEC for more complex heterostructures. In this work, we explore both the static and dynamic behaviors of complex heterostructures. EXPERIMENTAL AND SIMULATION DETAILS The multilayer Ni80Fe20(Py)/Ru NWs with fixed width W = 180 nm and period P = 400 nm were fabricated over an area of 4x4 mm^2 on top of a silicon substrate for direct comparison. Corresponding continuous films (CFs) were deposited on silicon substrates at the same time. The structures are Py(10 nm)/Ru(t_{Ru})/Py(20 nm) and Py(10 nm)/Ru(t_{Ru1})/Py(10 nm)/Ru(t_{Ru2})/Py(10 nm) as shown in Fig. 1(a). The t_{Ru} is in the range of 0 to 1.5 nm and the t_{Ru1} (and t_{Ru2}) is 1 or 1.4 nm. Typical scanning electron microscope (SEM) image of the NWs is shown in Fig. 1(b). The thickness t of the wires is varied in the range from 5 to 70 nm. The collective magnetization reversal processes of the arrays were characterized at room temperature using vibrating sample magnetometer (VSM) by sweeping the magnetic field along the easy axis of the NWs. The dynamic behaviors of the NWS were investigated using broadband ferromagnetic resonance spectroscopy (FMR). In order to understand the dynamic response of the wires, micromagnetic simulations were performed using the LLG micromagnetic simulator, which computes the equilibrium magnetization distribution of the NWs based on the Landau-Lifshitz-Gilbert (LLG) equation. The resonant mode profiles were extracted using spatially and frequency-resolved Fast-Fourier-Transform (FFT) imaging method. In all the simulations, periodic boundary condition was used to mimic the wire arrays. RESULTS AND DISCUSSION In conclusion, we have investigated the static and dynamic behavior of engineered interlayer exchange coupled Py/Ru with two coupling interfaces. We demonstrate a robust control of the coupling mechanism by varying the thickness of Ru. We found that the AFM strength affects both the static and dynamic behaviors of the FM layers. We observed a strong AFM coupling when the Ru thickness is 1 nm and negligible AFM coupling when Ru thickness is 1.4 nm. By fitting the simulated hysteresis loops with the experimental results, we find that the bilinear coupling parameter J1 dominated over a negligible biquadratic J2. For $t_{Ru1} = t_{Ru2}$ = 1 nm, the extracted exchange constants are J1 = -0.2 erg/cm2 and J2 = 0. For $t_{Ru1} = t_{Ru2}$ = 1.4 nm, the extracted exchange constants are J1 = -0.02 erg/cm^2 and J2 = 0. In addition, multiple resonant modes were found for five-layer NWs at remanence due to different IEC as shown in Fig. 2(b). The resonant frequencies can be explained by the Kittel's equation: $\omega_0 = \gamma\ ([H_{app}+(N_z-N_x)4\pi M_x]\times[H_{app}+(N_y-N_x)4\pi M_x])^{1/2}$ (1) In addition, we ran simulations for further understanding of the dynamic responses.[6] There is a good qualitative agreement between the experiments and the micromagnetic simulations.

AE-07. Three-dimensional localized spin textures in chiral magnets.

H. Du[1,2] and M. Tian[1,2]
1. High Magnetic Field Laboratory of Chinese Academy of Sciences, Hefei, China; 2. Collaborative Innovation Center of Advanced Microstructures, Nanjing University, Nanjing, China

The emergence of a topologically nontrivial vortex-like magnetic structure, the magnetic skyrmion, has launched new concepts for memory devices. Extensive studies have theoretically demonstrated the ability to encode information bits by using a chain of skyrmions in confined geometries. So far it is generally assumed that skyrmion is two-dimensional (2D) localized magnetic structure. In this talk, we report experimental evidence of three-dimensional (3D) skyrmions in confined helimagnets. The 3D skyrmion will give rise lots of novel phenomena that can not be observed in 2D one. Moreover, we report the discovery of another 3D localized spin texture, termed as magnetic bobber, in chiral magnets.

I. INTRODUCTION The spin dynamics in magnetic thin films have attracted much attention from both fundamental and application viewpoints. The dynamics are described using the phenomenological Landau-Lifshitz-Gilbert (LLG) equation consisting of both the precession torque of the magnetization and the damping torque. Especially, a Gilbert damping constant (α), which describes the strength of damping torque, is one of the dominant parameter to predict the dynamics. Until now, we reported the correlation between α and the saturation magnetostriction (λ_s) for Ni-Fe and Ni-Fe-M films[1]-[3] and found different behaviors of α depending on positive or negative values of λ_s. To investigate this correlation in more detail, these parameters must be estimated simultaneously for each film using a same measurement instrument. Herein, we proposed a new measurement technique, which employs a microstripe line probe to detect ferromagnetic resonance (FMR) spectra for a magnetic thin film either with tensile stress or stress free, which enables simultaneous evaluation of α and λ_s II. EXPERIMENTAL PROCEDURES In our proposed FMR measurement technique, a substrate such as a glass, a quartz, a Si and so on is bent with a certain curvature radius giving uniaxial tensile stress to the magnetic thin film on the substrate. The FMR frequency shifts to either lower or higher side by the uniaxial anisotropy derived from magneto-elastic effect. This frequency shift reflects the strength of λ_s of the films, that is, the relation between the FMR frequency and λ_s is expressed as $(f_{r\sigma}^2 - f_{r0}^2)/ f_{r0}^2 = (3\lambda_s t_{sub} E_f/2rM_s)/(H_{kf} + H_{ex})$, (1) where $f_{r\sigma}$, f_{r0}, t_{sub}, E_f, r, M_s H_{kf}, and H_{ex} are FMR frequencies under tensile stress and in stress free state, a substrate thickness, Young's modulus, curvature radius determined by position censor, saturation magnetization, other kind of uniaxial anisotropy field such as induced anisotropy, and the external magnetic field, respectively. Therefore, the difference of FMR frequency ($f_{r\sigma}$, f_{r0}) between the stress improved state and tensile free stress is carefully measured at each external magnetic field (H_{ex}) and λ_s is calculated with the curvature radius (r). Furthermore, the damping constants (α) of these films were evaluated from FMR spectrum with stress free. These measurements were performed at room temperature. The film to be measured is 10-nm Ni_xFe_{100-x} fabricated by DC magnetron sputtering onto glass substrates. The Ni composition (x) of Ni_xFe_{100-x} films varied from 66.6 to 90.7. The composition of the film was determined by energy dispersive x-ray spectroscopy (EDX). III. RESULTS AND DISCUSSION Figure 1 shows FMR spectrum in Ni_xFe_{100-x} films with and without stress and. In case of $Ni_{90.7}Fe_{9.3}$ (Fig. 1(a)), each FMR frequency with tensile stress ($f_{r\sigma}$) shifts to lower frequency side because of uniaxial magnetostrictive anisotropy. The frequency difference ($\Delta f_r = f_{r\sigma} - f_{r0}$) in external magnetic field (H_{ex}) increases from -716 to -383 MHz as H_{ex} increases. As can be seen in Fig. 2(a), λ_s was evaluated by fitting to the $|(f_{r\sigma}^2 - f_{r0}^2)/ f_{r0}^2|$ vs. H_{ex} plot using eq. (1) and was approximately -8.95 ppm. This value agrees well with that measured by the optical cantilever method (-16.0 ppm). α was evaluated from half width of the FMR spectra without tensile stress, which keeps constant for H_{ex} > 150 Oe and is approximately 0.0190. In case of $Ni_{75.5}Fe_{24.5}$ (Fig. 1(b)), every $f_{r\sigma}$ shifts to higher frequency. Δf_r in H_{ex} decreases from +484 to +181 MHz as H_{ex} increases. As shown in Fig. 2(b), λ_s was determined by fitting to the $|(f_{r\sigma}^2 - f_{r0}^2)/ f_{r0}^2|$ vs. H_{ex} plot using eq. (1), that is, approximately +3.22 ppm and is in good agreement with that measured by the optical cantilever method (+7.34 ppm). α is maintained constant for H_{ex} > 50 Oe and is approximately 0.00725. Therefore, these results demonstrate that our proposed measurement technique can determine both α and λ_s simultaneously for individual sample with high reliability allowing more precise evaluation of spin dynamics. AE-09. Effects of Anisotropic Dipolar Interaction on Spin-Wave Dynamics in $Ni_{80}Fe_{20}$ Nanodot Arrays with Honeycomb and Octagonal Lattice Symmetries.

S. Mondal[1], S. Barman[2], S. Choudhury[1], Y. Otani[3] and A. Barman[1]
1. S. N. Bose National Centre for Basic Sciences, Kolkata, India; 2. Institute of Engineering and Management, Kolkata, India; 3. Institute for Solid State Physics, University of Tokyo, Kashiwa, Japan

Investigations of ultrafast magnetization dynamics of two-dimensional nanodot arrays are significant for their potential applications in high density magnetic storage, memory, logic device, magnonic crystal, spin torque nano-oscillator and sensors. The spin-wave (SW) dynamics of such arrays strongly depend upon the shape and size of the nanodots as well as the lattice arrangements due to the modulation of the internal magnetic field as well as the inter-element interaction field. The collective magnetization dynamics of nanodot arrays arranged in square lattice symmetry has been studied in detail but the same in lower symmetry lattices have not been investigated in detail. Here, we have done a comparative study of collective magnetization dynamics in nanodot arrays arranged in octagonal and honeycomb lattice symmetry. Cylindrical $Ni_{80}Fe_{20}$ (Py) nanodots having diameter (*d*) of 100 nm and thickness (*t*) of 20 nm are fabricated in 10×10 μm^2 arrays on top of self-oxidized Si (100) substrate by a combination of e-beam lithography and e-beam evaporation. The collective dynamics in the above two lattice symmetry is studied by varying inter-dot separations (*S*) from 30 to 300 nm, by using an all optical time resolved magneto optical Kerr effect microscope (TR-MOKE) [1]. In this two-color pump-probe technique, the probe beam (λ = 800 nm, pulse width ≈ 80 fs, spot size ≈ 800nm) is exploited to detect the time varying polar Kerr signal of the sample while pump beam (λ = 400 nm, pulse width ≈ 100 fs, spot size ≈ 1 μm) excites the magnetization dynamics in presence of a bias field (fig.1(a)). The collective magnetization of the array undergoes a number of transitions between various weakly collective regimes with increasing inter-dot separation [2]. The rich band of SW spectra gradually converge to only two distinct self-standing modes corresponding to centre and edge mode of a single nanodot, for both the lattices. The SW modes show high stability with the bias magnetic field. Micromagnetic simulations qualitatively reproduce the experimental observations. Interestingly, we have observed a splitting of the centre mode in case of octagonal lattice (mode 1 and 2 for *S* = 75 nm) as a consequence of the anisotropic dipolar field between the nanodot pairs coupled horizontally and vertically, which is not found in the honeycomb lattice (fig. 1 (b), (c)). With increasing separation these two modes merge together to form the centre mode of an individual dot at $S \geq 150$ nm. Our findings will show that the usage of nanodot lattices with complex basis structures will provide more control parameters which can be advantageous for the designing of high density magnetic recording media, spin-wave filter and logic devices. AF-01. Comparison between Interlaced, Shingled, and Conventional Heat Assisted Magnetic Recording. ***(Invited)***

S. Hernandez[1], S.D. Granz[1], Z. Liu[1], P. Krivosik[2], P. Huang[3], G. Ju[3], T. Rausch[1] and E. Gage[1]
1. Seagate Research Group, Seagate Technology, Shakopee, MN, United States; 2. Recording Head Operations, Seagate Technology, Bloomington, MN, United States; 3. Recording Media Operations, Seagate Technology, Fremont, CA, United States

Recent advances in Heat Assisted Magnetic Recording (HAMR)[1][2] have solidified this technology's future as the leading candidate for hard disk drive products in the years to come. Most demonstrations have so far focused on Conventional Magnetic Recording (CMR), where tracks can be written and over-written at any time with no intentional overlap. Achieving high track pitch capability (TPIC) will require coupling HAMR with more advanced recording schemes. Shingled Magnetic Recording (SMR) [3] involves writing tracks sequentially on the disk, with overlap on one of the sides only. In Interlaced Magnetic Recording (IMR) [4] tracks are written in an "interlaced fashion". First, the bottom tracks are written at a large track width then top tracks are subsequently written at narrow track width between two bottom tracks. The final track pitch will be roughly half of the distance between the bottom tracks. The signal to noise ratio (SNR) is preserved at high areal density using this scheme: bottom tracks are written at a high laser power with wide track width thereby minimizing curvature, and top tracks are written at lower laser power with narrow track width but are not subject to adjacent track interference effects. Although both SMR and IMR require re-writing entire sections of tracks (or bands) to overwrite a single track, they enable much higher track pitch than possible with CMR. In addition to novel writing schemes, read-back can be engineered to increase areal density. Multi-Sensor Magnetic Recording (MSMR) [5] uses two or more readers to read-back the same track. By combining different signals from readers at different cross-track positions more of the signal can be resolved, therefore improving SNR compared to a single reader configuration. This work aims to compare HAMR combined with the technologies described above (CMR, CMR + MSMR, SMR, SMR + MSMR, IMR, IMR + MSMR) through spin-stand experiments and micromagnetic modeling. Table 1 lists the areal density capability (ADC) estimates for all of the recording technologies, obtained from a spin-stand. The ADC quoted is estimated using the ASTC Areal Density Metric [6], which is scaled for channel density. Spin-stand measurements were captured at a writer current of 55 mA, active clearance of 1 nm, radius of 23 mm, skew of 0 and 5400 RPM. MSMR signal processing was performed by reading back the same track with the same reader at different cross-track positions. The signals are combined for two and three reader configurations as described in [5], in order to find the optimal combination of readback signals. As expected, significant areal density gains are observed in SMR and IMR over CMR, for all MSMR configurations. SMR offers the best TPIC of all technologies, but no linear density entitlement. In fact, linear density is lower with a single reader configuration than CMR. This is likely due to adjacent track interference effects caused by the shingling. However, using multiple readers more of the SMR signal can be preserved, thereby enabling an increase in linear density. The TPIC of IMR is reduced compared to SMR, since it is limited by how closely you can place the top tracks without incurring an SNR penalty. Ultimately, the areal density is higher, given that the wide bottom tracks can have much higher linear density than CMR and SMR. Figure 1 shows (a) transition SNR and (b) BER as a function of the number of readers for a CMR configuration at 600 KTPI and 2100 KFCI, obtained using a micromagnetic recording model. HAMR magnetization dynamics are simulated using the renormalized Landau Lifshitz Gilbert equation [7]. Magnetic writer and near field transducer (NFT) designs are consistent with those used in the experiment. Transition SNR is calculated using the ensemble waveform analysis described in [8] and BER is estimated using a pattern dependent Viterbi detector [9]. Three tracks are written on fifty different media sections in order to obtain the proper statistics. The center track is a 31 bit pseudo random sequence, which remains the same for all 50 media sections. The side tracks are random and uncorrelated for all fifty writes. The maximum temperature of the thermal profile is chosen such that the width of an isolated track is the same as the intended track pitch. The effect of multiple read-backs is included using the method described in [5]. Results show that transition SNR increases and BER decreases for MSMR configurations compared to single-reader read-back. The gain in SNR when going from two reader MSMR to three-reader MSMR which is consistent with the minimal increase in areal density from CMR + 2 reader MSMR to CMR + 3 reader MSMR shown in Table 1. Given that the model replicates the effects observed at spin-stand for CMR with single, two and three reader configurations, SMR and IMR will be simulated and compared to experiment. The ultimate ADC entitlement of IMR and SMR will be modeled and optimal recording conditions and writer/NFT characteristics for each of these schemes will be quantified.

AF-02. Reader noise due to thermally driven asymmetric oscillations.

A. Stankiewicz[1], T. Pipathanapoompron[2,4], K. Subramanian[3] and A. Kaewrawang[4]
1. Seagate Technology, Bloomington, MN, United States; 2. Seagate Technology, Korat, Thailand; 3. Seagate Technology, Shakopee, MN, United States; 4. Department of Electrical Engineering, Khon Kaen University, Khon Kaen, Thailand

It has been shown that random excitations of a nonlinear asymmetric oscillator produce low frequency noise [1]. Such effects have been predicted to exist in magnetoresistive sensors [2], where precession asymmetry is introduced by anisotropy energy (either shape or crystalline). This effect has been used to explain the M-shape profiles of magnetic noise vs the external field [3]. In this work we provide direct experimental evidence of asymmetric ferromagnetic resonance in actual devices, and their contribution to low frequency noise. Typical magnetoresistive (tunneling) readers are comprised of ferromagnetic free, reference and pinned layers (FL, RL, PL, respectively), which are stabilized with interlayer interactions and bias magnetic fields. External fields (e.g. due to magnetic media) cause magnetization rotations in the FL, resulting in resistance changes. At finite temperature, the magnetization fluctuates around the energy minimum, resulting in output noise. In nanostructures, these oscillations may be quite large (10-20 deg), and go beyond the range of the harmonic approximation. However, the resonant frequency is large (~5 GHz), and the resulting noise in the operational band (<2 GHz) remains small, until the excitations become asymmetric around the equilibrium [2], resulting in 1/f-like noise. In this experiment, the quasi-static reader output signal has been probed in the time domain using an ISI FMR tester and an external oscilloscope. The system analog bandwidth was 18 GHz, and waveforms were collected at a sampling rate of 80 GSa/s. Fig. 1a shows a small section of a reader noise waveform, in which oscillation asymmetry is evident. Fig 1b represents the corresponding power spectral density (PSD) distribution, with a strong 1/f tail in the low frequency (LF) range. In order to prove that LF noise is a result of the observed oscillation asymmetry, the signal has been decomposed into LF (<2 GHz) and high frequency (HF, >2 GHz) components. Such operations can be done by either empirical mode decomposition (EMD), or by zero-phase-shift numerical filters. The HF portion was then used to produce the instantaneous amplitude waveform, using a simple envelope algorithm (the Hilbert transform may be used as well). A two-dimensional histogram of the LF noise and HF instantaneous amplitude is shown in Fig. 2. The strong correlation (~0.9) observed in Fig. 2 is direct proof that the LF noise is caused by random thermal excitations of the asymmetric magnetic precession in the FL. Another indicator of asymmetric oscillations is a shift of the equilibrium state signal, which can be attributed to very low instantaneous amplitudes. While this study was focused on the presence of low frequency noise in asymmetric magnetic readers, it is fully expected to be manifest in many other systems, possibly explaining the widespread presence of 1/f noise.

[1] A.Stankiewicz, to be published. [2] T.Pipathanapoompron, A.Stankiewicz, A.Grier, K.Subramanian, A.Kaewrawang, "1/f thermally excited noise in asymmetric oscillators", *Dig. Intermag 2018*, Singapore, Apr 2018. [3] A. Stankiewicz, "Low frequency thermal noise in magneto-resistive sensors," *Dig. 8th Joint European Magnetic Symposia (JEMS)*, Glasgow (UK), Aug 2016.

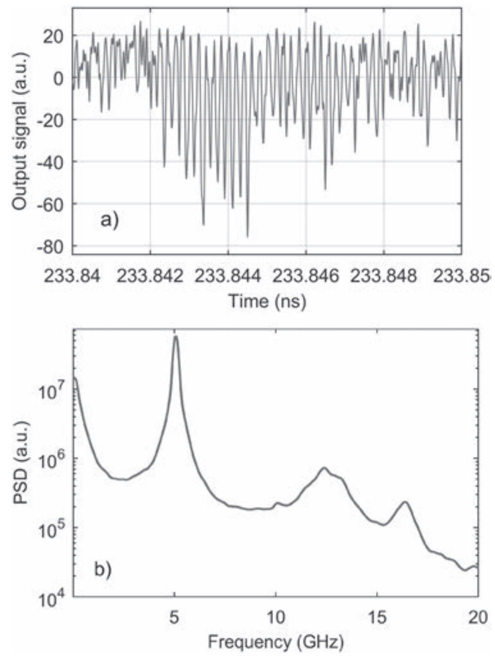

Fig. 1. Oscillation asymmetry is visible in time-domain data (a). Power spectrum density reveals a prominent FL resonance peak (at ~5 GHz), along with other resonance lines at high frequencies (>10 GHz), and strong 1/f-like noise below 2 GHz (b).

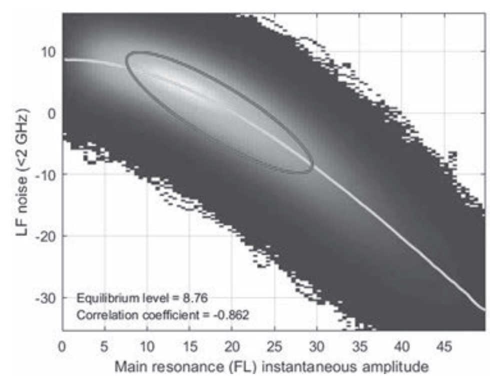

Fig. 2. 2-D histogram of filtered LF noise and FL resonance instantaneous amplitude. Strong correlation (red ellipse) and shift of the low equilibrium signal confirm oscillation asymmetry to be a source of LF noise, while regression nonlinearity (green line) reveals oscillation nonlinearity.

In magnetic hard disk technology, continued scaling of bit density requires higher coercivity and anisotropy media in order to maintain data retention time. This creates a major challenge for scaling the electromagnet-based write head, which is currently being addressed by heat-assisted magnetic recording (HAMR) technology. In this work, we investigate the use of spin transfer torque point contacts induced by spin-polarized current injected from a nanoscale probe tip across a very narrow gap into magnetic media to change magnetization direction. We present our recent experiment using a functional nanoprobe to substitute the disk writer structure. State-of-the-art He-ion focused ion beam (FIB) trimming was used to develop a nanoscale magnetic structure on top of a tip as shown in Fig 1(A). The standard Ta(5nm)/CoFeB(1nm)/MgO(0.9nm) on tip side and another Ta(5nm)/CoFeB(1nm)/MgO(0.9nm) stack on media side were deposited via sputter deposition and milled. The IV characteristics are shown in Fig 1(B) and show magnetization switching of the media through MTJ-type probing. The magnetization change of practical medial structures which consist of sub-10-nm L1(0) ordered FePt structures was observed using the fixed layer of the tip as shown in Fig 1(C). This result suggests a completely new approach for hard disk writing and could pave the way to the field of magnetic recording with ultra-small, ultra-high density, and ultra-fast data rate further.

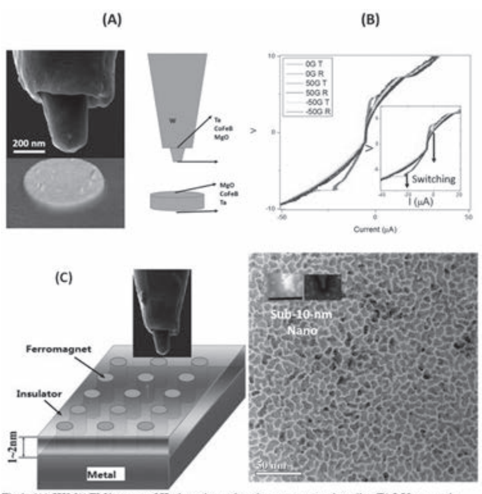

Fig 1. (A) HIM/AFM images of He-ion trimmed probe structure and media. (B) I-V curve via sweeping voltage by changing magnetic field. (C) Sub-10-nm FePt media structure. Bright and dark colors indicate two distinctive magnetization switching. The scale bar is 5 nm.

AF-04. Large magnetoresistive outputs in Heusler alloy-based CPP-GMR sensors using with AgInZnO spacers.

T. Nakatani[1], T. Sasaki[1], Y. Sakuraba[1] and K. Hono[1]
1. Research Center for Magnetic and Sprintronic Materials, National Institute for Materials Science (NIMS), Tsukuba, Japan

Non-magnetic nanolayer / conductive oxide-hybrid spacer structures for current-perpendicular-to-plane giant magnetoresistance (CPP-GMR) sensors such as Cu/ZnO [1], Ag/InZnO (IZO) [2] and Cu/AlMgO [3] are critical to realize large magnetresistive (MR) outputs at the resistance-area product (*RA*) of 0.05-0.2 Ω μm^2, which cannot be realized by either conventional all-metallic CPP-GMR or tunnel magnetoresistance devices. MR ratio ($\Delta R/R$) = 26% at RA = 0.1 Ω μm^2 has been reported using practical polycrystalline CPP-GMR spin-valves with the Ag/InZnO spacer and $Co_2(Mn_{0.6}Fe_{0.4})$Ge (CMFG) Heusler alloy ferromagnetic layers. [2] It should be noted that $\Delta R/R$ = 20% at RA = 0.1 Ω μm^2 has been predicted to be the minimum requirement of the MR output for the read sensor applicable to the 2 Tbit/in^2 areal recording density. [4] However, to ensure the process margins for the actual read sensor manufacturing, a realization of higher $\Delta R/R$ is strongly required. In this work, we systematically studied the MR properties of polycrystalline spin-valve (SV) and pseudo spin-valve (PSV) devices using AgSn/IZO-bilayer spacer. Also, we developed a new AgInZnO (AIZO) single-layer spacer which realized $\Delta R/R$ = 50% at RA = 0.08 Ω μm^2. Polycrystalline SV films with Ta(2) / Ru(2) / $Ir_{20}Mn_{80}$(6) / CoFe(3) / Ru(0.8) / CoFe(0.6) / CoFeBTa(0.8) / CMFG(2.5) / CoFe(0.4) / $Ag_{90}Sn_{10}$(0.4) / IZO(1.4-1.85) / CoFe(0.4) / CMFG(4) / CoFe(1) / Ru(8) (thickness in nm) structure was deposited by magnetron sputtering and annealed at 280 °C for 3 h. [5] The CPP-GMR devices showed *RA* values ranging from 0.05 Ω μm^2 to 0.2 Ω μm^2 and $\Delta R/R$ ranging from 20% to 30% depending on the IZO thickness. *RA* was larger for a thicker IZO layer. The maximum $\Delta R/R$ of ~30% at RA ~0.1 Ω μm^2 was obtained with a AgSn(0.4)/IZO(1.7) spacer. For comparison, SV devices with a AgSn(3.5 nm) conventional metal spacer showed $\Delta R/R$ of 13% at RA = 0.045 Ω μm^2. The output voltage (ΔV) *vs*. bias current density (J_{bias}) was tested for linearized *R*-*H* transfer curves under an application of a constant bias magnetic field of 80 mT perpendicular to the pinning direction (utilization ~33%), which simulates the actual read sensor operation (inset of Fig. 2(a)). The maximum ΔV (ΔV_{max}) of the sensor with the AgSn(0.4)/IZO(1.7) spacer (RA = 0.11 Ω μm^2, $\Delta R/R$ = 32%) was ~6 mV, whereas ΔV_{max} of the conventional all-metallic sensor with a AgSn(3.5) spacer was only 1.1 mV. PSV devices with a Ta(2) / Ru(2) / CoFe(0.5) / CoFeBTa(1.5) / CMFG(5) / CoFe(0.4) / spacer / CoFe(0.4) / CMFG(5) / CoFeBTa(1.5) / Ru(8) cap stacking structure annealed at 280 °C were also studied for so-called *scissors read sensors*. As shown in Fig. 1, the PSV devices showed larger $\Delta R/R$ at given *RA* values than the SV devices due to the thicker CMFG magnetic layers in the PSV films and the absence of the synthetic antiferromagnet pinned layer structure in PSVs. The PSV devices with the AgSn(0.4)/IZO(t_{IZO}) spacers showed $\Delta R/R$ ~ 33% at RA ~ 0.06 Ω μm^2 for t_{IZO} = 1.3 nm and $\Delta R/R$ ~ 38% at RA ~ 0.11 Ω μm^2 for t_{IZO} = 1.6 nm as shown in Fig. 1. Higher $\Delta R/R$ were obtained using a AgInZnO (AIZO) single-layer spacer. The AIZO films were co-sputtered from Ag and IZO. The PSV device with a 1.2 nm-thick AIZO spacer with a nominal Ag concentration of ~30 at. % showed $\Delta R/R$ up to 50% at RA ~ 0.08 Ω μm^2, which is higher by ~15% than that of the AgSn/IZO spacer at the same *RA* value (Fig. 1). The ΔV *vs*. J_{bias} of the PSV devices were tested by applying an external magnetic field (*H*) parallel to the minor axis of the ~60 nm×~120 nm elliptical shaped device, by which the magnetizations of the two free layers of PSV rotate gradually as the magnitude of *H* is increased due to the magnetic shape anisotropy of the device pillar. Fig. 2(b) shows ΔV (= ΔR × bias current)-*H* of a PSV device with RA = 0.08 Ω μm^2 and $\Delta R/R$ = 45%. ΔV_{max} was 18 mV at J_{bias} = 9.6×10^6 A/cm^2, which is much larger than that with a conventional AgSn spacer (RA = 0.03 Ω μm^2 and $\Delta R/R$ = 18%) of 3 mV. It should be noted that the PSV device shows a wide linear response range in -20 mT ≤ $\mu_0 H$ ≤ -80 mT with a large ΔV of 15mV as shown in Fig. 2(b). At J_{bias} = 1.3×10^8 A/cm^2, the magnetization of the CMFG-based ferromagnetic layers are destabilized by spin transfer torque in the high resistance state near the anti-parallel magnetization configuration, however, the linear response range is still stable. We will discuss the electric properties and the microstructure of the AIZO films and the CPP-GMR devices.

AF-05. Tailoring epitaxially grown exchange spring Fe/L10-FePt multilayers as perpendicular recording media.

A. Syed Mohd[1], S. Pütter[1], S. Mattauch[1] and T. Brückel[1,2]
1. Jülich Centre for Neutron Science (JCNS) at MLZ, Forschungszentrum Jülich GmbH, Garching, Germany; 2. Jülich Centre for Neutron Science JCNS and Peter Grünberg Institut, JCNS-2, PGI-4: Scattering Methods, Forschungszentrum Jülich GmbH, Jülich, Germany

High density storage in the hard disk drive (HDD) is realized using magnetic nanostructures which have perpendicular magnetic anisotropy (PMA) and is often termed as perpendicular recording media (PRM). $L1_0$-FePt films are very promising candidates for the PRM because of their large PMA [1]. In the HDD industry, $L1_0$-FePt films are replacing conventional CoCrPt films and extending the superparamagnetic limit. Hence they improve the thermal stability [2, 3]. Superparamagnetism is a phenomenon in which the magnetization direction may flip due to thermal activation without the application of an external magnetic field. This appears when the volume (V) of the magnetic particle is reduced in such a way that $K_uV \gg k_BT$ where K_u is magnetic anisotropy constant, k_B is Boltzmann constant and T is ambient temperature. But the problem with $L1_0$-FePt films is their hard ferromagnetic behavior which limits the writing process in the PRM due to the high switching field. One way to solve this issue is to combine a soft ferromagnet e.g. Fe with $L1_0$-FePt films to form an exchange spring magnet [4, 5]. In exchange spring magnet it is expected that the exchange coupling across the interface will reduce the coercivity as compared to hard ferromagnet alone. Further, exchange spring magnet Fe/$L1_0$-FePt has additional advantage that the increased out of plane saturation magnetisation will make the signal strong enough to be detected easily. However, previous studies have shown that the magnetic moments in Fe layers below ~ 2 nm remains collinear with respect to $L1_0$-FePt and there is insignificant change in the coercivity [6]. On one hand, for a Fe layer thickness above ~ 2 nm coercivity decreases with increasing thickness but on the other hand PMA decreases [7, 8]. In order to create a possible balance between the coercivity and the PMA, we have optimized the epitaxial growth of Fe/$L1_0$-FePt multilayers (MLs) which will have an addition interaction i.e. interlayer exchange coupling. The growth of thin ML is challenging because at room temperature (RT) the FePt film has an A1 (fcc) structure which is a soft ferromagnet with low magnetic anisotropy and undergoes to $L1_0$ (fct) structure only at high temperature [9]. However, high temperature growth of Fe/$L1_0$-FePt ML has the risk of interdiffusion at the interface so there is a strong demand of optimization. It is important to note that once the FePt film is in $L1_0$ structure, it remains in this phase even at RT.

AF-06. Data Temperature and Future Data Storage Architecture.

K. Gao[2,1]
1. Energy Systems, Argonne National Laboratory, Argonne, IL, United States; 2. International Business and Technology Service, North Oaks, MN, United States

There has been tremendous technological development over the past two decades in the magnetic data storage industry, with current products at an areal density of more than 1Tb/in^2 using shingled magnetic recording (SMR) and only until recently, the areal density capability (ADC) of hard disk drive (HDD) has been slowing down [1-3]. Over the past few decades, along with adoption of PC, small form factor HDDs became the new industry standard. There are a number of technologies that were invented/discovered, demonstrated and adopted as HDD industry standard over the past three decades, including: 1) GMR and TMR based read head technologies [4-6], implemented in 1997 and 2005 respectively; significantly improved the playback signal amplitude and the signal to noise ratio (SNR); 2) Transition from longitudinal magnetic recording (LMR) to perpendicular magnetic recording (PMR), where from a recording media perspective, leads to a higher media coercivity (Hc) and a reduced switching field distribution (SFD), which in PMR, are primarily due to media anisotropy and grain size distributions [7-9]. Media design combine coupled granular continuous (CGC) structure and the vertically exchanged coupled gradient anisotropy or exchange spring/composite structure helped to achieve this goal, which enables a steady improvement of the media SNR [10-13]; 3) PMR write head with a tapered write pole, as well as later added tapered wrap around shielded, enables early introduction and rapid adoption of PMR product, provide sufficient large write field and field gradient to allow high coercivity media to be utilized with a small grain size and a high SNR [7, 14-15]; 4) Introduction of heater to enable a further reduction of recording head to media spacing (HMS) in the read and write operations [16]. This approach primarily enables a down-scaling of HMS, which drives dynamic flying height to be less than 2nm; 5) The contact detection sensor (CDS), placed at the air bearing surface (ABS) of the recording head provide real time feedback on the HMS value for a given head and media interface, which helps to reduce the number of head media contact during read/write operations, and therefore significantly improves HDD's life spans [17]. Recently, the ADC of HDD has slowed down, even when including new technologies such as heat assisted magnetic recording (HAMR), the demonstrated ADC gain is around 15%/year [3]. Therefore, beyond component technology, drive systems and write architectures were optimized to further improve HDD capacity, despite most are "one time change", with success, such as 1) Shingled Magnetic Recording (SMR) as a write architecture to extend the ADC of HDD, has been demonstrated and implemented. Although due to excessive latency, SMR has slowly gained markets, mostly in the data archive systems, nevertheless, it is an approach enable further improvement of drive capacity. 2) Helium filled drive, an approach does not increase ADC, but increase HDD drive volumetric capacity due to reduction of disk to disk spacing, has been implemented, mainly for cloud based data centers with large capacities. 3) Interlaced Magnetic Recording (IMR) or Blocked Magnetic Recording (BMR), which further optimize write configurations for different tracks to improve ADC with reduced latency penalty as compare to SMR [19-21]. Recent study shown using IMR in HAMR, 30%$^+$ ADC gain can be achieved as compared to conventional random access recording condition, consistent with theoretical predictions [20, 22]. The BMR modeled results also shown ADC gain in addition to SMR [21]. Here the impact of write architecture will be reviewed and potential ADC gain in each approach are given. From data storage perspective, the write architecture change may incur data rate, and more precisely, the random accessed read and write operation frequency penalty. Over the past 10 years, due to wide adoption of mobile and social network, large amount of data are migrated to the Cloud. In the meantime, 3D NAND based solid state drive (SSD) starts to take over part of the HDD markets [23]. This type of technology evolution and transition cannot be explained using ADC or drive capacity comparison between different technologies. A STANDARD "*Data Temperature*" for all digital data stored, based on the frequency of the data being accessed is given, where the archived data, personal user data, work place storage and the most searched data at a given time can be represented as freezing, room temperature, hot data and boiling data respectively [24]. Different data storage technologies and their evolutions can be illustrated together using data temperature definition, to identify what will be future technologies for data storage. It is desired to have different technologies to store data with different *Data Temperature*, in reality, most data stored in a given device has much lower *Data Temperature* than the device average *Data Temperature* capability. As the size of the digital universe increases, the amount of cold data increased rapidly. This leads to new opportunity for data archive storage technology. In addition to the write architecture, new HDD based data storage architecture is proposed. Based on the detailed analysis, a solution for low cost data archive system well below current HDD system is given. Based on the detailed analysis, the proposed data storage solution has the potential to replace existing HDD, Tape and Blu-ray based storage for cloud based data centers.

AF-07. CoPt capped FePtC based ECC media for HAMR.

T. Dutta[1,2], S. Piramanayagam[3], M. Saifullah[2], C.S. Bhatia[1] and H. Yang[1]
1. Electrical and Computer Engineering, National University of Singapore, Singapore; 2. Institute of Material Research and Engineering, Singapore, Singapore; 3. School of Physical and Mathematical Sciences, Nanyang Technological University, Singapore, Singapore

$L1_0$ FePtC granular media is extensively researched as potential future magnetic recording media and is set to be used with Heat assisted magnetic recording (HAMR) to enable recording at write fields within the range of current day recording heads [1, 2]. The current media designs suffer from SFD issues during high temperature writing. FePtC based media structures with a capping layer can alleviate the switching field distribution (SFD) requirements of HAMR. Consequently, it can reduce the noise originating from the writing process. In accordance to this we investigated a CoPt/FePtC exchange coupled composite (ECC) structure, where FePtC serves as the storage layer and CoPt (with higher Curie temperature, T_c) as the capping layer. CoPt remains ferromagnetic at near T_c of FePtC. A stack structures of $L1_0$ CoPt (t_{CoPt})/$L1_0$ FePtC (10 nm)/MgO (3 nm)/CrRu (25 nm)/Glass were fabricated by sputter deposition. The CoPt layer thickness (t_{CoPt}) was varied from 2 to 6 nm. The $L1_0$ FePtC and $L1_0$ CoPt layers were deposited at nominal temperatures of 600 °C and 640 °C, respectively. An uncapped sample (without any CoPt capping) was also prepared under similar conditions for reference. Switching field (H_s) and SFD was extracted from the out-of-plane hysteresis loops for each sample. SFD was calculated as $SFD=(H_s\text{-}H_n)/H_c$, where H_n is the nucleation field and H_c is the coercive field, extracted from the out-of-plane loops. Both H_s and SFD decreased steadily with an increase in the CoPt thickness. In fact, for the t_{CoPt} = 6 nm sample, H_s and SFD decreased by 23.11% and 26.03%, respectively, as compared to that of the uncapped granular sample. For such capped media design it is important that the capping layer remains ferromagnetic at temperature near T_c of $L1_0$ FePtC ($T_{c,FePtC}$ < 700K). Out-of-plane hysteresis loops of the samples were measured at high temperatures of 250, 300, 350 and 400 °C as presented in Fig. 1. It was observed that 400 °C is well above the Curie temperature of FePtC but lower than that of CoPt. Two additional samples were also prepared with 4 nm and 6 nm $L1_0$ FePt capping layer on $L1_0$ FePtC granular layer. The H_c, Hs, and H_k for all the samples at 250 °C were lower than that at room temperature and continued to decrease with a further increase in temperature. At 300 °C the uncapped FePtC sample turned paramagnetic while all other samples exhibited reduced ferromagnetism. On increasing the temperature beyond 350 °C, the sample with 4 nm $L1_0$ FePt capped sample also turned paramagnetic. However, the all the CoPt capped media and the 6 nm FePt capped media remained ferromagnetic. Although the 6 nm FePt capped sample remains ferromagnetic at 400 °C, the magnetization was much lower compared to the CoPt capped samples. Clearly, the CoPt capping layer remains ferromagnetic at 350 °C and 400 °C, although the uncapped FePtC granular media becomes paramagnetic at those temperatures. During the actual recording process using HAMR, the target grains are heated to T_c of the media, at which they become paramagnetic. Subsequently, during the cooling process, the presence of the $L1_0$ CoPt capping layer (which remains ferromagnetic near T_c of $L1_0$ FePtC) will facilitate a counter exchange energy to minimize the stray field from the adjacent grains. Therefore, the magnetization in the target grains would no longer be affected by the stray field during the recording process. Thus, we have demonstrated that $L1_0$ CoPt capping for $L1_0$ FePtC granular media can lead to lower switching fields, and improved switching field distribution during the high temperature writing process. The presence of ferromagnetic exchange coupling from $L1_0$ CoPt capping layer makes $L1_0$ CoPt/$L1_0$ FePtC media best suited for future HAMR technology.

AF-08. Order-disorder Temperature of MnGa Thin Films on Glass Substrate.

C. Huang[1], Y. Chen[2], S. Wang[1] and A. Sun[2]
1. Institute of Materials Science and Engineering, National Taipei University of Technology, Taipei, Taiwan; 2. Chemical Engineering and Materials Science, Yuan Ze University, Taoyuan, Taiwan

Introduction MnGa with $L1_0$ phase was firstly discovered by Tsuboya and Sugihara in 1965 [1]. $L1_0$-MnGa has attracted much attention due to its large coercivity (H_c) [2], high magneto-crystalline anisotropy ($K_u \sim 10^7$ erg cm^{-3}), high perpendicular magnetic anisotropy (PMA) [3], and Pt element free, which massively reduces the cost during the materials preparation. Thus, it is regarded as the promising candidates to replace $L1_0$-CoPt and $L1_0$-FePt thin films for next generation of hard magnetic phase film applications, such as magnetic sensor, magnetic recording media, spintronic devices, etc. However, the amount of related reports were much fewer than those of the $L1_0$-CoPt or $L1_0$-FePt cases, so that people seem not clearly to realize what the magnetic material is. Thus, in the presented work, MnGa alloy thin films with different thicknesses (t) were directly sputtered on an amorphous glass substrate at varied substrate temperature (T_s). The results demonstrated that high H_c MnGa thin film could be prepared on glass substrate if the film had sufficient growth volume. The coercivity mechanism and the effects of t and T_s on magnetic properties and microstructure of MnGa thin film will be discussed in full article. Experiment In this study, MnGa magnetic alloy thin films with different t were deposited on an amorphous glass substrate at varied T_s by an ultrahigh vacuum magnetron sputter system, where t and T_s were 10-200 nm and RT(room temperature)-600 °C, respectively. The working Argon pressure was set to 5 mTorr during sputtering. The thickness of the film was cheched by an Atomic Force Microscope (AFM). The phase and magnetic domain structures were characterized by a X-ray diffractometer (XRD) and a Magnetic Force Microscope (MFM). The magnetic properties were carried out with the vibration sample magnetometer (VSM). Mircostructure of the films were investigated by a Transmission Electron Microscope (TEM) with a accelerating voltage of 200 keV. Results and Disscussion Figure 1 shows XRD diffraction patterns of MnGa films with different T_s. The thickness of films is kept at 200 nm. In Fig. 1, the film shows poor crystallization at T_s = RT. When T_s is 300 °C, Mn_8Ga_5(330) and Mn(101) peaks are presented clearly. The diffraction peaks of $L1_0$ MnGa (111), (200), (220), and (202) peals can be observed as T_s increases to 350 °C. The intensity of $L1_0$-diffraction peaks would be further increased with increasing the T_s, indicating that the crystallinity of $L1_0$-type MnGa thin films are enhanced when T_s is increased. Therefore, phase transformation MnGa thin films from amorphous to $L1_0$ phase needs thermal energy during heat treatment process. Figure 2(a)-(d) show the magnetic hysteresis loops of MnGa thin films with t = 200 nm at varied T_s, where T_s are 300, 400, 500 and 600 °C, respectively. Of course, Fig.2(a) presents that the film shows poor magnetic properties at T_s = 300 °C due to Mn_8Ga_5(330) and Mn(101) are poor magnetic phases. However, H_c is largely enhanced and clear hysteresis loops are observed when T_s is further increased, as shown in Fig.2(b)-(d). The higher H_c is about 7.1 kOe which is obtained at T_s = 600 °C. Nevertheless, the presented results are sufficient to demonstrate that the order-disorder temperature of MnGa thin film is between 300 to 350 °C. The is also a strong evidence that $L1_0$ MnGa thin film with high H_c can be prepared at low processing temperature, an outstanding advantage in hard magnetic film application. Conclusion MnGa films with high H_c have been deposited on glass substrate. MnGa films show poor magnetic properties with $T_s \leq 300$ °C, because the films presented nonmagnetic phases. MnGa thin films start to transfer into $L1_0$ phase at T_s = 350 °C, and exhibit hard magnetic properties with large coercivity. The the order-disorder temperature of MnGa thin film is thus confirmed between 300 to 350 °C. The detail mechanism would be discussed in the manuscript.

FePt-C granular film structure has been considered as the most promising candidate for heat-assisted magnetic recording (HAMR) media since its first successful demonstration of well-isolated FePt grains with ~ 6 nm thickness and a size distribution ($\sigma \approx 2.3$ nm) in 2008. [1] However, the FePt-C based media still have some vital issues hindering its practical application and to reach uniform grain size distribution without losing number density of grains is one of them. Wide grain size distribution causes grain-to-grain variation in chemical ordering (S), curie temperature (T_c), anisotropy field (H_k), affecting the recording performance of HAMR. We believe that one of the reasons causing the wide distribution in grain size of granular FePt-C based media is the size non-uniformity of FePt nuclei in nucleation stage. Therefore, it is crucial to obtain a uniform FePt nuclei in order to narrow the grain size distribution in granular FePt films. In our previous works, we demonstrated the strategy of utilizing templated layer in order to control the grain size distribution.[2][3] In this work, we explore the possibility of modifying the kinetic energy and thus the mean free path of ad-atoms FePt-C by varying the sputtering conditions in order to reach more uniform nucleation. All films were sputtered on thermally grown a-SiO_2 substrates using an AJA Orion-8 system with base pressure better than torr. All substrates are cleaned by acetone, IPA, DI water and dry etching by O_2 plasma. The film stack is Si | SiO_2 | MgO (9nm) | FePt + 35 vol.%C (1.5nm). Media layer was kept constant at 1.5 nm for all samples, since the nucleation stage of FePt-C grains is the main focus in this study. MgO was sputtered at 10mTorr with at room temperature with deposition rate of 0.57 nm/min. FePt alloy target and carbon target were co-sputtered at substrate temperature of 650°C with different deposition pressure (5 – 20mTorr) in order to modify the kinetic energy of FePt and C when it arrives at MgO surface so that to examine the effect of deposition pressure on FePt grain nucleation. The film microstructures were examined by in-plane transmission electron microscope (TEM). Fig.1 (a) and (b) shows the plane-view TEM images of FePt-C films deposited at 5 and 20 mTorr, respectively. Note that in the case of 5 mTorr, there are significant amount of small size nuclei relative to that of majority nuclei, typically with diameter < 1.5nm, whereas in the case of 20 mTorr, the small nuclei are rarely observed. This observation is confirmed by the grain size distribution histogram, shown in Fig. 1 (c) and (d), for both cases. Multiple number of plane-view TEM images, taken from different regions of each sample, are used for calculating the statistical distribution with total number of grains counted exceeding 500. For FePt-C film deposited at 5 mTorr, the bimodal distribution shows one peak in between 0.5-1.0 nm and the other in between 2.5-3.0 nm. The mean grain size is 2.2 nm. The smaller grain size peak is actually quite significant, counted as 30% of the total number of grains. Experimental evidences show that with continued film growth, this bimodal distribution would continue with both peaks moving to larger sizes. The bimodal grain size distribution have been reported in several other previous studies, all at slightly different grain size [4] and we tend to believe they all arises from the bimodal distribution at nucleation stage. At the high deposition pressure, 20mTorr, the grain size distribution only shows a single peak located in between 2.0-2.5 nm. The total number density of FePt grains and packing fraction listed in table 1 are similar for both cases. It clearly shows that by tuning the deposition pressure of FePt-C in the nucleation stage, more uniform FePt nuclei can be obtained without scarifying the number density of FePt nuclei.

AF-10. Influence of Stress and Strain on the $L1_0$-ordered Phase Formation in FePt Thin film.

M. Futamoto[1], T. Shimizu[1], M. Nakamura[1] and M. Ohtake[1]
1. EECE, Chuo University, Shinjuku, Japan

Introduction FePt thin films with $L1_0$-ordered structure have been investigated for magnetic recording media application. The film involves phase transformation from disordered fcc ($A1$, $c/a = 1$) to $L1_0$-ordered phase with tetragonal structure ($c/a = 0.97$). For applications, the easy magnetization axis (*c*-axis) must to be controlled to be perpendicular with respect to the substrate surface while achieving a high ordering degree. Previous studies have shown that *c*-axis orientation and ordering degree of FePt crystal depend on various factors including substrate material, processing condition, film thickness, etc., where the stress distribution in FePt material is interpreted to have influenced on the resulting film structure[1-3]. The stress/strain in FePt material varies depending on the film morphology and the stacking structure[4]. In the present study, structure analysis using a high-resolution TEM is carried out for $L1_0$-FePt thin films with different film morphology or stacking structure, where the average thickness of 10 nm and the final processing temperature of 600 °C are employed. The effect of stress/strain in FePt material on the ordered phase formation has been investigated. Experimental procedure FePt films of 10 nm thickness were prepared on MgO(001) substrates using an UHV RF magnetron sputtering system, by direct deposition at 600 °C (sample A), by a two step-process consisting of low temperature (200 °C) deposition followed by annealing at 600 °C without (sample B) and with 2-nm-thick MgO cap-layer (sample C) [4,5]. The film structures were observed by AFM, XRD, and TEM. The magnetic properties were measured by using a VSM. Results and discussion Figure 1 compares the film morphology and the magnetic property of samples A, B, and C. The volume fraction of $L1_0$-(001) crystal with the c-axis perpendicular and the ordering degree determined by XRD are also shown in the lower part of this figure. Although the final processing temperature is same at 600 °C, the highest perpendicular anisotropy is observed for the sample C, while the sample A is showing even an in-plane magnetic anisotropy. The magnetic property is influenced by the volume fraction and the ordering degree, both of which apparently strongly affected by $L1_0$-ordering through atomic diffusion under an influence of stress/strain within the FePt thin films. The lateral tension stress is presumably in the sample order of C > B > A, where a lateral tension caused by lattice mismatch with MgO material (-9 %) is provided from both the substrate and the cap-layer sides for the sample C, from only the substrate side for the sample B, and a curved surface profile of isolated FePt crystal in the sample A is apparently reducing the lateral tension from the surface-side. Figure 2 shows the atomic structure analysis around the FePt/MgO interfaces for the sample C. Although the lattice misfit is nearly relieved by introduction of misfit dislocations, there still remains a lateral tension strain in the FePt material, which has possibly promoted formation of $L1_0$(001) crystal. A relation between the strain/stress and formation of $L1_0$-phase will be discussed at the conference.

AG-01. Design of a Novel Variable-stiffness Permanent Magnetic Mechanism for Flexible Robots.

M. Zhang[1], L. Fang[2] and F. Sun[3]
1. School of Mechanical Engineering and Automation, Northeastern University, Shenyang, China; 2. Faculty of Robot Science and Engineering, Northeastern University, Shenyang, China; 3. School of Mechanical Engineering, Shenyang University of Technology, Shenyang, China

ABSTRACT: This paper describes the design, modeling, and analysis of a novel variable-stiffness mechanism for wire-driven flexible robot joint. Compared with the mechanical device, it can effectively increase the range of variable-stiffness, without increasing the wire-tension. Then improve the energy efficiency, safety and lightweight of the robot joint. Based on Ampere' molecular current hypothesis, through estimating the induced magnetic field and magnetic force in the system, the variable-stiffness mechanism force and stiffness models are obtained. It is verified by the FEM simulation and experiment. The variation regulation of the magnetic force and stiffness between permanent magnets is consistent with that of magnetic field. Therefore, the variable-stiffness law of the permanent magnet mechanism can through the design of the magnetic field of the air-gap. 1. Introduction Variable-stiffness robot joint is a kind of flexible joint with adjustable stiffness, which can greatly improve the safety and environmental adaptability, has become the future robot joint development. Wire-driven variable-stiffness joints are usually connected with nonlinear elastic components on both sides of the joint, that can buffer the collision, absorbing energy. This form is closest to the position and stiffness control of human skeletal muscle. Scholars have done a lot of research on these components, such as the add-on nonlinear spring unit [1], compact nonlinear spring unit using natural rubber latex [2]. The variable-stiffness ability of the above elastic components are directly related to the wire-tension. Due to the limit of motor torque, the range of variable-stiffness is not wide. In this paper, we propose a variable-stiffness mechanism for robot joint which can realize more wide stiffness range without increasing wire-tension. 2. Structure and principle The permanent magnet mechanism consists of permanent magnetic spring and wire-driven system as shown in Fig.1-(a~b). One pair of magnet rings arranged in coaxial direction and same permanent poles are opposite. Moveable magnet ring just can slide in axial direction due to the limit of slideway that can form a permanent spring. The magnetic force and stiffness increase nonlinearly with decreasing air-gap. The wire-driven system is composed of a movable pulley and two fixed pulleys, that arranged in isosceles triangle. When we apply some force to the wire, the movable pulley is pulled up, the air-gap z_0 decreases, the wire angle α increases. The relationship between the wire-tension T and magnet force F is $T=F/2\cos\alpha$. The increasing of wire length and the wire-tension (stiffness) are nonlinear. The nonlinear combined effect of the permanent magnet spring and the wire-driven system makes more wide variable-stiffness range than pulley systems with linear springs [1-2], therefore, the motor power and volume can reduce. The variation range and slope of tension and stiffness curves can change through optimization the structural parameters. 3. Model and theoretical analysis The nonlinear force and stiffness characteristics of permanent magnet mechanism are mainly caused by the air-gap magnetic field between permanent magnets. The magnetic flux density of the air-gap determines the changing law of magnetic force and stiffness. The magnetic flux density model is established, as shown in Fig.1-(c). Due to the symmetry, the magnetic components along the x-axis and along the y-axis between the permanent magnet rings offset each other, the magnetic force is only in the z-direction. According to Ampere' molecular current hypothesis, the magnetic force between permanent magnets is obtained. Based on model mechanics, as shown Fig.1-(b), the wire tension T and stiffness K are obtained. 4. FEM model and experimental measurement In order to show the magnetic field distribution and verify the correctness of the mathematical model, the FEM model was build, FEM results were as shown in Fig.1-(d). Experimental prototype was built as shown in Fig.2-(b). Calculation, simulation and experimental values are basically the same. The nonlinear laws of magnetic flux density and force with axial air-gap z_0 are basically the same, as shown in Fig.2-(a,c). Therefore, the law of the magnet force and stiffness can change through the design of the magnetic field of the air-gap. The variable-stiffness range of permanent magnet mechanism is much wider than mechanical ones when the wire-tensions are the same, as shown in Fig.2-(d). 5. Conclusion This paper describes a novel variable-stiffness mechanism used for wire-driven flexible robot joint. Compared with the traditional mechanical ones, it can effectively increase the range of variable-stiffness without increasing the wire-tension. The variation regulation of the magnetic force and stiffness between permanent magnets can change through the design of the magnetic field of the air-gap. The method described in this paper for calculating the air-gap magnetic flux density is very close to the FEM simulation and experimental measurement value. Based on this, the calculation of the force and stiffness between permanent magnets is closer to the true value.

AG-02. Two-Converters Based Synchronous Operation and Control of a Brushless Doubly-Fed Reluctance Machine.

R. Rebeiro[1] and *A. Knight*[1]
1. Electrical Engineering, University of Calgary, Calgary, AB, Canada

I. Introduction The Brushless Doubly Fed Reluctance Machine (BDFRM) has promising prospect as a commercial machine, since it's a low cost, low maintenance machine. It does not require brushes, slip rings, rotor circuit or magnets. Having a robust winding-free ducted rotor, it can also work with a simpler control technique than a doubly fed induction generator (DFIG). Therefore, BDFRM can be very useful for applications like wind turbine system and electric vehicle. Apart from research on BDFRM [1-9], recent research efforts also address the analysis of other similar machines [10-13], and their comparisons with BDFRM [14-16]. However, topics like control and operation of prototype machines have remained largely unexplored. This paper focuses on this side of BDFRM research. An analytical magnetic design process is carried out, and a prototype machine is built based on the proposed optimum design. Subsequently, two-converters based control approach and real-time synchronous operation are investigated. II. BDFRM Analysis for Synchronous Operation Two sets of 3-phase windings with different numbers of magnetic poles are wound on the stator. The magnetic pole numbers of the windings chosen for this BDFRM are 8 and 4. Control of power flow between the windings and the rotor shaft occurs through the salient rotor design, which modulates the magnetic coupling between the windings. Coupling between the windings occurs under the following constraints [9]: $2p_r = p_8+p_4$ and $p_r\omega_m = \omega_8+\omega_4$; where p_8, p_4 and p_r are the 1st winding, 2nd winding and rotor pole numbers respectively; ω_8 and ω_4 are the 1st and 2nd winding electrical angular supply frequencies, and ω_m is the rotor mechanical speed in rad/s. The desired number of rotor poles is 6 according to the first equation. For synchronous operation, ω_4 is set to zero such that the 4-pole winding acts as the field circuit of a conventional synchronous machine. A ducted rotor pattern has been followed in this design following the example of [8]. Structural FEA has been carried out on several variations to find out the optimized ducted rotor. Detailed machine design and mathematical analysis can be presented in full paper. The *q-d* axes currents in the arbitrary rotating reference frame of angular frequency ω_8 can be expressed as, $i_{q8}=I_8cos(\theta_{8\text{-}0})$, $i_{d8}=-I_8sin(\theta_{8\text{-}0})$, $i_{q4}=I_4cos(\omega_8t+\theta_{8\text{-}0})$, $i_{d4}=I_4sin(\omega_8t+\theta_{8\text{-}0})$ where I_8, I_4 are the two windings peak currents and $\theta_{8\text{-}0}$ is the relative phase of 8-pole winding current with respect to the arbitrary reference frame at $t=0$. From these equations, corresponding *q-d* axes flux linkages can be deduced as, $\lambda_{q8}=L_8I_8cos(\theta_{8\text{-}0})+L_{84}I_4cos(\theta_{8\text{-}0}+\theta_{r\text{-}0})$, $\lambda_{d8}=-L_8I_8sin(\theta_{8\text{-}0})-L_{84}I_4sin(\theta_{8\text{-}0}+\theta_{r\text{-}0})$, $\lambda_{q4}=L_4I_4cos(\omega_8t+\theta_{8\text{-}0})+L_{84}I_8cos(\omega_8t+\theta_{8\text{-}0}-\theta_{r\text{-}0})$, $\lambda_{d4}=L_4I_4sin(\omega_8t+\theta_{8\text{-}0})+L_{84}I_8sin(\omega_8t+\theta_{8\text{-}0}-\theta_{r\text{-}0})$ where $\theta_{r\text{-}0}$ is the rotor initial position. It can be observed from these equations that the *q-d* axes 8-pole winding flux linkages are constant dc quantities in its reference frame while the 4-pole winding flux linkages act as ac variables in the opposite reference frame. III. Control Approach The block diagram of the field oriented control scheme is shown in Fig. 1. The diagram has two almost identical halves; the top half is showing the control blocks for the 8-pole winding and the bottom half is associated with the 4-pole winding. The 3-phase currents for both windings i_{abc8} and i_{abc4} are measured by two sets of current sensors, and they are fed to the respective Clarke transformation modules. The outputs of these projections are the stationary two-axes current components $i_{\alpha\beta 8}$ and $i_{\alpha\beta 4}$. These current components are the inputs for the Park transformation modules which yield i_{qd8} and i_{qd4} currents in the respective *q-d* rotating reference frames. These *q-d* axes actual current components are subsequently compared with the corresponding flux component references (i_{d8}^* & i_{d4}^*) and torque component references (i_{q8}^* & i_{q4}^*). Reference i_{q8}^* is the output of the speed PI controller. The current errors are fed as the inputs to the four current PI controllers. The outputs of the current controllers are v_{qd8} and v_{qd4} which are applied to the inverse Park transformation modules. The outputs of these modules are $v_{\alpha\beta 8}$ and $v_{\alpha\beta 4}$ which are the components of the stator vector voltage in the (α, β) stationary orthogonal reference frame. These are the inputs for the SVPWM modules. The SVPWM modules generate the gating signals to drive the two power converters which supply power to the two stator windings. Electrical angle calculations (θ_{8e} and θ_{4e}) required for the Park transformations are carried out from the following relations: $\omega_e=p_r.\omega_m$, $\omega_{8e}=x.\omega_e$, $\theta_{8e}=\int\omega_{8e}\,dt$, $\theta_{4e}=\theta_e\text{-}\theta_{8e}$. Here, x defines the ratio of the 8-pole winding frequency to the total applied frequency. For synchronous operation, x is set to 1 as the total frequency is applied on the 8-pole winding. IV. Experimental Data The BDFRM drive is implemented by using the PwrCon system from Denkinetic Pty Ltd. which is a DSP based system. A permanent magnet synchronous machine is used as the load machine. In this test, the BDFRM drive is operated as a synchronous machine at different speed levels with a fixed dc field (4-pole winding) current to yield optimum torque output. The experimental torque and output power responses are plotted in Fig. 2. V. Conclusion This work discusses the analysis and control approach for a two-converters based synchronous operation of a prototype BDFRM. The motor drive is also tested in real-time.

AG-03. A Novel Two-Phase Excitation Switched Reluctance Motor with Symetrical Winding Distribution.

Y. Zhu[1], C. Yang[1] and Y. Zhang[1]
1. Tianjin University of Sicence and Technology, Tianjin, China

Abstract Two-phase simultaneous excitation mode of the switched reluctance motor (SRM) has been shown to effectively improve the average torque output of electric vehicles compared to traditional single-phase excitation mode. But the torque ripple of the two-phase excitation SRM with traditional winding distribution increases because of the inconsistent electromagnetic field. In order to reduce the torque ripple, a two-phase excitation 8/6 SRM with novel winding distribution is proposed in this paper. The torques generated by various magnetic circuits are analyzed and obtained to verify the torque increase. Finally, a prototype of the novel SRM is manufactured and an experiment for measuring the SRM electromagnetic characteristics is designed based on the novel mode, and the comparison results show that the proposed excitation mode is effective. I.INTRODUCTION Most SRMs applied in industries are operated in single-phase excitation mode. Another excitation way of the SRM is the two-phase excitation mode in which the windings of two phases are energized simultaneously and excited regularly. Compared with single-phase excitation mode, two-phase mode has some advantages, including torque ripple reduction, torque density improvement and efficiency raise [1-5]. However, for further analysis, the two-phase simultaneous exciting magnetic field of the four-phase 8/6 SRM with traditional winding structure is inconsistent, which can result in asymmetrical torque output and increased torque ripple. II.Novel SRM with Symmetrical Winding Distribution In order to avoid the inconsistent magnetic field distribution of the two-phase simultaneous excitation mode to reduce the torque ripple of the SRM, a novel winding distribution leading to consistent magnetic field is proposed in this paper based on the two-phase simultaneous excitation mode. The novel winding distributions of all phases are shown in Fig.1 b). It can be seen that the distribution of the four phases is the same, which is different than the traditional winding as shown in Fig.1 a). The adjacent exciting stators' magnetic poles near the rotor are N and S respectively when two phases of the proposed SRM are simultaneously excited by current i_{AD}. Take phase A and D for example, the current i_{AD} successively flows through phase A and D from the connection terminal of phase A to that of phase D. Thus, AD is energized by power U, in which the negative and positive poles are connected to terminal of phase D and phase A respectively. As a result, the magnetic field distribution of the motor is short magnetic circuits(SMC) when phase AD is excited. Furthermore, the magnetic paths of AB, CB, and CD are the same as AD and all the field distributions are SMC in one working cycle of the motor. However, for the two-phase SRM with traditional winding shown in Fig.1 a), it should be noted that magnetic circuits of CD, CB, and AB are also SMC, which is completely different from AD defined as the LMC. Therefore, it can be confirmed that the novel winding distribution will avoid the torque ripple caused by the inconsistent and variable magnetic fields. III.Comparisons and Verification Fig. 2 is the transient analysis results when the SRM drive system works under speed closed-loop and current chopping control mode. Fig.2 a) is the current waveforms with speed of 750 r/min and load torque of 17 Nm,where the blue, green, red and light blue curve represent phase CD, CB, AB and AD. Fig.2 b) is the total torque waveforms of the SRMs with two winding distributions, which are respectively traditional and proposed distributions. Compared to the SRM with traditional winding which has three SMC and one LMC within a cycle, the proposed SRM has absolute four SMC. It can be seen from Fig. 2 b) that, for the SRM with traditional winding distribution (TSRM), the torque waveforms will change and decrease obviously when phase AD is energized in one cycle due to the variation of magnetic circuits, which will lead to a reduction of the average torque. And a periodic vibration will be occurred as shown in the red curve, which will directly cause more torque ripple. However, the output torque of the SRM with proposed winding distribution (NSRM) shown in the blue curve can keep steady and smooth. The generated torques of each two-phase are uniform and the average torque increases approximate 11.3% in one cycle and 22.3% during exciting phase AD period, compared to the SRM with traditional winding. IV.Conclusions In this paper, electromagnetic field for the single-phase and the two-phase excitation mode were analysed respectively with the traditional winding distribution of the 8/6 SRM. And an inconsistent flux field distribution was found when the 8/6 SRM with traditional winding works in the two-phase excitation mode, which can result in additional torque ripple. In order to reduce the ripple caused by the inconsistent electromagnetic field, a novel winding distribution for the 8/6 SRM which works in the two-phase simultaneous excitation mode was proposed. The prototype of the novel mode SRM was developed and manufactured. The analysis and experimental results have demonstrated that the proposed SRM can improve the torque performance of the two-phase excitation mode. AG-04. Rotor Design Optimization of a new Flux Assisted consequent Pole Spoke type Permanent Magnet Torque Motor for low speed applications.

M. Onsal[1], Y. Demir[1] and M. Aydin[1,2]
1. R&D, MDS Motor Ltd., Kocaeli, Turkey; 2. Mechatronics Engr., Kocaeli University, Kocaeli, Turkey

I. INTRODUCTION Permanent magnet (PM) motors are frequently used for special applications over decades. Direct drive PM motors with high torque capability without any gear system have some benefits over high speed motors. In this study, a new spoke-type PM synchronous torque motor with consequent pole rotor (CPR) and flux assisted magnets is proposed for low-speed high-torque direct-drive applications with reduced permanent magnet volume compared to conventional surface PM motors. The new rotor structure is composed of two different rectangular magnets: The large rectangular magnets are used consecutively in the spoke-type rotor and the others are small magnets located below each rotor segments. The small magnets are used to assist the flux which are produced by spoke-type magnets. The motor performance of the proposed motor is compared with a conventional SPM motor which has the same OD and slot-pole combinations. The newly proposed PM motor with CPR and flux assisted magnets offers lesser amount of magnet than surface permanent magnet (SPM) rotor and wider torque-speed range in constant power region as compared to SPM synchronous motor. In addition, especially in constant power region, magnet and iron losses of the CPR motor are lower than that of SPM motor. II. DESIGN AND FINITE ELEMENT MODELING OF CONSEQUENT POLE TORQUE MOTOR The preliminary motor design is carried out considering the design criteria summarized in Fig. 1(a). The DC bus voltage value of the CPR torque motor is 24V. Winding layout and MMF distribution of the motor are respectively shown in Fig. 1(b) and Fig. 1(c). As seen from the both figures, motor has a conventional concentrated winding distribution. After completing the preliminary design process, magnet and airgap optimizations are performed using 2D finite element analysis (FEA) to obtain optimum rotor design. 2D FEA model and flux density levels of the final design are respectively shown in Fig. 2(a) and Fig. 2(b). Cogging torque variation for CPR torque motor is given in Fig. 2(c). As seen from the figure, the cogging torque value is only 0.025% of the average torque. Fig. 2(d) shows the back-electromotive force (EMF) voltage waveform of CPR torque motor. As seen from the figure, line back EMF waveform is almost sinusoidal with a THD level of 0.1%. On-load analyses of the motors are also performed. Torque output of the both motors is almost the same with very low ripple. The proposed CPR torque motor has 39.1 Nm average torque with 0.57% ripple while the conventional SPM torque motor has 40.46Nm average torque with 0.54% torque ripple. As the magnet weights are compared, it is seen that the proposed CPR motor, has 0.6345kg magnets while the SPM motor has 0.691kg magnets. Considering the average output ratio to magnet weight, CPR motor has roughly %5.4 more torque-to-weight ratio compared to conventional SPM synchronous motor. Flux weakening capability of the proposed CPR motor is determined using 2D-FEA tools and compared with that of SPM torque motor. Torque-speed curve of CPR torque motor and comparison with SPM motor are illustrated in Fig. 2(f). As seen from the figure, CPR motor has much more continuous power range than SPM motor. Additionally, iron loss levels of both motor are shown in Fig. 2(g). Structural FEA is also carried out to determine stress level of the rotor bridges. Von-Misses stress result on rotor is given in Fig. 2(h). Lastly, the design was completed and a prototype was produced to verify the FEA results. One piece of rotor lamination which are cut during manufacture process of motor and final shape of CPR torque motor are respectively given in Fig. 2(i) and Fig. 3(j). More detailed information and test results will be given in the final version of the paper. III. CONCLUSION In this paper, a new flux assisted consequent pole spoke type PM synchronous torque motor is proposed, analyzed and designed. Initial design, detailed magnetic and structural finite element modelling and torque quality investigation are all carried out to validate the proposed motor for high-torque, low-speed application. The motor offers wider constant power region than conventional SPM motor which is has same outer dimensions and same stator. The main benefits of the proposed motor are lower magnet cost, higher torque-to-weight ratio with comparable torque density and high-speed capability as opposed to conventional SPM synchronous torque motors. Detailed test data, comparison with the FEA results will also be presented in the final paper. AG-05. Manufacturing Condition and Variations of Soft Magnetic Composite Cores for Application in PM Motors Based on Taguchi Method.

G. Lei[1], Y. Guo[1] and *J. Zhu*[1]
1. University of Technology Sydney, Sydney, NSW, Australia

Soft magnetic composite (SMC) material has been investigated for the development of cores for permanent magnet (PM) motors in recent years. Compared with the cores made of traditional silicon steel sheet, there are several special properties of SMC cores, including (1) the isotropic performance in electromagnetic and thermal properties due to the powder nature of SMC, making it ideal for the PM motors with 3D flux path, such as transverse flux machine (TFM) and claw pole motor (CPM); (2) the lower eddy current loss and magnetic permeability because of the isolation coat of the particles, (3) the easier manufacturing ability of stator/rotor cores by using molding technology [1]-[3]. On the other hand, there are two main challenges for the manufacturing and application of SMC cores in PM motors. First, heat treatment is a crucial process in the manufacturing of SMC cores. There are several control parameters in this step such as the burn-off and curing temperatures and times. They will determine the core loss and magnetic permeability of the manufactured SMC cores. Therefore, optimal manufacturing factors should be investigated to obtain the best magnetic properties of the cores. Second, there are some manufacturing variations of the SMC cores like core densities and dimension, which will lead variations of the motor performances, such as output power and efficiency. Thus, the quality of the manufactured SMC cores will affect the quality of the SMC motors. To gain the best performances and good quality of the SMC cores and motors, manufacturing uncertainty analysis should be investigated for both SMC cores and motors. This work will consider these two challenges by using the Taguchi method. The Taguchi method is a robust design method with consideration of manufacturing variations and other noise factors in the manufacturing and usage of a product like motor. It is a structured approach for determining the best combination of inputs to produce a product or service, based on the orthogonal design technology and quality loss functions (or S/N ratio). It is one of the most powerful methods available to reduce product cost, improve quality, and simultaneously reduce development interval [4]-[6]. In this work, this method will first be used for the determination of the best parameters for the heat treatment of SMC cores, and some manufacturing variations will be discussed. Then, to decrease the effects of manufacturing variations of SMC cores on the motor performances, this method will be investigated again to find out the best dimension of a 3D TFM to increase the manufacturing quality of the motor. 1. Determination of the best heat treatment parameters of SMC cores Fig. 1 illustrates several manufacturing facilities and samples for a 3D TFM with SMC cores. The hydraulic compact machine (Fig.1(c)) uses the die tools (Figs.1(a) &(b)) to compact the SMC powders to produce the raw SMC core (Fig.1(e)), then the high-temperature furnace will cook the raw core with a controlled heat treatment plan as shown in Fig. 1(g) to obtain a cooked core (Fig.1(f)). As shown in Fig.1(g), there are five main parameters for the heat treatment of the SMC cores. They are Te1, Te2, Te3, Ti1 and Ti2. Te1 is the initial temperature of the furnace. The basic effect of temperature Te2 is to ensure the mechanical strength of the compacted SMC core. The effect of temperature Te3 is to eliminate the stress and improve the magnetic performance. Ti1 and Ti2 are the cooking times. To determine the best parameters of them, an orthogonal design is adopted with three levels for each factor. Table 1 lists the details of the orthogonal array. As shown, there are 18 experiments. For each experiment, the relative permeability and the core loss are measured for the cooked core. The measured results are shown in the table as well. Based on the analysis of Taguchi method, it is found that the best levels for those five heat treatment parameters are [200 °C, 480 °C, 60 mins, 500 °C, and 30 mins]. The obtained relative permeability is 267 and core loss is 4.48 W/kg. 2. Determination of the best dimension of a SMC motor Based on the experimental results, it is found that there are some manufacturing variations for the cooked SMC cores. The most important one is the relative permeability, which will affect the electromagnetic analysis and performances of the designed motor. However, it is hard to decrease these variations in the core manufacturing step (high cost will be required to upgrade the equipment like the high-temperature furnace). Therefore, the dimension of the motor is optimized to decrease the sensitivity of these variations by using the Taguchi method. In the implementation, seven parameters including PM dimension and air gap are selected as the control parameters and the relative permeability is regarded as noise factor. With a similar analysis to the heat treatment part, an optimal design is obtained. This design can increase the motor reliability from around 76% to 98% by using the proposed method. In conclusion, Taguchi method benefits the manufacturing of good quality SMC cores and PM-SMC motors.

AG-06. Design of Cryogenic Permanent Magnet Synchronous Motor for Submerged Liquefied Natural Gas Pump.

C. Guo[1], S. Huang[1], J. Wang[1] and *Y. Feng*[1]
1. College of Electrical & Information Engineering, Hunan University, Changsha, China

Abstract—Cryogenic motors, as the key component of submerged liquefied natural gas (LNG) pumps, have gradually attracted the attention of researchers with the vigorous development of LNG industry. This paper presents the design of cryogenic permanent magnet synchronous motor (C-PMSM) submerged in LNG pump. In cryogenic environment of –161 °C, the magnetic and electric characteristics of PMSM differ greatly from the operating conditions at room temperature. So, in order to obtain the operating characteristics corresponded with theory and design of the motor are discussed. Finite element method (FEM) is adopted to establish models and to carry out the multi-field coupling simulation. A prototype is fabricated and built, in order to validate the theory. I.Introduction Because of its cleanliness, innocuity and many other advantages, the LNG have been widely accepted. Submerged pumps with simple structures and safety operation, are used in many aspects of the LNG industrial chain, such as pipeline transportation, tank filling, vehicle fueling etc.. The motor is sealed in the pump chamber and soaked in the LNG fuels under a very low temperature of -161°C. It is obvious that the conventional motors may not meet the operating requirements well in the cryogenic environment. Therefore, cryogenic motors have been investigated in recent years. For example, in [1], it present the design of cryogenic induction motor submerged in LNG for operating LNG spray pump, and the result of designed motor was fabricated and torque performance measured agreed well with design goals. However, the measured efficiency of the motor is only 88.8% at a rated speed of 3920 rpm. In [2] investigated a radial flux super-high speed PMSM, which operates to drive a two-stage cryocooler in the temperature of 77K, the operation efficiency was as high as 90%. However, the experiment was only carried out in water cooling test. In combination with practical application, excessive heat may cause a lot of LNG gasification and affect the operation efficiency of the pump system. Therefore, this paper the theory and design method of C-PMSM for submerged LNG pump are discussed, A prototype a rated power of 18.5kW at a rated speed of 6000 rpm has been fabricated and tested to verify the design methodology. II.theory and design of the C-PMSM In order to detect the magnetic and electric characteristics at cryogenic environment, the Sm2Co17 permanent magnet (PM) was tested after soaking in liquid nitrogen (-196°C) for one hour, the magnetic remanence (B_r) of PM is a little higher than at room temperature, and the resistivity ratio (ρ_{Cu}) of copper at room temperature and cryogneic temperature can be averaged by multiple measurements with three-arm bridge, and the specific value are shown in Fig.1 (a), the decrease of the increase of PM remanence [3] and winding resistance [4] will be changed which directly affect the operation characteristics of the motor, the magnetic properties of silicon steel are not sensitive to temperature changes known from the previous studies, similar to the results introduced in [5]. The cryogenic (CT) method suggests the redesign process that the stator slot area determined by conventional method can be reduced by the same ratio of the decreasing rate for ρ_{Cu} with temperature, also the PM volume can be reduced by the same ratio of the increasing rate for PM B_r with temperature. Fig. 1 (b) shows the shape and dimensions of stator and PMs for the CT design. The proposed submerged C-PMSM is soaked in -161°C, so the stress field should also be taken in consideration to ensure that there is no locking, crack or abnormal gap in the motor components caused by different degree of shrinkage or expansion. A coupled simulation model of electromagnetic-fluid-thermal-stress field will be analyzed in detail in the full paper. III.Experimental Study In consideration of the cost and safety, liquid nitrogen is used as the experimental medium instead of LNG, the prototype is enclosed in the pump and submerged in liquid nitrogen (-196°C), as shown in Fig. 2 (a). When C-PMSM is no loaded, the pump bypass channel opened, at this time both the readings of export pressure gauge and flow meter are zero; When it is loaded, the controller is adjusted to provide a frequency of 400Hz, when the outlet pressure gauge reading reaches 2MPa, the flow meter reading is greater than 20m^3/h, and temperature gauge in stable condition, it is determined that the load at this time is rated. The comparison between the simulation results and experimental data is shown in Fig. 2 (b), because of the physical difference between the two liquids, current tested is about 1.6 times. IV.Conclusion In this paper, an 18.5kW C-PMSM for submerged LNG pumps is designed with consideration of the low temperature influence on material properties. In cryogenic environment, the the magnetic, electric characteristics and key dimensions of stator and PM would differ greatly from the operating conditions at room temperature, Therefore, CT design method is proposed to redesign the slot area and PM volume as well as the whole motor volume by conventional design. Designed C-PMSM for cryogenic environment was fabricated, and measured results agreed well with design goals.

AG-07. Study on Optimal Current Allocation Strategy for Doubly Salient Electromagnetic Machine based on Particle Swarm Optimization.

A. Wang[1], Z. Chen[1], H. Li[1] and C. Zhang[1]
1. Department of Electrical Engineering, Nanjing University of Aeronautics and Astronautics, Nanjing, China

I. Introduction The magnetic field of doubly salient electromagnetic machine (DSEM) can be controlled by the field current, and it can be used in flux-weakening control of motor and voltage control of generator [1]. However, due to the existence of field windings, the efficiency of DSEM is lower. And the efficiency optimization control is needed. The research focuses on two aspects: based on loss model and on-line searching technology [2-3]. Based on asymmetric current control, this paper builds the loss model of a four-phase DSEM, defines the torque constraint and improves efficiency by particle swarm optimization (PSO). In the end, validity is confirmed by simulation and experiment. II. Asymmetric Current Control The output torque (eq.1) of DSEM can be expressed as the sum of reluctance torque T_r and mutual torque T_m. In eq.1, i_p is the armature current, i_f is the field current, L_{pp} is the self-inductance of phase winding, L_{pf} is the mutual inductance between phase and field winding. Because the field current does not change, it is necessary to inject the positive current into the armature winding when the inductance is rising and the negative current in the opposite situation to make mutual torque positive. In the method of asymmetric current control, the positive and negative current are controlled by the H-bridge topology respectively, so that the effective control can be realized. III. Optimal Current Allocation Strategy Eq.1 shows that the output torque of DSEM is mainly linked to the field current, the armature current and the rate of change of mutual inductance with respect to angle. The rate is determined in the motor design, therefore the essence of controlling torque is the control of the field current and the armature current. The optimal current allocation strategy proposed in this paper is to reasonably allocate the above currents when the inductance of armature windings is ignored, i.e., armature current is constant within the conduction interval. The idea is to find the minimum value of the copper loss function *f(ij)* under the condition of nonlinear torque constraint *g(ij,T)*. In eq.2&3, the relationship expression $T_{input}(W'_f)$ between the torque and the magnetic co-energy can be obtained by using Matlab. The torque and magnetic co-energy of different current combinations are fitted to get it. Magnetic co-energy (W'_f shown in eq.4) is positively correlated with the output torque. To solve it, the relationship between the flux and the current is needed. Two boundary magnetization curves are selected and fitted by first-order and piecewise fitting [4]. Considering the conservation of the field and armature ampere turns, W'_f is gotten by integral. The problem is a single-objective optimization problem with constraints. PSO shown in Fig.2 uses penalty function to satisfy constraints and competition to solve the border issue. Population size is 40 and learning factors are 2 [5]. Linearly decreasing inertia weight is used in inertia factor [6]. III. Verification The optimized and non-optimized current combinations (i_f, i_p, i_n) of ideal torque 0-40Nm are chosen to compare the efficiency. The rated power is 1kW and rated speed is 240 rpm. According to P=TΩ, the torque under the rated condition is about 40Nm. Due to it, the maximal torque in the simulation is 40 Nm and the step size is 5. The losses in the model include copper loss (p_{cu}), core loss (p_{fe}) and mechanical loss (p_m). The input power (P_{in}) is the sum of losses and electromagnetic power (P_e). Efficiency (η) is the ratio of P_e to P_{in}. Computational formulas are shown in eq.5. Core loss is gotten by the finite element analysis. The result is shown in Fig.3&4. In order to verify the feasibility of the algorithm in practical situation, the H-Bridge topology is built to excite the armature windings and standard angle control (Fig.5) is used. Due to the phase inductors, the phase current has a certain rise and fall time, and the current in the conductive interval is fluctuating, the phase current cannot keep the maximum. As shown in Fig.6&7, the torque is lower than ideal one. To mend the error, correction factor will be introduced into $T_{input}(W'_f)$ in the strategy. Related test platform is being built. IV. Conclusion Based on PSO and asymmetric current control, the optimal current allocation strategy can suppress copper loss significantly and improve efficiency. Some key issues remained to be solved: finding other control modes to improve the output torque and reducing core loss. AG-08. A Novel Coupled Auto-transformer and Magnetic Control Soft Starter for Super Large Capacity High Voltage Motor.

J. Yuan[1], *C. Wang*[1], Y. Zhu[1], H. Zhou[1], L. Wei[1,2], C. Tian[1], Y. Gao[3], K. Muramatsu[3] and B. Chen[1]
1. Electrical and Engineering, Wuhan University, Wuhan, China; 2. Department of Electrical Engineering, Graduate School of Engineering, Kyoto University, Kyoto, Japan; 3. Department of Electrical and Electronic Engineering, Saga University, Saga, Japan

I. Introduction The start current can reach up to as high as 4-7 times of the motor's rated current when high voltage motors start directly. For super large capacity motors (voltage above 6 kV, power above 10000 kW), the direct start current could reach 5000 Ampere or more[1]. Such large start current will not only have a huge impact on the motor itself but also cause a sudden decline of the grid voltage[2]-[3]. In order to resolve this issue, a novel coupled auto-transformer and magnetic control (CATMC) soft starter method was proposed in this paper. The new structure of CATMC soft starter combines the two functions of the auto-transformer and the magnetic control reactor (MCR) through ingenious electric and magnetic circuit design. Hence the start current is reduced in two ways and the structure becomes more compact and flexible. II. Basic Principle Fig.1 (a) shows the configuration of the CATMC soft starter studied in this digest. The device consists of eight windings. The two DC excitation windings and two AC windings are included in the upper and lower sections respectively. The two AC windings are connected in parallel and then connected in series. AC power supply is connected between AX and aX link to AC load. The two DC excitation windings are inversely connected in series, and then connected to the DC excitation source. The upper and lower DC magnetic fluxes regulate the excitation reactance of the high and low voltage side windings respectively. Utilizing the saturation characteristic of the iron core magnetic material, DC excitation is injected into the excitation winding to change its magnetic saturation, thereby changing the equivalent permeability and changing the reactance value and the reactance capacity smoothly. Fig.1 (b) shows the magnetic circuit for iron core of single phase CATMC soft starter. The magnetic circuit decomposition approach proposed in literature[4] is used to analyze the magnetic circuit model and obtain the winding voltage equations: U_1-U_2=$i_{11}R_{11}$+$N_1(d\Phi_5/dt+d\Phi_{11}/dt)$ (1) U_1-U_2=$i_{21}R_{21}+N_1(d\Phi_7/dt+d\Phi_{21}/dt)$ (2) $U_{d1}=i_{10}R_{12}+i_{10}R_{22}+N_{10}(d\Phi_5/dt+d\Phi_{12}/dt)-N_{10}(d\Phi_7/_{\mathrm{dt}}+d\Phi_{22}/dt)$ (3) $U_2=i_{12}R_{13}+N_2(d\Phi_6/dt+d\Phi_{13}/dt)$ (4) $U_2=i_{22}R_{23}+N_2(d\Phi_8/dt+d\Phi_{23}/dt)$ (5) $U_{d2}=i_{20}R_{14}+i_{20}R_{24}+N_{20}(d\Phi_6/dt+d\Phi_{14}/dt)-N_{20}(d\Phi_8/dt+d\Phi_{24}/dt)$ (6) By applying the Kirchhoff's first law of magnetic path, the node equations are shown as follows: $\Phi_1=\Phi_4+\Phi_6$ (7) $\Phi_8=\Phi_4+\Phi_2$ (8) $\Phi_5=\Phi_0+\Phi_6$ (9) $\Phi_8=\Phi_0+\Phi_7$ (10) $\Phi_5=\Phi_1+\Phi_3$ (11) $\Phi_2=\Phi_3+\Phi_7$ (12) By applying the Kirchhoff's second law of magnetic path, the loop equations are shown as follows: $H_1l_1+H_5l_5+H_6l_6=N_1i_{11}+N_{10}i_{10}+N_2i_{12}+N_{20}i_{20}$ (13) $H_2l_2+H_7l_7+H_8l_8=N_1i_{21}-N_{10}i_{10}+N_2i_{22}-N_{20}i_{20}$ (14) $H_0l_0+H_3l_3+H_5l_5-H_7l_7=N_1i_{11}-N_1i_{21}+2N_{10}i_{10}$ (15) $H_0l_0+H_4l_4-H_6l_6+H_8l_8=-N_2i_{12}+N_2i_{22}-2N_{20}i_{20}$ (16) $H_0l_0=H_3l_3+H_4l_4$ (17) In addition, each magnetic circuit also satisfies the corresponding magnetization curve: $\Phi_k=f_k(H_k)$, k=0,1,…8. Assume that: $i_{11}=i'_{11}+i''_{11}$ (18) $i_{12}=i'_{12}+i''_{12}$ (19) $i_{21}=i'_{21}+i''_{21}$ (20) $i_{22}=i'_{22}+i''_{22}$ (21) And it satisfies the following constraints: $H_5l_5=N_1i'_{11}+N_{10}i_{10}$ (22) $H_6l_6=N_2i'_{12}+N_{20}i_{20}$ (23) $H_7l_7=N_1i'_{21}-N_{10}i_{10}$ (24) $H_8l_8=N_2i'_{22}-N_{20}i_{20}$ (25) The magnetic potential drop expressions for the remaining magnetic paths are obtained: $H_0l_0=1/3(N_1i''_{11}-N_2i''_{12}-N_1i''_{21}+N_2i''_{22})$ (26) $H_1l_1=N_1i''_{11}+N_2i''_{12}$ (27) $H_2l_2=N_1i'_{21}+N_2i''_{22}$ (28) $H_3l_3=2/3N_1i''_{11}+1/3N_2i''_{12}-2/3N_1i''_{21}-1/3N_2i''_{22}$(29) $H_4l_4=-1/3N_1i''_{11}-2/3N_2i''_{12}+1/3N_1i''_{21}+2/3N_2i''_{22}$ (30) According to the winding voltage equations (1)~(6) and the magnetic potential drop expressions (22)~(30), the nine-segment magnetic path model of CATMC soft starter is constructed as shown in Fig.1 (c). In Fig.1 (c), the magnetic circuit is represented by the double winding saturation transformer model. T0~T8 respectively represent the middle transverse iron core, the left paraxial column and the left upper and lower yoke, the right paraxial column and the right upper and lower yoke, the middle upper yoke, the middle lower yoke, the left upper center column, the lower left center column, the right upper center column and the right lower center column magnetic circuits. III. Simulation and Experimental Results To validate the effectiveness of CATMC soft starter, 18MW/10kV model is established in ANSOFT. Fig.2 (a) shows the flux density distribution of CATMC soft starter and motor. Simulation results of stator current for direct start and CATMC soft start are shown in Fig.2 (b). It can be seen that, the start current can be reduced to about 2570 A (2.5 times of the rated current) from 4680 A (4.5 times of the rated current) when starting directly. The soft starter based on CATMC for super large capacity high voltage motor has been designed successfully. The 18MW/10kV motor is selected as the experimental object, whose rated current is 1039A. The start curve is shown in Fig.2 (c). According to actual measured data, the start current is 2210 A. IV. Conclusion From the simulation and experimental results, we know that the start current can be restricted within 2.5 times of the rated current, which is very favorable to reduce harm to the power grid and the motor. Therefore, the CATMC method exhibits a promising alternative for popularization and real application in motor soft start.Contrast analysis with traditional soft start methods will be carried out soon.More details will be analyzed in full paper.

AG-09. A novel vector control strategy for six-phase induction motor with low torque ripples and harmonic currents.

H. Heidari[1], *A. Taheri*[1] and M. Holakooie[1]
1. University of Zanjan, Zanjan, The Islamic Republic of Iran

Abstract: In this brief, a new vector control strategy is proposed to efficient control of six-phase induction motor (SPIM). In order to reduce torque ripples represented in switching table-based direct torque control (ST-DTC), a new set of inputs is provided for switching table (ST). These inputs are based on the decoupled current components in synchronous reference frame. Indeed, using both field-oriented control (FOC) and direct torque control (DTC) concepts, precise inputs are used for ST to achieve better steady-state torque responses. Considering duty cycle control strategy, the loss subspace components are eliminated through a suitable set of virtual voltage vectors. Each virtual vectors are based on a combination of a large and a medium voltage vectors to make the volt-sec outcome near to zero. The proposed strategy not only notably reduces the torque ripples, but also suppresses low frequency current harmonics. I. Introduction With emergence of power electronic devices and adjustable-speed drives, the usage of multiphase machines has been widely developed in some industrial applications such as electrical trackers, renewable-energy generation, aerospace applications, and electric ship propulsions. The key needs to apply these machines are reliability, fault tolerance capability, higher motive power and current, lower torque pulsation, and lower DC-link voltage requirement [1], [2]. Direct torque control (DTC) strategy is a simple, powerful and effective scheme for adjustable-speed drives of SPIM, providing high performance torque and stator flux control. However, it suffers from some serious drawbacks, especially for multi-phase machines, including high torque ripples and low-frequency current harmonics which can degrade the performance of the drive system [3]. A great deal of efforts have been done to amend high torque ripples of DTC, which mostly include modification of hysteresis controller [4],[5] switching table [6],[7], replacing the hysteresis controller with another regulators, such as proportional-integral (PI) regulator, to provide PWM-based DTC [8], [9]. A global minimum torque ripple using modified switching pattern are proposed in [10]. In [11], torque ripples have been reduced by applying active and zero vectors in each sampling period using a predictive DTC. On the other hand, for reduction of harmonic currents, elimination of z_1-z_2 subspace components, using duty cycle concept in DTC are proposed in [12], [1] and [5] for six-phase induction motor, five-phase induction motor, and six-phase permanent magnet motor, respectively. Simultaneous reduction of torque ripple and low-order harmonic currents is a is still a challenging research task. II. Proposed method for the SPIM drive The block diagram of the proposed scheme is shown in Fig. 1. In order to decrease the torque ripples in the SPIM, a new approach is made by improving the ST's inputs. Using FOC framework [13], since the inputs of ST in classical ST-DTC are the errors between set and actual values of T_e and Ψ_s, it is a good idea to use the errors between the set and actual values of i_{ds} and i_{qs}, instead. In this case the steady-state torque ripple is considerably reduced because of adding an inner control loop to the drive system. According the sign of $\Delta i_{qs\ \mathrm{and}}$ Δi_{ds} and also flux position, propoer voltage vector is selected and applied during each sampling period. The digital output signals of the hysteresis controllers are described as Δi_{qs}=1 if $|i_{qs}|\leq|i_{qs}{}^*|$-|hysteresis band| Δi_{qs}=0 if $|i_{qs}|=|i_{qs}{}^*|$ (1) Δi_{qs}=-1 if $|i_{qs}|>|i_{qs}{}^*|$+|hysteresis band| Analogically, for the changes required for the d-axis of the stator current, Δid_s is described as Δi_{ds}=1 if $|i_{ds}|\leq|i_{ds}{}^*|$-|hysteresis band| Δi_{ds}=0 if $|i_{ds}|>|i_{ds}{}^*|$+|hysteresis band| (2) To reach low THD in the phase current of the SPIM, the proposed vector control scheme is synthesized with duty cycle control strategy. The ST applies two voltage vectors in each sampling period in order to eliminate z_1-z_2 subspace components. In comparison to the conventional DTC, the switching frequency of the proposed scheme is increased. In contrary, both harmonic currents and torque ripples are reduced. Moreover, the proposed scheme has fast dynamic, similar to the conventional DTC, and do not need any PWM modulator, which produces complexity and time delay. III. Experimental setup The performance of the proposed method is validated by the experimental tests. The experimental setup contains the SPIM and its coupled load, the main processor, two three-phase VSIs, current and voltage transducers, shaft encoder and single phase bridge rectifier. The processor used in the driver is eZDSP F2812. The motor speed is measured by an Autonics incremental shaft encoder coupled mechanically to the SPIM with resolution of 2500 P/R. The LEM LTS6np current transducers are implemented to measure all the currents. The dc-link voltage is also measured using LV 25-p voltage transducer. The selected experimental results are shown in Fig. 2. These tests confirm the good tracking capability of the proposed method. The proposed method provides significant reduction of torque ripples, stator flux ripples, and harmonic currents in comparision with the conventional DTC method while maintaining the simplicity and also the fast dynamics of the drive system.

AG-10. A Novel Dual-Sided PM Variable Flux Memory Machine.

H. Yang[1], H. Lin[1], Z. Zhu[2], S. Lyu[1] and K. Wang[1]
1. School of Electrical Engineering, Southeast University, Nanjing, China; 2. Department of Electronic and Electrical Engineering, The University of Sheffield, Sheffield, United Kingdom

I. INTRODUCTION Memory machine (MM) was regarded as a promising candidate for wide-speed-range applications [1]-[6]. Since the low coercive force (LCF) PM is employed in MM, the air-gap flux can be flexibly adjusted by changing the magnetization state (MS) of PM with a temporary current pulses. The speed range can be subsequently extended with high efficiency maintained. According to the magnetizing current pattern, MMs can be generally categorized into AC- [1]-[3] and DC-magnetized [4]-[6] types. The former MM normally employs vector-control algorithm to apply *d*-axis current pulse in stator windings to vary the magnetization level of LCF PMs, while the latter one adopts auxiliary DC magnetizing coils to facilitate the magnetization control. Besides, the rotor-PM topologies of MMs have structures similar to conventional interior PM machines, which shows comparable torque density with those conventional surface-mounted PM machines [3]. Nonetheless, LCF magnets on the rotor generally suffer from to armature reaction demagnetization effect, and the integration of armature and magnetizing functions in the stator winding results in complicated online FW control. On the other hand, the stator-PM MMs have the advantages of easy online magnetization control, and a simple and robust salient rotor as well as easy thermal management can be obtained. Nevertheless, the fact that two kinds of PMs, i.e., NdFeB and LCF PMs, as well as two sets of windings are located on stator leads to excessively crowded stator space and low torque density. Therefore, this paper attempts to propose a novel dual-sided PM memory machine (DSPM-MM) by combing the distinct advantages of "high torque density" of rotor-PM MM and "simple online PM flux control" of stator-PM MM. In the proposed design, the consequent-pole NdFeB PMs are placed in the rotor, while LCF PMs are mounted between the adjacent stator teeth to enable flexible air-gap flux adjustment. The machine topology and operating principle are introduced and addressed, respectively. Then, the electromagnetic performance is analyzed, which confirms the feasibility of the proposed design. II. MACHINE TOPOLOGY AND OPERATING PRINCIPLE Fig. 1 (a) shows the topology of the proposed DSPM-MM with 6-stator-slot/7-rotor-pole configuration, which is characterized by a combination of two single-sided machines having two kinds of magnets on rotating and stationary sides, respectively. For the rotor, the alternate arrangement of homopolar NdFeB PMs and iron poles forms a consequent-pole configuration. For the stator, the LCF PMs are alternately buried in air space between adjacent stator tooth poles, and the DC magnetizing coils are wound on the LCF magnets. The NdFeB PMs serve as a dominant contributor for air-gap flux, while the LCF PMs work as a flux adjustor by applying the current pulse in the magnetizing coils. The flux regulation principles for the flux-enhanced and flux-weakened operations are illustrated in Figs. 1(b) and (c), respectively. The air-gap flux can be flexibly varied as the LCF PMs are either remagnetized or demagnetized in same or opposite direction with the NdFeB PMs, i.e., the flux-enhanced and flux-weakened states. For low-speed region, NdFeB and LCF PMs are with identical magnetization direction, the torque density can be subsequently improved. On the other hand, for high-speed region, the LCF PMs are reversely demagnetized to short-circuit and weaken the NdFeB PM fields, and hence the constant-power operating range (CPSR) can be effectively extended within the limitation of inverter power rating. The major advantages of the developed machine, which combines the distinct synergies of the conventional rare-earth magnet machine and stator-PM MM, which can be summarized as follows: 1) The merits of high torque density in conventional rotor-PM machine and easy magnetization control in stator-PM MM can be well synthesized; 2) The wide speed range and high efficiency at CPSR can be realized due to excellent flux adjusting capability and negligible excitation copper loss in the proposed DSPM-MM. 3) The ferromagnetic stator and rotor iron poles provide an effective circulating path for the armature fields as well as the magnetizing fields. That is to say, the parallel PMs and armature reaction fields can prevent the LCF PMs from accidental armature demagnetization. III. ELECTROMAGNETIC PERFORMANCE Fig. 2 (a) shows the open-circuit field distributions of the proposed machine under different MSs of LCF PMs. It can be observed that the machine shows fairly good flux adjusting capability. The corresponding radial air-gap flux density and phase back-EMF waveforms at 1500 r/min are shown in Figs. 2(b) and (c), respectively. The fact that the machine exhibits basically sinusoidal EMFs regardless of MS indicates that the proposed machine is suitable for brushless AC operation. Furthermore, the efficiency maps subject to different MSs are plotted in Fig. 2(d). The results confirm that the proposed machine can achieve high efficiency within a wide range of speeds and loads by choosing appropriate MSs under different operating regions. The detailed design considerations and experimental results will be given in the full paper.

AG-11. Analysis of Torque Characteristics of A Parallel Hybrid Excitation Machine Drives with Sinusoidal and Rectangular Current Excitations.

Y. Wu[1], L. Sun[1], Z. Zhang[1], Z. Miao[1] and C. Liu[1]
1. Nanjing University of Aeronautics and Astronautics, Nanjing, China

I. Introduction A new paralleled hybrid excitation machine (PHEM), consisting of axial paralleled permanent magnet machine (PMM) part and doubly salient excitation machine (DSEM) part, has the advantages of simple structure and independent flux path [1]. The synthetic phase inductance and back electromotive force (EMF) performances of the PHEM are different from the separated PMM and DSEM. Therefore, the optimized control schemes for the PMM and DSEM are not suitable for the PHEM [2]. In this paper, the torque characteristics of the PHEM drives with sinusoidal and rectangular current excitations are comparatively analyzed. II. Configuration and Control Scheme The 3D model of the PHEM is presented in Fig.1. It consists of two separated parts and a flux barrier gap sandwiched between them. The left part is 12/8-pole DSEM, while the right part is 24-slot/16-pole spoke-type PMM. The two rotors are installed in the same shaft and the two stators share one set of armature winding. The field source consists of non-overlapping concentrated windings allocated on the stator of DSEM and permanent magnets (PMs) mounted interior in the rotor of PMM. The independent flux paths of two parts present the merit of stable operation point of PMs with an attractive flux regulation capability. The driving strategies are commonly classified as either brushless AC (BLAC) drives, or brushless DC (BLDC) drives based on the waveforms of back-EMF. Fig.2 shows the back-EMF waveforms at open circuit and corresponding ideal current waveform. The back-EMF of PHEM is the sum of PMM and DSEM, which can be regulated by the field current. In BLAC drives (Fig.2 (a)), the phase current waveforms are sinusoidal, whereas in BLDC drives (Fig.2 (b)) the phase current waveforms are rectangular. Back EMFs of PHEM (I_f =5A n=1600rpm) and PMM are neither sinusoidal nor trapezoidal. Both sinusoidal and rectangular current excitations can be adopted in PHEM. III. Comparative Study of BLAC and BLDC Drives The sinusoidal and rectangular current excitations are used in two driving strategies and the current rms values are equal. Fig.3 shows the relationship between the torque and armature current when the field current is 5A. The BLAC drives exhibit greater torque density at the same armature current. Fig.4 shows the torque versus current angle with different armature current. In BLAC drives, when the armature current is relatively small, the current angle at the maximum torque per amp (MTPA) point is small. The dashed line shows the MPTA trajectory. An increase in the armature current causes an increase of the reluctance torque and thus the current angle becomes larger. In BLDC drives, the torque characteristics are similar to BLAC drives, except for the smaller current angles on the MPTA trajectory. When the armature current is larger than 100A, the current angles on the MPTA trajectory in BLDC drives are smaller. Fig.5 shows the torque ripple versus current angle for different armature current. In BLAC drives (Fig.5 (a)), the torque ripple decreases first and then increases with an increase in the armature current at a constant current angle. Due to the flux path saturation and the severe q-axis armature reaction, overload condition will cause a large torque ripple. In BLDC drives, the overall torque ripple are larger than the BLAC drives. The torque ripple becomes larger as the armature current increases. This is because the higher armature current is, the higher commutation torque ripple will be. IV. Experimental Verification A prototype PHEM has been designed and developed as shown in Fig.6. The line voltage of PHEM versus field current at open-circuit is shown in Fig.7. The excellent flux regulation capability can be realized. In detail, Fig.8 shows the back EMF of PMM and PHEM at 1600rpm under open-circuit condition. Fig.9 and Fig.10 show the torque versus armature current under the sinusoidal current excitations and rectangular current excitation, respectively. Fig.11 shows the torque versus current angle. It can be seen that the simulations agree well with the experiments. V. Conclusion In this paper, the torque characteristics of PHEM are comparatively analyzed in different current excitations. It shows that in BLAC drives, the PHEM exhibits a larger torque density with a lower torque ripple. A prototype PHEM has been designed and developed. Experiments shows the PHEM has an excellent flux regulation capability.

AG-12. Improved Analytical Eddy Current Loss Modelling Considering Carrier Harmonics towards Maximum Efficiency Control of PMSM- Drive Systems.

A. Balamurali[1], C. Lai[1], H. Dhulipati[1], V. Loukanov[2] and N. C. Kar[1]
1. University of Windsor, Windsor, ON, Canada; 2. D&V Electronics Ltd., Woodbridge, ON, Canada

I. Introduction Efficiency improvement of permanent magnet synchronous motor (PMSM) drive systems through control techniques has been of vital interest in the literature [1]-[4], [6]. The understanding of loss sources, accurate calculation of various losses and motor parameters are important during motor drive control development towards increased efficiency [1] - [3]. The pulse-width modulated (PWM) inverter generates time harmonics that leads to increased stator harmonic core losses and magnet eddy current losses, especially at higher speeds [2], [5]. In conventional loss minimization procedures for PMSM, core loss computations generally ignore the harmonic components and consider no-load conditions and fundamental air-gap flux density (B_g) [3]. In some of the methods, harmonic loss models were considered but in a simplified manner [4]. In order to fully exert the advantages of maximum efficiency control techniques to improve PMSM drive system efficiency, accurate loss models that include controllable fundamental and harmonic losses and non-linearities in the motor parameters should be considered. In [1], investigations were performed towards system level loss reduction using hybrid model of motor- drive system. It was seen that current angle, γ can be used as a control variable to reduce total motor and motor-drive system losses. In order to achieve improved efficiency, this paper proposes novel loss models to accurately calculate the total losses to be used towards the calculation of optimal γ. The effect of carrier order time harmonics in copper and core losses are considered in addition to improving core loss calculation by including armature reaction effects due to loading. II. Fundamental and Harmonic Loss Models in PMSM In this paper, improved loss models for PMSM have been developed considering fundamental and harmonic copper and core losses to be used towards efficiency improvement control. The results of the loss models can be used for offline loss minimization approach using look-up table (LUT) or can be solved online using terminal measurements. The source of harmonic losses is the voltage harmonics from inverter. The voltage harmonic spectrum from a sine- PWM modulated (SPWM) inverter is used to derive the current harmonics for the 4.25 kW test interior PMSM (IPM). The derived current harmonics are used to calculate harmonic copper losses. A magnetic circuit model (MCM) given in Fig 1(a) has been used to derive the flux density considering current harmonics using magnetomotive force in the airgap [5]. This paper extends the work in [5] by developing a novel, accurate loss model for core losses incorporating PWM time harmonics. The stator teeth and yoke flux densities are derived from the resultant on-load air-gap flux density. The flux density is calculated using a Fourier decomposition of the time series waveform derived from the MCM which includes fundamental and harmonic components. This method improves existing core loss calculation methods by predicting the flux densities during loaded condition. The space harmonics have been neglected intentionally in the MCM as the source of harmonic core loss is considered to be eddy currents from PWM carrier harmonics [2]. The comparison of air-gap flux density calculated using the developed model with that from finite element analysis (FEA) follow closely as shown in Fig 1 (b). The total losses in the motor is calculated as the summation of fundamental copper and core losses and harmonic copper and core losses and used further in the search for optimal efficiency. Sample results for total motor losses and core loss variation with γ are given in Figs. 1 (c) and 1 (d) for 575 rpm. The relationship between core loss and γ can be used to obtain an optimal point different from conventional maximum torque per ampere (MTPA) technique that consider only copper losses, leading to improved efficiency [6]. III. Validation of Loss Models and Implementation in Maximum Efficiency Control The loss values from the developed method have been compared with 2-D FEA co-simulation model as well as experimental loss segregation results for same operating conditions. Fig 2 (a) shows the harmonic loss comparison with FEA and Fig 2 (b) shows total electrical loss comparison with experimental results. The experimental loss values were measured using a power analyzer to measure the three- phase input power to motor and a torque sensor at the shaft between test IPM and dynamometer for output power. The results have been applied towards the loss minimization search for optimal current vector in *dq*-axis for varying operating conditions. The derived optimal values have been used to create a LUT for varying loads and speeds. The control diagram for current control implementation is given in Fig 2 (c). The results of the maximum efficiency control utilizing the developed model and conventional loss model considering no-load core losses and neglecting harmonic losses are compared in Fig 2 (d). IV. Conclusions It is concluded that the consideration of harmonic losses changes the optimal point for maximum efficiency and the efficiency can be improved, especially at higher speeds. The full paper will include detailed derivations of the analytical loss model, application of maximum efficiency control and further experimental validations conducted on the test IPM.

AH-01. Integrated NEMS Magnetoelectric Sensors and Antennas.

N. Sun[1]
1. ECE, Northeastern University, Boston, MA, United States

The coexistence of electric polarization and magnetization in multiferroic materials provides great opportunities for realizing magnetoelectric coupling, including electric field control of magnetism, or vice versa, through a strain mediated magnetoelectric coupling in layered magnetic/ferroelectric multiferroic heterostructures [1-9]. Strong magnetoelectric coupling has been the enabling factor for different multiferroic devices, which however has been elusive, particularly at RF/microwave frequencies. In this presentation, I will cover the most recent progress on new integrated magnetoelectric materials, magnetoelectric NEMS (nanoelectromechanical system) based sensors and antennas. Specifically, we will introduce magnetoelectric multiferroic materials, and their applications in different devices, including: (1) novel ultra-compact RF NEMS acoustic magnetoelectric antennas immune from ground plane effect with $< l_0/100$ in size, self-biased operation and potentially 1~2% voltage tunable operation frequency; and (2) ultra-sensitive RF NEMS magnetoelectric magnetometers with ultra-low noise of $\sim 1 pT/Hz^{1/2}$ at 10 Hz for DC and AC magnetic fields sensing. These novel magnetoelectric devices show great promise for applications in compact, lightweight and power efficient sensors and sensing systems, ultra-compact antennas and for radars, communication systems, biomedical devices, IoT, etc.

AH-02. Giant photo-Hall effect in metals.

A. Ruotolo[1,2] and D. Li[1,2]
1. City University of Hong Kong, Kowloon, Hong Kong; 2. City University Shenzhen Research Institute, Shenzhen, China

The Hall-effect in semiconductors has been used for more than one century to measure the intensity of magnetic fields. While Hall sensors have been replaced by magnetoresistive sensors in digital systems, they still retain two features which make them preferable to the latter in analog applications: they are intrinsically linear because they do not make use of magnetic materials and their sensitivity is directly proportional to the bias current J through the charge velocity v. Yet, the latter of these features is more theoretical than practical. Commercial Hall sensors are engineered to work at a specific, and very low, bias current because Joule heating severely compromises their linearity. The Hall effect exists in metals, where the low resistance to electrical current would make Joule heating be negligible. Yet, so would be the transverse voltage. We engineered a system in which the Hall effect in a metal is greatly enhanced and Joule heating suppressed [1]. The device recovers tunable sensitivity, without compromising linearity, by replacing current bias with light bias. Our system consists of an extended metal/semiconductor junction, where the metal is highly transparent to light and forms a Schottky interface with the semiconductor (see figure 1). Light reaching the interface is the driving force to diffuse carriers across the bilayer. A magnetic field applied in the junction plane exerts a magnetic force on the carriers diffusing in the metal, which accumulate on opposite sides, according to their sign. This charge accumulation can be detected as an open-circuit voltage transverse to the metal. The voltage is proportional to the field strength, as well as to light intensity. At equilibrium, the net current is zero and no Joule heating is produces, regardless light intensity. In order to demonstrate this effect, we deposited three metallic films, platinum (Pt), gold (Au) and aluminum (Al) with thickness t = 3 nm on 1 × 1 cm^2 un-doped (100) silicon (Si) dice. These metals were chosen because they have progressively lower work-functions (Φ_{Pt} = 5.9 eV, Φ_{Au} = 5.5 eV and Φ_{al} = 4.20 eV)[6]. A Si dye and a sample consisting of Pt with the same thickness deposited on insulating sapphire, α-Al_2O_3 were used as references. The magnetic field was generated by using an electromagnet. The voltage was measured by connecting the midpoints of two opposite edges of the metallic film to a voltmeter. a controlled light source consisting of a bulb lamp and a manual shutter were employed. The bulb lamp emitted unpolarized light with a spectrum that covers all and only the visible range from 450 nm (violet) to 750 nm (red). One can see from Figure 1 that no voltage appears when a Si dye is used, which excludes that the effect is due to photo-Hall effect in the semiconductor [2]. Similarly, no signal was detected on a Pt/sapphire chip, which excludes that the voltage is due to excitation of electrons in the Pt. One can also see that the effect diminishes with decreasing work-function, which suggests that the establishment of a Schottky barrier is a necessary condition for the effect to exist and that light is absorbed in the space-charge layer of the junction. The experiment was repeated by using optical polarizers. The voltage signal was found to be insensitive to light polarization, which excludes any contribution from optical-Hall effect or photo voltaic-Hall effect [3]. For Pt and Au, the effect was found to be strongly linear with both magnetic field strength and light intensity. Similarly the voltage increased linearly with light intensity for fixed values of magnetic field. The current-voltage (I_S /V_S) characteristics across the metal/Si interfaces were measured by placing the electric contact on the Si as close as possible to the edge of the metal. As expected, the I_S / V_S was found to be Schottky-like, strongly dependent on the light and independent on the magnetic field. The experimental evidences lead us to draw the following scenario. Metals with high work-functions form a Schottky contact with the semiconductor. A space-charge region arises in the semiconductor, near the interface. If the light penetration depth through the metal is longer than the film thickness, photons can be absorbed and charge can overcome the Schottky barrier, hence be injected into the metal. More specifically, once an electron-hole is photo-generated in the Si, the hole crosses the space-charge region to recombine with an electron in the metal and an electron crosses the space charge region to replace the recombined electron. In the Hall configuration of figure 1, no net current flows and the effect is strictly confined near the interface. Yet, electrons and holes *diffusing* across the space charge region are accelerated by the high built-in electric field and acquire a substantial velocity. The force $F = qv \times B$ exerted by the magnetic field is large because so is v. This is what makes the effect *giant*. The magnetic field bends the trajectory of the charge and an imbalance of charge appears at the edges of the metal. The voltage is detected in open-circuit conditions and no bias current across the junction. Therefore, no Joule heating is produced. The system shown here can reach the same sensitivity of a standard Hall-sensor but has a linearity-error that is independent on sensitivity because no Joule heating is produced.

Magneto-optical magnetic field sensors are devices that use magneto-optical effects, in particular the Faraday effect, to record magnetic fields by magneto-optical reading of the magnetization state of a sensitive medium under the influence of an external field. In some cases optical fiber is used as a sensitive element [1]; in others, a magneto-optical material [2], including iron garnet [3-4], is used as a sensitive element. The simplest way to increase the sensitivity of the magneto-optical method with respect to the magnetic field is a multi-pass method, i.e.stretching the optical path of light within the magnetic medium, which should lead to an accumulation of the Faraday effect. However, due to high losses on long optical trajectories, this approach does not allow achieving threshold sensitivity of more than 10 $\mu T/Hz^{1/2}$. In [4], the sensitivity level of 100 pT is demonstrated by using a waveguide iron garnet microstructure with homogeneous magnetization and oscillating (along the direction of light propagation) pump field. Nevertheless, the size of the sensitive element in the experiment is a few millimeters, that leads to a low spatial resolution. The present work is devoted to the development of a magneto-optical magnetic field sensor using the advantages of magnetomodulation method with high-quality monocrystalline low magnetic dissipative iron garnet films [5] and the advantages of the method of resonant amplification of magneto-optical effects with the help of a magnetoplasmonic crystal [6]. The sensor consists of a ferrimagnetic dielectric film with a diffractive metal grating deposited on its surface, in which plasmon eigenmodes are excited, leading to a tenfold enhancement of the magneto-optical effects. For optical detection of the magnetization state of a sensitive element is proposed to use the newly discovered longitudinal magnetophotonic intensity effect (LMPIE), which consists in changing the intensity of light reflected or transmitted through a magnetic film with a plasmon grid, when the film magnetization is reversed in the direction lying in the plane of the film perpendicular to the lattice slits. This effect is sensitive to the planar component of the magnetization, and, unlike other intensity magneto-optical effects, is maximal at normal incidence, which makes one possible to realize a magneto-optical reading circuit with magnetization reversal of the sample by uniform rotation of the magnetization and to read the signal by an ordinary photodetector. In this case, the LMPIE arises at the frequency of the second harmonic, with respect to the frequency of the external rotating plume, and the signal corresponding to the measured feild arises at the frequency of the third harmonic. In a series of experiments with test magnetic fields, the sensitivity for gratings with different periods and films with different thicknesses and compositions has a maximum sensitivity of 4 nT in a band from 1 to 60 kHz.

AH-04. Phase Transitions in Spin-Crossover Thin Films Probed by Graphene Transport Measurements.

J. Dugay[1], M. Aarts[2], M. Giménez-Marqués[1], T. Kozlova[2], h. Zandbergen[2], E. Coronado[1] and H. van der zant[2]
1. Molecular Materials, Institute of Molecular Science (ICMol), Paterna, Spain; 2. Department of Quantum Nanoscience, Delft University of Technology, Delft, Netherlands

Future multifunctional hybrid devices might combine switchable molecules and 2D material-based devices. Spin-crossover compounds are of particular interest in this context since they exhibit bistability and memory effects at room temperature while responding to numerous external stimuli. Atomically thin 2D materials such as graphene attract a lot of attention for their fascinating electrical, optical, and mechanical properties, but also for their reliability for room-temperature operations. In this work [1], we demonstrate a new concept to detect, in a noninvasive way, the spin-state switching of a thin film containing nanoparticles made of the SCO compound $[Fe(Htrz_2)(trz)](BF_4)$ and for a chemical alloy $[Fe(Htrz)_{2.95}(NH_2trz)_{0.05}](ClO_4)_2$ nanoparticle system. The method consists of measuring the electric properties of graphene in a four-probe field-effect configuration, while covered with a monolayer of switchable nanoparticles. The coupling between the spin-state dependent physical properties and the scattering in the graphene layer is ascribed to a changing contribution of remote interfacial phonon scattering. Using model calculations, we showed that the charge carrier-nanoparticle coupling changes due to the spin-state dependence of the dielectric constant. As the contact printing method yields a homogeneous coverage of a thin film with single nanoparticle thickness, this graphene field-effect sensor device is already able to probe small volumes of ca. 2000 μm^3 in the experimental setup presented here, while exhibiting a clear spin-change dependence in the graphene resistance. In the near future, this method should pave the way for the investigation of even smaller amounts of spin crossover materials using optimized graphene nanosensor platforms.

Magnetic field sensors are extensively used in today's information technology, automotive control, and industrial process management because of their ability to provide accurate data without physical contact. A variety of sensor types exists, however, magnetoresistance sensors have the benefit of being small, low-cost, and easy to produce. By using oblique-incidence deposition (OID) [1], we overcome one of the major challenges in these sensors: the control of the easy axis and the coercive field of one or both magnetic layers. In practice, often one of the two magnetic layers is pinned, meaning magnetically fixed via coupling to an antiferromagnet [2] while the other magnetic layer is free and can follow an external magnetic field. Alternatively, the relative orientation of the two magnetic layers' easy axes can be defined to be antiparallel by choosing specific spacer thicknesses to maximize the Ruderman-Kittel-Kasuya-Yoshida (RKKY) interaction [3]. Both of these techniques to engineer a magnetoresistive sensor are widely used, however, they lack flexibility and only allow for a few selected sensor characteristics. By oblique-incidence deposition of magnetic layers, an additional and tunable shape anisotropy is induced that enables full control over the coercivity and preferred magnetic orientation of each individual layer without the limitations of interlayer exchange or exchange-biased pinning. With this technique, the coercive field of a magnetic material is no longer a material constant but a function of the incidence angle during deposition. The coercive field of iron, for example, can then be tuned from 0.5 mT to almost 40 mT by increasing the polar deposition angle from 0° to over 80°. Although interlayer coupling between the magnetic films is still available, it is no longer necessary, making it possible to orient adjacent layers' easy axes in arbitrary angles instead of only antiparallel. In a magnetoresistive sensor system, tunable switching fields and arbitrarily crossed easy axes now allow for a versatile and individual tailoring of the single layers' properties to adapt the functionality to the needs of an application [4]. In the angular GMR measurements shown in Fig. 1, the magnetic field is rotated at constant field strength. In all four cases, the layer sequence is Co/Cu/Co with identical thicknesses, only the deposition angles are varied. The resulting functionalities change from sinusoidal to various peaked periodicities. Figure 2A demonstrates how different polar deposition angles lead to a step-like GMR characteristic in a field sweep. The magnetic field strength, at which the sensor has a plateau in the GMR curve is adjustable, which makes this system valuable for a variety of applications. In Fig. 2B the azimuthal deposition angle is altered, which leads to canted easy axes. This enables new functionalities, e.g., the linear GMR signal can be used to detect the absolute field strength within an adjustable working range (0-100 mT). Both figures clearly demonstrate the potential of sensor tuning via OID. Presently, we are taking the next steps towards actual industrial application of OID. The sensors have been optimized regarding temperature stability and performance, which remains unaffected by the preparation method. First experiments with TMR systems yield very promising results even with ultra-thin MgO barriers. Furthermore, OID can be combined with industry-compatible fabrication and microstructuring, see Fig. 2C. The additional surface shape anisotropy induced via OID is stronger than the shape anisotropy resulting from the aspect ratio of structured magnetic elements in circuits. Thus, the electrical resistance can be adjusted by sensor stripes of the required geometry without altering their magnetic properties. Oblique-incidence deposition is an alternative or complementary way to tailor the properties of magnetoresistive sensors. It enables a large variety of new functionalities and, thus, solves the main disadvantage of exchange-coupled systems. As the coercivity and orientation of the magnetic materials can be tuned and no interlayer coupling is needed, the technique provides an easy accessible handle to tune each layer's properties. Simply by changing the polar and azimuthal deposition angle, a custom-made sensor can be created to match the needs of an application. In addition, OID can be combined with industry-compatible microstructuring to yield desired base resistances and sensor sizes. It is valuable for all magnetoresistive systems, especially GMR and TMR sensors, and beyond that to create more complex multilayers.

AH-06. Magnetic tunnel junctions with perpendicular synthetic antiferromagnetic CoPt pinned layers for magnetic sensors with wide dynamic range.

T. Ogasawara[1], M. Oogane[1], M. Tsunoda[2] and Y. Ando[1]

1. Department of Applied Physics, Tohoku University, Sendai, Japan; 2. Department of Electronic Engineering, Tohoku University, Sendai, Japan

Introduction Magnetic tunnel junctions (MTJs) based magnetic sensors have been actively investigated for detection of a quite small magnetic field such as a bio-magnetic field. Moreover, it is possible to apply them to magnetic sensors with wide dynamic range, for example, magnetic sensors for current monitoring in electric vehicles require wide dynamic range above 1 kOe. In order to obtain wide dynamic range, large switching field of pinned layers of MTJs is required. One of the most promising materials to increase the switching field is perpendicular synthetic antiferromagnetic (p-SAF) pinned layer. Yakushiji et al., have demonstrated extremely large switching field of ca. 10 kOe in $[Co/Pt]_x/Ru/[Co/Pt]_x$ p-SAF structure [1]. In addition, MTJ-based magnetic sensors with $[Co/Pd]_x/Ru/[Co/Pd]_y$ p -SAF pinned layer showed a wide dynamic range of 2.5 kOe [2]. In this work, we investigated nonlinearity, which is one of the most important properties for current monitoring, for MTJ sensor devices with p-SAF pinned layers. Especially, we focused on the relationship between the nonlinearity and dispersion of magnetic anisotropy in CoFeB free layers. Experimental method Films were deposited on thermally oxidized Si(001) substrates using DC/RF magnetron sputtering ($P_{base} < 1\times10^{-6}$ Pa) at room temperature. Films of the MTJs with structure of Si/SiO_2-sub/Ta(3nm)/ Ru(10)/Pt(2)/$[Co(0.28)/Pt(0.16)]_9$/Co(0.28)/Ru(0.4)/Co(0.28)/$[Pt(0.16)/Co(0.28)]_5$/Co(0.28)/Ta(0.2)/$Co_{40}Fe_{40}B_{20}$(1.0)/MgO(2)/$Co_{20}Fe_{60}B_{20}$(t_{CoFeB} = 1.5 – 2.0)/Ta(5)/Ru(8) were fabricated into circular devices with 100 mm diameters. After the micro-fabrication, MTJ devices were annealed at T_a = 300 - 400°C for 1 hour without applying magnetic field. The magnetoresistance curves were measured by dc four-probe method. The films with structure of Si/SiO_2-sub/Ta(3)/MgO(2)/$Co_{20}Fe_{60}B_{20}$(t_{CoFeB} = 1.45 – 1.70)/Ta(5) were also prepared and annealed at 300°C to investigate their magnetic properties which were measured at room temperature by vibrating sample magnetometer (VSM) and ferromagnetic resonance (FMR). Results Fig. 1 shows conductance curves for MTJ sensor devices with various thicknesses of $Co_{20}Fe_{60}B_{20}$ free layers after annealing at T_a = 300°C. All of the MTJ sensor devices showed a linear conductance response within H = ±1 kOe. The jump of conductance curves at H = ±4.8 kOe corresponds to the switching field of the p-SAF pinned layer. In contrast, magnetic anisotropy field (H_k) of $Co_{20}Fe_{60}B_{20}$ free layers was 1.8, 2.3 and 2.9 kOe for the t_{CoFeB} = 1.50, 1.55 and 1.60 nm respectively. The sensitivity which is defined as the slope of conductance curves increased with decreasing CoFeB thickness due to the decrease of H_k. The highest sensitivity evaluated in the range of H = ±1 kOe was 0.055 %/Oe for t_{CoFeB} = 1.50 nm. This sensitivity is much higher than reported value of 0.0053 %/Oe [2] thanks to both high TMR ratio and low H_k in $Co_{20}Fe_{60}B_{20}$ free layers because of large interfacial perpendicular anisotropy at MgO barrier interface. The nonlinearity defined as $(G_{meas.}-G_{fit.})/(G_{meas.max}-G_{meas.min})\times100$ (% FS) was also investigated. According to Stoner-Wohlfarth [3] and Slonczewski models [4], a conductance curve is expressed as $G_0(1+P^2H/H_k)$ and should linearly respond against external magnetic field H, where G_0 is the conductance at H=0 and P is tunneling spin polarization. Fig. 2 shows the $Co_{20}Fe_{60}B_{20}$ thickness dependence of nonlinearity in the MTJ sensor devices. The nonlinearity decreased with increasing $Co_{20}Fe_{60}B_{20}$ thickness. In order to investigate the mechanism of nonlinearity, dispersion of magnetic anisotropy (ΔH_{keff}) was measured by FMR in Si/SiO_2-sub/Ta(3)/MgO(2)/$Co_{20}Fe_{60}B_{20}$(t_{CoFeB} = 1.45 - 1.80)/Ta(5) films. As shown in Fig. 2, the magnitude of $\Delta H_{keff}/H_{keff}$ decreased with increasing $Co_{20}Fe_{60}B_{20}$ thickness, similarly to the nonlinearity. These results indicate that the dispersion of magnetic anisotropy in $Co_{20}Fe_{60}B_{20}$ free layer is the main origin of nonlinearity in the MTJ sensor devices. Summary We investigated the performance of MTJ sensor devices with wide dynamic range using p-SAF pinned layers. The sensitivity was improved by optimizing the thickness of $Co_{20}Fe_{60}B_{20}$ free layers and achieved a high sensitivity of 0.055 %/Oe for t_{CoFeB} = 1.50 nm. This is the highest sensitivity in the MTJ-based magnetic sensors with a wide dynamic range above 1 kOe. Conversely, the nonlinearity increased with decreasing thickness of $Co_{20}Fe_{60}B_{20}$ free layers due to the increase of magnetic anisotropy dispersion. We found that the reduction of magnetic anisotropy dispersion is needed in order to achieve both high sensitivity and nonlinearity in the MTJ sensor devices.

AH-07. Magnetic Sensor Using Spin-orbit Torque Effective Field as Transverse Bias.

Y. Xu[1], Y. Yang[1], Z. Luo[1] and Y. Wu[1]
1. Electrical and Computer Engineering, National University of Singapore, Singapore

I. INTRODUCTION Magnetic biasing is commonly used to enhance the linearity, sensitivity and dynamic range of magnetic sensors[1-4]. For anisotropic magnetoresistance (AMR) sensor, the two most commonly used biasing schemes are soft-adjacent layer (SAL) biasing and barber pole biasing, as shown schematically in Fig.1a and b. The SAL biasing (Fig. 1a) normally requires a soft magnetic layer, or SAL, layered with the sensing layer via an insulating spacer. When the thickness and magnetization of both the sensing and SAL layers are optimized, the angle between the current and magnetization of the sensing layer can be readily set to be 45^o by adjusting the sensing current. While the SAL scheme was successfully implemented in AMR sensors, it requires dedicated process work to optimize the structure and, moreover, it also suffers the drawback of non-uniformity in the biasing field, particularly at the edges. On the other hand, in the case of barber pole biasing, instead of changing the magnetization direction, the local current is directed away from the easy axis direction by patterned conducting strips deposited directly atop the sensing layer (Fig.1b). The strips are aligned at an angle of 45^o from the easy axis direction of the sensing element, leading to a linear response to transverse field. It is apparent that the barber pole design also suffers from requirement of additional process steps and current shunting by the conducting strips. To simplify the biasing structure and at the same time provide a uniform bias across the active area of the sensor, we have recently introduced a biasing technique based on spin-orbit torque[5] (SOT) effective field (see Fig.1c). The SOT, present in ferromagnet (FM) / heavy metal (HM) heterostructures, has been widely studied as a promising mechanism for switching the magnetization of ultrathin FM layers. It is commonly accepted that both damping-like (DL) and field-like (FL) SOTs are present in FM/HM bilayers. The FL effective field, which in-plane and perpendicular to the current (Fig.1d), forms naturally as a transverse bias. As demonstrated in our recent work, the use of SOT biasing greatly simplifies the sensor structure and, in fact, what one needs is only a FM/HM bilayer. A byproduct of this is that the sensor can also be made semi-transparent. Here we present a systematic study of SOT-biased AMR and spin Hall magnetoresistance (SMR) sensors by focusing on how the dimension of the sensor would affect its dynamic range, linearity, sensitivity and power consumption. II. RESULTS AND DISCUSSION In order to evaluate the field sensing performance of SOT biased sensors with different dimensions, we fabricated full Wheatstone bridge sensors with ellipsoidal shape in NiFe(1.8)/Pt(2) bilayers. The long to short axis ratio is fixed at $a/b = 4$, with a = 800, 400 and 200 μm, respectively. Fig.2a shows the scanning electron micrograph of the four sensor elements with a = 800 μm, which are connected to form a Wheatstone full bridge. When a current source is connected to the top and bottom terminals of the bridge sensor as depicted in the Fig. 2a, the magnetization of the sensor elements, 1 and 4, are rotated to the direction opposite to that of the sensor elements, 2 and 3, with respect to the easy axis, leading to a linear response to the external field which is detected as a voltage signal from the other two terminals of the bridge. Fig. 2b and 2c (symbols) summarized the simulated and experimental power consumption, sensitivity, and dynamic range of sensors with different dimensions. By changing the long and short axis length (a and b), the shape anisotropy of the sensor can be changed accordingly; this leads to tunable bias current density, power consumption, sensitivity and dynamic range. The solid curves in Fig.2b and 2c are simulation results based on a macro-spin model, using parameters extracted experimentally. From the calculation results, we can observe, by reducing a from 1000 μm to 100 μm, the power consumption decreases significantly from 2.06 mW to 0.05 mW, the sensitivity decreases from 243.2 to 157.0 mΩ/Oe and the dynamic range increases from 0.83 to 1.28 Oe. These changes are attributed to the increased shape anisotropy and reduced current as the dimension decreases. The agreement between experimental and simulated results shows clearly that it is possible to tune the sensor's power consumption, sensitivity and dynamic range via adjusting the dimensions. Potential applications of the AMR/SMR sensors will be discussed.

AH-08. Co/Pd Multilayer Structure for Hydrogen Sensing.

J. Liang[1], K. Chang[1], K. Chen[1] and Y. Tseng[1]
1. Materials Science & Engineering, National Chiao Tung Universoty, Hsin-chu, Taiwan

This paper reports on a magnetic device with a Co/Pd multilayer structure for use in the detection of H_2. In a magneto-optical, transport and gas-detection system, the proposed device presented sharp, reproducible H_2-dependent magnetic/electrical properties. The electrical signal-to-noise ratio of the device can be restored ~ 50% by exposing it to a magnetic field of 1000 Oe, even when the sensitivity of the device dropped at low H_2 pressure (0.7 KPa). This demonstrates the applicability of the device for use as a low-pressure H_2 detector. Arduino prototyping platform was adopted to test the modularization of Co/Pd with a Hall bar structure, through which the device displayed a read-out signal (R_{Hall}) exceling traditional resistivity-type (R_{xx}) structure by a factor of ten. By varying the Co/Pd interface number we were able to vary the H_2-detetcing sensitivity as a result of the change of magnetic anisotropy. Operando x-ray spectroscopy and in-situ Kerr microscope were used to explore the underlying mechanism. It revealed that the changes in H_2-induced magnetism arose from a Co-Pd charge transfer effect coupled to magnetic domain reversal.

AH-09. Enhanced annealing stability of exchange biased pinned layer in magnetic tunnel junctions using a thin Ta/Ru/Ta/Ru underlayer for analog sensor applications.

K. Okamoto[1], Y. Fuji[1], Y. Higashi[1], S. Kaji[1], T. Nagata[1], S. Baba[1], A. Yuzawa[1] and M. Hara[1]
1. Corporate Reserch & Development Center, Toshiba Corporation, Saiwai-ku,Kawasaki, Japan

MgO-based magnetic tunnel junctions (MTJs) are a key component technology for spintronic devices such as hard drive heads and magnetic random access memory (MRAM). Moreover, there is a great deal of interest in utilizing MTJs in analog sensor applications such as magnetic field sensors [1], current sensors, and angle sensors because of the large tunneling magnetoresistance (TMR) effect of MTJs. In a new analog sensor application of MTJs, it has been reported that MTJs can also serve as a strain sensor by using a magnetostrictive sensing layer [2]. These MTJ strain sensors can be applied to various kinds of physical sensors by combination with micro-electro-mechanical-system (MEMS) technology, and we have recently reported a novel MEMS microphone utilizing MTJ strain sensors [3]. As seen from the above, the range of possibilities for analog sensor application using MTJs have greatly expanded, and there is strong demand for further improvements in the signal-to-noise ratio (SNR) of MTJ elements. To obtain high SNR in analog sensors, it is important to have not only a high TMR ratio, but also low 1/f noise. Annealing is effective for improving the TMR ratio because it enhances the crystallinity of the MgO barrier layer, and it has also been reported that annealing is effective for decreasing MgO barrier noise [4]. Thus, a higher annealing temperature is preferable in order to enhance these effects. However, in the case of MTJs with an exchange biased pinned layer, which is generally used in analog sensor applications, excessively high-temperature annealing causes degradation of the exchange bias field (H_{ex}). This degradation decreases the effective TMR ratio and increases the magnetic 1/f noise coming from pinned layer [5], thus creating an obstacle to the adoption of high-temperature annealing. In this study, we aimed to improve the annealing stability of the exchange biased pinned layer in MgO-MTJ for analog sensor applications. We therefore focused on enhancing the crystallinity of the anti-ferromagnetic IrMn layer and investigated the effect of an underlayer structure on the crystallinity of the IrMn layer and annealing stability of the exchange biased pinned layer. We fabricated MTJs consisting of underlayer/IrMn7/CoFe2.5/Ru0.9/CoFeB3/MgO1.8/CoFeB4/Cu1/Ta2/Ru20 (layer thicknesses shown in nanometers). We prepared two kinds of underlayer structures: a generic Ta1/Ru2 underlayer (TR-UL); and an improved Ta1/Ru2/Ta2/Ru2 underlayer (TRTR-UL). Fig. 1 (a) and (b) show the R-H curves for the MTJ with TR-UL (TR-MTJ) and MTJ with TRTR-UL (TRTR-MTJ) annealed at 380 °C. As can be seen in Fig. 1, the TRTR-MTJ exhibits a larger H_{ex} and larger TMR ratio compared with those of TR-MTJ, We also evaluated the noise level of these MTJs, with the Hooge parameter α estimated by fitting the frequency dependence of the noise level measured at 200 Oe. The estimated α values for both MTJs are shown in Fig. 1(a) and (b). The value of α at 200 Oe for TRTR-MTJ is lower than that for TR-MTJ. Therefore, the magnetic 1/f noise is clearly improved by using TRTR-UL thanks to the high annealing stability of the exchange bias field. To clarify the microstructure of both MTJs, cross-sectional high-resolution transmission electron microscopy (HRTEM) and electron energy-loss spectroscopy (EELS) were performed. Insets of Fig. 1(a) and (b) show the HRTEM and EELS results for TR-MTJ and TRTR-MTJ annealed at 420 °C, solid lines in the figure show the EELS intensity of Mn. These results confirmed that the Mn diffusion is quite different between TR-MTJ and TRTR-MTJ. For TR-MTJ, Mn diffused from the IrMn layer to the pinned layer, whereas for TRTR-MTJ, there is almost no Mn diffusion from the IrMn layer to the neighboring layer. To investigate why TR-MTJ and TRTR-MTJ exhibited different Mn diffusion, the crystallinity of IrMn for both MTJs was analyzed by X-ray diffraction measurement. As a result, the crystallinity of IrMn on TRTR-UL was found to be clearly improved compared with that on TR-UL. Furthermore, we investigated the detailed structure of TR-UL and TRTR-UL. TEM measurement and fast Fourier transform measurement (FFTM) analysis were used to confirm the detailed d spacing of each layer in TRTR-UL (Fig. 2). From Fig. 2, it was successfully confirmed that the first Ta layer and second Ta layer in TRTR-UL have different d-spacing. The second Ta layer deposited on Ru layer has the d-spacing corresponding to the (110) textured α-Ta structure and highly crystallinity, whereas the first Ta layer does not have the component of (110) textured α-Ta structure. These results indicate that Ta-on-Ru structure is responsible for the high crystallinity of IrMn layer disposed on TRTR-UL, resulting in the high annealing stability thanks to small Mn diffusion. Therefore, Ta/Ru/Ta/Ru structure is promising as an underlayer for realizing a high SNR in MTJ analog sensor applications.

AH-10. Modification of Ce valence states by Y/Dy co-doping of CeO_2 nano-particles for effective Electrical and Sensing properties.

C. Madhusudan[1,2]

1. Department of Physics, Osmania University, Hyderbad, India; 2. S.R.R Govt. Arts & Science College, Karimnagar, India

Abstract Improved electrochemical and sensing properties of CeO_2 nanoparticles were obtained by co-doping with Y^{3+} and Dy^{3+} to attain Ce^{4+}/Ce^{3+} valence states with the associated generation of oxygen vacancies. $Ce_{0.8}Y_{0.20-x}Dy_xO_{2-\delta}$ (x=0.00,0.10,0.20) nanoparticles were synthesized by sol-gel auto combustion method, calcined at 800^0C for 2hr in air and innovatively sintered by means of microwave heating at 1300^0C for 30min. The phase identification, structural and morphological analysis were characterized by XRD, SEM, TEM and Raman Spectroscopy. The ionic conductivity was analyzed by Impedance Spectroscopy. The gas sensing properties were tested at room temperature. Intense F_{2g} Raman band at 460cm^{-1} from Raman spectra in concurrence with XRD diffractograms revealed that the investigated samples exhibited the cubic fluorite structure of CeO_2. SEM and TEM results ascertained the nano level microstructure. The shift in XRD peak ascertained that the dopants were dissolved into the host lattice, and the subsequent creation of oxygen vacancies, due to the change in valence state from Ce^{4+} to Ce^{3+}. The generation of oxygen vacancies and the resultant enhancement in ionic conductivity was validated by the results of Raman specta and Impedance analysis. Because of special microstructure, the obtained sample showed excellent gas sensing properties towards the ethanol at room temperature. High response, fast response-recovery time and excellent selectivity to ethanol gas, suggested the promising gas sensing application of the sample $Ce_{0.8}Y_{0.10}Dy_{0.10}O_{2-\delta}$. 1. Introduction In the recent past, Cerium oxide or Ceria (CeO_2) has been extensively studied due to its potential applications in devices such as a catalyst, gas sensor, magnetic semiconductors and electrolytes in Intermediate Temperature Solid Oxide Fuel Cells (ITSOFCs) [1-3]. In principle, when Ce^{4+} cationic sub-lattice gets partially substituted with a trivalent Rare earth (RE) ion, oxygen vacancies are created in anionic sub-lattice in order to compensate the effective negative charge produced by the substituent cations. In the nano regime, easily accessible oxidation states from Ce^{3+} to Ce^{4+} gives ceria advantageous properties by the creation of oxygen ion vacancies and Ce^{3+} defects and hence the materials become good ionic conductors for a variety of applications mentioned [4]. Many researchers found that ceria doped with two or more cations (co-doping) showed improved electrical, magnetic and sensing properties than the best singly doped ceria. Co-doping aims to obtain an average or effective cation radius that is very close to that of Ce^{4+}, hence the average strain introduced by the dopant cations is minimized [5-7]. Ethanol is one of the most commonly and widely used alcohols and has many applications in food, medicine, chemical industries and beverages. Ethanol is volatile and flammable, and a long time exposure to it can cause central nerous disorders. Thus, its detection is important in many aspects [15-17]. the present work, investigates the possibility of improving the sensing and electrochemical properties of Y and Dy co-doped ceria $Ce_{0.8}Y_{0.20-x}Dy_xO_{2-\delta}$ (CYDO) nanoparticles synthesized via sol-gel auto combustion route and innovatively sintered by means of microwave heating [8-9]. 2. Results and discussion: Powder XRD patterns of the as-grown samples confirmed the dissolution of the dopants into the host lattice due to conversion of Ce^{4+} to Ce^{3+} and the subsequent creation of oxygen vacancies without any significant change in the lattice structure of host [10-11]. SEM and TEM results confirmed the nano-level dense microstructure with negligible porosity. Raman spectra of the samples consisted of a less predominant broad band at and around 570 cm^{-1} along with the characteristic F_{2g} peak of pure ceria at 460 cm^{-1}, which confirms the creation of oxygen vacancies [12]. The relative number of oxygen vacancies was found to be highest for the sample $Ce_{0.8}Y_{0.10}Dy_{0.10}O_{2-\delta}$. Impedance data collected for the obtained samples showed high ionic conductivity of 7.5 mS cm^{-1} at 500°C for $Ce_{0.8}Y_{0.10}Dy_{0.10}O_{2-\delta}$ with a low activation energy of 0.90 eV. These results can be attributed for high concentration of oxygen vacancies [13-14]. The gas sensing properties of $Ce_{0.8}Y_{0.10}Dy_{0.10}O_{2-\delta}$ nanoparticles were investigated by testing their gas response towards ammonia, acetone, methanol and ethanol with 1000 ppm concentrations at room temperature (R.T.). The response studies confirm that CYDO sensor show high response to ethanol (72%) compared to ammonia (6%), acetone (2%) and methanol (53%). So CYDO sensor can be treated as ethanol sensor and further gas sensing properties were studied. The gas sensing response of CYDO sensor was tested towards ethanol gas for different concentrations at R.T. It is clearly demonstrated that the response of the sensor increased with increase in concentration of ethanol gas. A sensor with fast response and recovery are needed to real-time usage in practical applications. For 1000 ppm ethanol gas, response time found to be 32 s and recovery time is 29s for $Ce_{0.8}Y_{0.10}Dy_{0.10}O_{2-\delta}$, as shown in Fig 1. 3. Conclusions The sensor developed in the present work has higher response and exhibited excellent gas sensing abilities toward ethanol gas. Results reported are promising and encouraging for application as a sensor in ethanol monitoring in breath analyzers and other fields. Also with nano regime microstructure and good oxide ion conductivity, it can also be used as electrolyte in ITSOFCs.

AH-11. Dural Field Frequency Mixing in Piezoelectric/Piezomagnetic Laminates at Acoustic Resonance.

P. Li[1], L. Bian[2], Y. Wen[1], X. Ji[1], T. Han[1] and Y. Wang[1]
1. Instrument Science and Engineering, Shanghai Jiaotong University, Shanghai, China; 2. Mechanical Engineering, Nanjing Technology University, Nanjing, China

Piezoelectric/piezomagnetic laminates can exhibit strong magnetoelectric (ME) coupling mediated by the strain, which may be produced either by magnetic field or electric field. A class of magnetic sensors are straightforward derived from piezoelectric/piezomagnetic laminates and their sensing output are the direct ME voltage, i.e. the electric response in piezoelectric layer produced by the magnetic-field-induced stain. Because of the nature of piezoelectric output, only a dynamic electric response is detectable. Hence, in this way ME composite laminates can only be exploited as dynamic magnetic sensors. To realize DC magnetic sensors, composite laminates have to be AC excited to oscillate and the sensed static magnetic field modulate the acoustic oscillation in terms of the dependences of ME coupling parameters on magnetic field.[1][2]Usually it is applying an AC magnetic field on a piezoelectric/piezomagnetic laminate to make it oscillating. In actual, an AC magnetic field used for excitation is produced by a coil. This configuration makes complicated the constitution of a practical device and loses the advantage of device simplicity from ME heterostructure. It is generally accepted that manipulating magnetism using pure electric fields instead of magnetic fields or large currents in multiferroic heterostructure is a goal for low-power spintronics. Both the constituents of a composite ME laminate have nonlinear properties. The nonlinearity in piezomagnetic material seems more noticeable as there is obvious saturation in magnetization. In most composite ME applications, usually it is desirable to avoid the saturated magnetostriction by biasing composites with appropriate DC magnetic fields. However, the nonlinearity may be beneficial to specific applications. Researchers have reported the resulting nonlinear ME effects, including frequency doubling of the voltage response at either low frequencies or resonance,[3] frequency mixing of the voltage response for magnetic fields with different frequencies applied to ME composites.[4]These nonlinear behaviors derive from the action of the nonlinearity on identical field-the magnetic field. In this work, we study the frequency mixing of electric field and magnetic field in piezoelectric/piezomagnetic laminates to retain strong ME effect and larger ME response even for a DC/low frequency magnetic field. This way, magnetic sensors with high sensitivity and enhanced resolution can be realized simply by electrically exciting ME composite laminates to oscillate around or at acoustic resonance. We design the composite with two electric terminals: one used for electric field (voltage) excitation, another for the strain-induced voltage output. To realize this, a piezoelectric/piezomagnetic heterostructure is made by sandwiching a piezomagnetic layer into two piezoelectric layers as shown in Figure1. Either piezoelectric layer can be used as input or output port. The laminate is magnetically biased at the nonlinear range and electrically excited to oscillate at its acoustic resonance. In the fabricated sandwiched ME laminate, the longitudinal resonant frequency of the laminate is about 231.5 kHz. We let the sandwiched laminate be excited by an AC voltage at the longitudinal frequency 231.5 kHz (f0) with an amplitude respectively of Vp-p=2.5 V and 3.5 V. To evaluate the dual field frequency mixing performance, an AC magnetic field of 0.5Oe at 1 kH(fH) is applied superposed with a DC biased field. Checking the electric output from another piezoelectric layer, we can see that due to the nonlinearity, the output contains frequency-mixing components, which are at the either sides of the exciting frequency: 230.5 kHz (f0-fH, left) and 232.5 kHz (f0+fH,right). The magnitudes of the frequency-mixing components vs. DC fields are recorded in Figure 2. At the optimal DC field, the ME voltage coefficients for the left modulated components are about 300mVOe^{-1} and 240 mVOe^{-1} respectively with electric voltage excitation of 3.0 Vp-p and 2.5 Vp-p and that for the right modulated components are about 250mVOe^{-1} and 170 mVOe^{-1}. These coefficients are almost the same as the resonant ME voltage coefficient. From the results, we conclude that through the nonlinearity a piezoelectric/piezomagnetic composite laminate can respond DC and low frequency magnetic fields at the maximum ME gain (the resonant ME coefficient). Principally in this scheme the piezoelectric/piezomagnetic composite can respond magnetic fields from zero to the resonance frequency by controlling the E-H mixing frequency in the pass band with electrically exciting frequency and share the high ME gain at mechanical resonance. Such features makes the sandwiched piezoelectric/piezomagnetic composite laminate greatly available for magnetic sensors required to sense both static and dynamic magnetic field in a rather wide frequency band.

Eldelstein [1] was the first to realize that in a Rashba two-dimensional electron system [2], the flow of a charge current is accompanied by a non-zero spin accumulation coming from uncompensated spin-textured Fermi surfaces. The opposite effect, spin-to-charge conversion through inverse Edelstein effect or IEE (also known as spin galvanic effect [3]), was recently demonstrated and its efficiency quantified at Ag/Bi(111) interfaces [4]. Here, we make use of such interface-driven spin–orbit coupling mechanism—the Rashba effect—in the oxide two-dimensional electron system (2DES) $LaAlO_3/SrTiO_3$ [5] to achieve spin-to-charge conversion with unprecedented efficiency [6]. Through spin pumping at 7 K, we inject a spin current from a NiFe film into the oxide 2DES and detect the resulting charge current, which can be strongly modulated by a gate voltage. We highlight the importance of a long scattering time to achieve efficient spin-to-charge interconversion. Thus we can explain why the IEE efficient at LAO/STO interface is much higher than metallic Ag/Bi Rashba interface or than topological insulator alpha-Sn capped with Ag [7].

AI-02. An Electromagnetic Field Reduction Method for Inductive Power Transfer in Transportation System.

J. Kim[1], K. Kim[1] and S. Ahn[1]
1. The Cho Chun Shik Graduate School for Green Transportation, Korea Advanced Institute of Science and Technology (KAIST), Daejeon, The Republic of Korea

1. Introduction Currently, inductive power transfer (IPT) applications to transportations are being researched for safe and convenient power transmission [1,2]. However, the IPT system for transportations require to use high electrical power. This means that high density of magnetic field would be generated during IPT system operation and some magnetic fields would be a leakage magnetic field. These leakage magnetic fields influence negative effects to human body or other electrical device. Therefore, an leakage field reduction method for high power IPT system is necessary. In this paper, an adaptive active shield system is proposed that can eliminate leakage magnetic field generated from source and pickup coil by using one shield coil. Canceling magnetic field strength is controlled by measuring source current of IPT system for effective magnetic field reduction. 2. Proposed adaptive active shielding method The active shielding methods are already used for reducing leakage magnetic field but precedent researches require two shield coils [3]. In addition, canceling magnetic field strength is controlled by adjusting coil turns so efficient canceling magnetic field generation is limited. Fig. 1(a) shows the conceptual diagram of proposed active shield system using one coil. In order to achieve leakage magnetic field reduction, 1)radius and array, and 2) magnetic field strength and phase should be considered. *A. Shield coil radius selection* Biot-savart law can estimate the magnetic field strength over the distance as (A.1) [4]. r is the radius of the coil, x is the specific position from the center of the coil, u_0 is the permeability of free space, and R=root(r^2+x^2). In the case of rectangular coil, magnetic field strength will be decreased as $1/r^2$, and magnetic field strength will be a half when x and r are same. This means that decreases of magnetic field strength will be different in accordance with coil radius. In order to maintain the powering magnetic field, compensation region can be employed by tuning coil radius of active shield. The magnetic field strength is increased in the area between active shield coil and the source and pickup coil in accordance with magnetic vector directions. Consequently, shield coil radius could be determined as (A.2) when source and pickup coil are identical. r_{TX}, r_{TX}, and r_{SH} are radius of the source, pickup, and active shield coil respectively. *B. Strength and phase of canceling magnetic field* Fig. 1(b) is an equivalent circuit model of IPT system with active shielding system. When l_1 and l_2 are width and height of coil, magnetic flux B can be calculated as (B.1). If the parameters related to pickup system such as inductance L_{RX}, capacitance C_{RX}, and resistance R_{RX} are determined, induced voltage V_{RX} and current I_{RX} of pickup system can be calculated by (B.2.) and (B.3). M is the mutual inductance between source and pickup coil. This means that magnetic flux can be calculated not only B_{TX} generated from source but also B_{RX} generated from pickup coil by only measuring source current. $B_T(x)$ is the total magnetic field at specific position at x, and it is determined by subtracting leakage magnetic field $B_{LK}(x)$ and $B_{SH}(x)$. Therefore, current of active shielding system can be controlled for minimizing leakage magnetic field by measuring source current. In order to achieve effective magnetic cancelation, phase of canceling magnetic field should be tuned. Shielding performance is maximized when achieving 180 degree of phase difference with the leakage magnetic field. Phase of leakage magnetic field can be estimated by calculating current of source and pickup current with the magnetic flux R_{TX} and B_{RX}. Phase of canceling magnetic field for leakage magnetic field can be controlled as (B.5). 3. Simulation For the EM simulation setup of the proposed active shielding system, current of source and pickup coil was set as 500A and 392A respectively with 60 kHz of operating frequency. In order to measure the total magnetic field, two observation points were set. In order to measure the total magnetic field in the vicinity of IPT system for human influences, 1.5m of vertical observation points at the side of train body has set [5]. In addition, 10m of horizontal observation points at 1.5m of height from source coil has set for measuring total magnetic field at far distance [6]. Fig. 2(a) shows the simulation results for magnetic flux at the vicinity of IPT system. The case that is applied active shield has shown 3.1uT, 1.2uT, and 0.6uT for the distance of 0.5m, 1m, and 1.5m respectively. The reduction rate at each point is 53%, 64%, and 73% respectively. Fig. 2(b) shows the simulation result of total magnetic field at the far distance from IPT system. The case that is applied active shield was 95.7, 87.6, 80.2, 73.1, and 66dBuA/m respectively. For the all observation points, about 20dB A/m of magnetic field strength has decreased. Although total magnetic field at the close and far distance were reduced, powering magnetic field between source and pickup modules were hardly reduced. 4. Conclusion In this paper, an active shield system for reducing leakage magnetic field generated from IPT system has been proposed. A proposed method has advantages that uses only one coil and provides efficient magnetic cancelation through adaptive shielding current control. A proposed method has shown the performance that electromagnetic fields at the closed and far distance were effectively reduced without powering magnetic field loss between source and pickup coil.

AI-03. Optimal Design of Quadrature-Shaped Pickup for Omnidirectional Wireless Power Transfer.

Z. Zhang[1], B. Zhang[1], R. Tong[1], W. Ai[1], *S. Chang*[1] and J. Wang[1]
1. School of Electrical and Information Engineering, Tianjin University, Tianjin, China

INTRODUCTION Omnidirectional wireless power transfer (WPT) technology is a brand-new way of energy supply which is able to transfer power to the pickup unit wherever it locates around the transmitter. One of the most important purposes of such a system is to ensure the pickup unit can obtain enough energy evenly at all directions in 3-dimensional space around the transmitter [1]. However, there exists some special positions where the received power decreases to a lower level, such as the position as Fig.1 (a) depicts. Taking the current limit of transmitting coils into consideration and avoiding the input excitation beyond the restriction, this paper proposes a quadrature-shaped pickup which can effectively enhance the ability of capturing power at specific positions instead of just increasing the input. The optimized load power and transmission efficiency are able to be achieved according to different requirements by adjusting the key size variable. PROPOSED QUADRATURE-SHAPED PICKUP The widely-accepted omnidirectional WPT system consists of an orthogonal transmitting unit and a single coil as the pickup as depicted in Fig.1 (a). Besides, the load power of such a position where the pickup coil is vertical to one or two of transmitting coils will reach an extremely low level compared to other positions. Thus, the quadrature-shaped pickup is designed to improve the obtained power which is composed of three vertical coils connected with compensation capacitor and the load in series, as shown in Fig.1(b). The two crossed coils that have the same number of turns *N* are wound closely around a magnetic core called PC40 at the center. The width *a* of the cross-shaped core is a key variable which determines the turns *N* as each millimeter can be wound around one turn of the wire and also affects the performance of the system. By selecting appropriate value of width *a*, either maximum load power or maximum efficiency at specific positions is able to be achieved. VERIFICICATION The simulation is carried out to validate the enhancement of the proposed pickup and analyze how the width *a* affects the load power and efficiency of the system by JMAG. Moreover, the experimental prototype is also built up with a 7W bulb as the load to verify the feasibility of the proposed pickup for omnidirectional WPT as shown in Fig.1(c). The transmission distance is 100mm and the operation frequency is 100kHz both in simulated and experimental verifications. When the transmitting coils are all fed with current of 3A without phase difference, as depicted in Fig2. (a) and (b), the maximum magnetic flux density value reaches around 1.9mT and 5.5mT respectively when utilizing the conventional pickup and the proposed pickup, which reveals that the proposed pickup has the ability to obtain more power than the conventional one under the same condition. In order to optimize the design, the relationship between the width *a* and the load power, as well as efficiency, is also studied as shown in Fig.2 (c), and it represents that the conventional pickup is applied in the system when the value of *a* equals to zero. The result demonstrates that the load power increases from 6W to 54W while the efficiency drops from 83% to 64% as width *a* gets larger, which means that the width *a* can be designed at different values according to the different requirements of the load. Fig.2 (d) and Fig.2 (e) are the waveforms of the experiment using the conventional and proposed pickup, respectively, which are both tested at the position as shown in Fig.1 (a). V_{L1}, V_{L2}, and V_{L3} are the inductance voltage of three transmitting coils, and V_R represents the voltage of the load. Without varying the input, the RMS of load voltage is around 8V when adopting the proposed pickup, while it drops to 3V when using the conventional one. The comparative result illustrates that the proposed pickup can effectively improve the load power with the same input and position. The simulated and experimental results can verify the feasibility of the proposed pickup for the power improvement of omnidirectional WPT system. Furthermore, the optimal design of the quadrature-shaped pickup can be achieved depending on the different demands of load power and efficiency. CONCLUSION This paper proposed a quadrature-shaped pickup which can effectively enhance the transmitted power without varying the excitation for specific positions where the receiving power is weak. By adjusting value of the width *a*, the optimal design can be achieved to satisfy various application demands, such as high load power and high efficiency. The experimental results well agree with the simulated analysis, which validates that the proposed quadrature-shaped can effectively improve the performance of the omnidirectional WPT system without changing the input through the proposed optimal design. Besides, the detailed parameters, theoretical analysis, simulated results, and experimental waveforms will be presented in the full manuscript.

AI-04. A 3D-Printing Magnetic Forward Method for Objects in Motion.

Y. Sui[1] and K. Liu[1]
1. Jilin University, Changchun, China

I.Introduction Magnetic forward methods are of great importance in many areas such as geophysical exploration, electric machine, and have been investigated by a lot of scholars [1-3]. Many commercial or open-source software like Comsol Multiphysics and Ansoft Maxwell reliant on the finite element analysis can be used to calculate the magnetic fields generated by the 3D objects, but they require tremendous computational time and large numerical resources, especially for objects in motion [3-5]. Take COMSOL Multiphysics and Ansoft Maxwell for example. When simulating the complicated movements of 3D objects with COMSOL Multiphysics, the arbitrary Langrangian-Eulerian (ALE) moving mesh has been often used to trace their movements [4]. If the mesh displacement becomes large, the mesh elements will have a bad quality or even become inverted, so remeshing has to be used [6]. For the similar situation, Ansoft Maxwell does not have an adaptive mesh solution and requires significant mesh operations to help the transient solver [7]. The magnetic field of a static 3D object could be derived by dividing the object into an array of magnetic dipoles, calculating the field of each dipole, and then summing the effects of all dipoles [1]. Therefore, we proposed a 3D-printing magnetic forward method for objects in motion. The core idea is to design and create the virtual 3D objects with 3D printing technology, and replace the magnetic materials emitted from nozzles of a 3D printer with a collection of magnetic dipoles. Then superpose the effects of all dipoles, and the magnetic forward of static 3D objects is accomplished. In view of the fact that each component in a rigid body has the same laws of motion while the body moving and rotating in three-dimensional space, coordinate transformations can be used to implement the six-degrees-of-freedom (6DoF) motions of 3D objects. Similarly, the magnetic fields generated by objects in motion are calculated by summing the effects of all dipoles. The advantages of the proposed 3D-pringting magnetic forward method could be summarized as follows: (1) It is simple and easy to implement. The computational accuracy can be improved regardless of whether the user is a sophisticated expert or not. (2) It has strong practicability. The computational accuracy and the amount of time and memory consumed by the forward method are independent of the mode and complexity of motion. (3) It is perhaps the simplest method to obtain multiple-order magnetic gradient tensors of magnetic objects because of the analytical tensor expressions of a magnetic dipole. (4) The forward process for multiple magnetic objects in motion is consistent with that for a single object, so it has powerful expansibility. The proposed method could be used in many applications such as the magnetic test for a scientific spacecraft, the analysis of magnetic interference on instruments with high precision. II.The process of the 3D-printing magnetic forward method The steps of the 3D-pringting magnetic forward method are listed below: (1) Models of 3D magnetic objects may be obtained via a computer-aided design (CAD) package, medicine imaging techniques or a 3D scanner. Then the 3D magnetic models are exported in STL format, which is an interface in rapid prototyping system. (2) Import the STL file into Slic3r, which is a 3D slicing engine for 3D printers. Slic3r converts the model into a series of thin layers, and then produces a G-code file (a numerical control programming language used in computer-aided manufacturing). The height of layers and the filling density can be changed according to different discrete accuracy. (3) Parse the G-code file to gain printing positions of the nozzle of a 3D printer and other useful information. Simulate the extrusion process of the nozzle by interpolating new printing positions within the moving path. (4) Set each point as a magnetic dipole, then the magnetic materials emitted from nozzles of a 3D printer are replaced with a collection of magnetic dipoles. With regard to the magnetic objects whose components have various magnetic properties or positions, we can output the corresponding STL files for each component or use multiple extruders setting in the Slic3r to accomplish the modeling. (5) Use coordinate transformations to implement the 6DoF motions of 3D objects. The magnet fields generated by 3D objects in motion are derived by calculating the fields of each magnetic dipole and summing the effects of all dipoles. III. Application of magnetic test of satellites Rotating the spacecraft about the vertical axis and the horizontal axis of a swivel table is a practical and proven method in magnetic test [8-10]. As the representatives of soft and hard materials respectively, we rotated three magnetorquers and three momentum wheels which have been widely utilized in attitude control of satellites [11-13]. The satellite was simulated as a 400 mm×400 mm×400 mm cube. The radial permanent magnetic bearings has the axial magnetic moment of 2 Am^2. Bearings are simulated by two inner loops in the momentum wheel. Set three momentum wheels along yaw, pitch and roll axis, respectively. The magnetorquer has the magnetic moment of 1.3 Am^2. Six components are shown in Figure 1. Set the observation point along the yaw axis with distance of 600 mm from the center of the satellite and the results are illustrated in Figure 2.

AI-05. Fabrication technology of low-propagation-loss plasmonic waveguide containing a ferromagnetic metal.

V. Zayets[1], H. Saito[1] and S. Yuasa[1]
1. Spintronics Center, National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan

The optical isolator is an important element of optical networks. It protects optical elements from an unwanted back reflection. The integration of optical elements into Photonic Integrated Circuits (PIC) is an important task, because it reduces the cost and improves the performance of high speed optical data processing circuits of the optical networks. Figure 1 (a) shows the proposed design of the plasmonic isolator[1,2]. It consists of a Si nanowire waveguide, a part of which (about 2-16 mm) is etched out, and a ferromagnetic metal is deposited in the gap. The ferromagnetic metal is not transparent and the direct light propagation from the input Si waveguide to the output Si waveguide is blocked by the Co. However, a surface plasmon is excited at the Co / TiO_2 / SiO_2 interface. As a result, light reaches the output fiber. The Co is a magneto-optical material. When its magnetization is perpendicular to the light propagation direction and is in the film plane, its optical constants are different for two opposite light propagation directions. The plasmonic waveguide is optimized so that a plasmon is excited only in one direction, but a plasmon can not be excited in the opposite direction. Therefore, light can pass from input to output only in forward direction, but light is blocked in the opposite direction. A device, which is transparent only in one direction, is called the optical isolator. Figure 1(b) shows a top view of a Co / TiO_2 / SiO_2 plasmonic waveguides of different lengths integrated with a Si nanowire waveguides. Figure 1(c) shows the fiber-to-fiber transmission as function of wavelength for different lengths of the Co / TiO_2 / SiO_2 bridge-type plasmonic waveguide integrated with a Si nanowire waveguide. The measured propagation loss is 0.7 dB/mm and the measured coupling loss between plasmonic and Si nanowire waveguides is 4 dB per a facet. A metal is an essential material of a plasmonic waveguide. Any metal significantly absorbs light. Therefore, some optical loss is unavoidable in a plasmonic waveguide. In case if this loss is too large, all light is absorbed in plasmonic waveguide. Even if such plasmonic waveguide might have a unique property, it has no any practical use. Therefore, any practical plasmonic waveguide should have a reasonably-low propagation loss. It is known[3] that the propagation loss of the surface plasmons in a structure made of a ferromagnetic metal like Fe, Co or Ni is at least an order of magnitude larger than that of plasmons in structure made of Au, Ag and Cu, which are the conventional metals for the plasmonic devices. We have found that the in-plane and out-plane optical confinement are critically important in order to fabricate a low-optical loss plasmonic waveguide. When both the in-plane and out-plane optical confinement are well optimized, the propagation loss of a plasmon in ferromagnetic metal becomes even smaller (See Fig.1(c)) than the propagation loss in a conventional plasmonic waveguide, which is made of Au or Ag or Cu. The out-of-plane confinement is important because it minimizes the loss due to the absorption of light in the bulk of a metal. Since a metal absorbs light, the less light is inside of the metal and the more light is inside of the dielectric, the smaller propagation loss is. In a double-dielectric or multi-dielectric plasmonic structure, the thickness of one dielectric can be optimized so that the amount of light in the metal becomes smaller and the amount of light in the dielectric becomes larger. Additionally, in such structure a substantial enhancement of MO effect is observed[1,2,4,5]. The in-plane confinement is critically important because it minimizes the loss due to the scattering at a side edge of a plasmonic waveguide. Often a metal stripe is used for in-plane confinement of a plasmon (Fig.2 (a)). In this case a surface plasmon propagates just under the metallic stripe. Even though the fabrication of a stripe-type plasmonic waveguide is very simple, the propagation loss of a plasmon in such structure is very high. We have studied 3 types of in-plane confinement for a surface plasmon: groove-type[6], wedge-type and bridge-type (Fig. 2 (b)-(d)). All these types of the in-plane confinement are effective for the reduction of the propagation loss of a plasmon. The reduction is at least in 10 times comparing to the stripe confinement. The reason of the reduction of the propagation loss is that light is removed from the place of the metal edge. This work was partially supported by a Grant-in-Aid for Scientific Research (No. 16H04346) from JSPS.

AI-06. Area Efficient Multi Level Cell SOT-MRAM with Shared Diode for High Density Memories Applications.

K.A. Ahmed[1,2], L. Fei[1], S.Y. Lua[1] and C. Heng[2]
1. NVM, Data Storage Institute, Singapore, Singapore; 2. ECE, National University of Singapore, Singapore

Spin-orbit torque magnetic random access memory (SOT-MRAM) is considered as one of the most promising technologies to replace or co-exist with the current leaky CMOS charge based memories such as SRAM and DRAM, thanks to SOT-MRAM's non-volatility, high energy efficiency, endurance and reliability. However, conventional SOT-MRAM bit-cell [1] requires two access transistors to fully separate the selected bit from the non-selected bits, which limits the density of SOT-MRAM. Hence, in this work, we propose a diode based multilevel cell (MLC) SOT-MRAM with only one access transistor per 2-bits, which will at least double the density compared to various designs in the literature. Our proposed cell, shown in Fig. 1(a), employs a shared diode between two in-parallel MTJs to eliminate the need for a read transistor. The diode is oxide based, thus, it can be 3D stacked over the MTJs and does not consume any additional silicon area. The employed diode is unidirectional, where it conducts current only under forward bias. In SOT programming, the read transistor only needs to supply a relatively small unidirectional read current (10's of μA) during the read operation. Hence, the proposed shared diode can satisfy the requirements to replace the read transistor in conventional SOT-MRAM. The two MTJs are connected in-parallel and have different low (R_P) and high (R_{AP}) electrical resistances. Four different states could thus result based on their equivalent resistance. The four resistance states can thus be mapped into four different 2-bit configurations, i.e. '00', '01', '10' and '11'. The two MTJs are placed in-contact to a common heavy metal (HM) electrode that allows accessing the two MTJs (i.e. 2 bits) using only single transistor. The bias conditions for the different signals during read/write operations in our proposed cell are shown in Fig. 1(b). During the write operation, all the RWL signals are pulled low to ensure that the diodes in all cells are reverse biased and no leakage current would flow across the cells. In addition, the WWL of the row comprising the targeted cell is set high to activate the cell's write access transistor. To write a '0' ('1') on either of the MTJs, the BL and SL of the column comprising the targeted cell are asserted high (low) and low (high), respectively. This permits the write current (I_{write}) to flow through the HM electrode in the essential direction, as indicated in Fig. 1(a). It should be pointed out that to permit writing the two MTJs per cell with different data, the two SOT-MTJs are designed to have different critical currents (I_c). Hence, they require different switching time for the same supplied I_{write}. Writing the two MTJs with identical data ('00'or '11') is done simultaneously by passing I_{write} with one longer pulse width that follows the SOT-MTJ with longer switching time requirement, under spin charge conservation assumption. To program the 2nd bit differently, i.e. '01'or'10', I_{write} with shorter pulse width is sent subsequently. Due to the larger I_c of 1st bit, the 2nd write pulse would not vary the bit-content of 1st bit. SOT-MTJs with distinct I_c can be realized by either employing MTJs with different free layer thicknesses (t_{fl}) or using different widths of the HM (W_{HM}) below each MTJ, as both t_{fl} and W_{HM} have a direct impact on the SOT-MTJ's I_c. During the read operation, the WWL signals are pulled low to deactivate all the write transistors, allowing the read current to flow through the targeted MTJs by activating its corresponding RWL. Thereafter, the SL of the column comprising the targeted cell is set to ground, while its row RWL is connected to the sense amplifier to forward-bias the diode. Depending on combined resistance states of the two MTJs, four different currents level could be sensed by the amplifier, which can then be mapped into the corresponding 2-bit stored data. The proposed cell operation is validated in a 2×2 array as shown in Fig. 1(c). The simulations are performed using a Verilog-A model of a SOT-MTJ and a diode with a 32-nm CMOS technology library. As demonstrated in Table I, our proposed cell offers at least 50% smaller 1-bit effective area compared to other designs with nearly similar energy consumption. Furthermore, the in-parallel combination of the two MTJs results in lower overall equivalent resistance, which permits reducing the read voltage compared to design in [2] that uses a diode with single MTJ stack. In addition, an improvement of at least 30% in a figure-of-merit defined as energy area product is obtained compared to various designs.

AI-07. Rowhammer for Spin Torque based Memory: Problem or not?

S. Agarwal[1], H. Dixit[3], D. Datta[1], M. Tran[2], D. Houssameddine[2], D. Shum[2] and F. Benistant[2]
1. GLOBALFOUNDRIES Engineering Pvt. Ltd, Bangalore, India;
2. GLOBALFOUNDRIES Singapore Pte. Ltd, Singapore, Singapore;
3. GLOBALFOUNDRIES, 400 Stone Break Rd Extension, Malta, NY, United States

Rowhammer is a known security vulnerability in recent Dynamic Random Access Memory (DRAM) devices, where repeated access to an array of memory can flip the bits in the adjacent row owing to the charge leakage/capacitive coupling. Several studies have documented the Rowhammer effect [1,2] and Google's project zero demonstrates two working examples of a security exploit [3]. Furthermore, many published scenarios highlight that scaled DRAM below 32nm [1] is exposed to potential hacking attacks because of the Rowhammer problem [3], owing to reduced spacings in DRAM bits. Thus, it is only natural to test any new upcoming technology for a similar problem. Though the working mechanisms of DRAM and spin transfer torque magnetic random access memory (STT-RAM) are drastically different, whether the STT-RAM is also potentially vulnerable to an analogous Rowhammer effect or not is not documented or discussed in literature. While the mechanism of failure is high enough charge leakage in DRAM, the corresponding mechanism in STT-RAM may be the lowering of the thermal barrier because of the dipolar magnetic field exerted by adjacent selected bits. The lowering of the thermal barrier in turn can increase the probability of an erroneous bit flip. To ascertain whether the effect is substantial, nearest (A bit) and next nearest neighbour bits (B bit) adjacent to an unselected bit (O bit) are simulated as shown in Fig 1. The bit diameter is 55nm and the center to center bit spacing is 200 nm. The magnetic field at the O bit is simulated, when all the A and B bits have been assumed to have the magnetization pointing in the same direction. While this configuration does not necessarily conform to the conventional idea of selecting an adjacent row of bits or even both the adjacent rows (double sided hammering), it provides a scenario where the most favorable conditions for an erroneous bit flip can be evaluated in STT-RAM. Three magnetic layers are assumed in each bit separated by appropriate non-magnetic regions corresponding to the STT-RAM stack. The top most layer corresponds to the Free layer (FL) and can be flipped while the others are held fixed. While calculating the magnetic field at the O bit, the middle layer is assumed to have a magnetization opposite to the topmost and bottom layers. The other configuration in which the topmost layers is flipped and is parallel to the middle layer is known to give a smaller magnetic field. A magnetostatic calculation is done to determine the magnetic field at the site of the FL layer of the O bit. The average of the field over the entire volume of the O bit is evaluated as a function of bit spacing using magnetostatic calculations as shown in Fig 2. For the largest bit spacing of 200 nm the simulated field is only around 7 Oe while for a 100nm bit spacing it increases to 60 Oe. The analytical calculation assumes each magnetic layer in each bit to be a point. The vector sum of all of these at the location of the O bit is shown here. The discrepancy between the simulated and the analytical results increases as the bit spacing decreases. This is because of the assumption that each layer is assumed to be a point. To assess the impact of these fields, the string method is used to evaluate the energy barrier between two magnetic states corresponding to 0 or 1 stored on the O bit. Inset of Fig 2 shows that for a field of 7 Oe the change in energy barrier is less than 1 kT which is not large enough to cause an appreciable change in the bit error rate. For example based on Eqn 18 of [4] the bit error rate will only double for a 1 kT change in energy barrier assuming a retention time of 10 years and a relaxation time of 1 ns. Even for a bit spacing of 150 nm the increase in the BER will be less than an order of magnitude. However for a smaller bit spacing of 100 nm the BER can go up by 3 orders of magnitude. Therefore, as it stands rowhammer effect in STT-RAM does not appear to be appreciable at the 200 nm bit spacing. However at lower bit spacings the effect might become prominent and would require additional design rules to circumvent. As in the case of DRAM different techniques might have to be adopted to mitigate the problem.

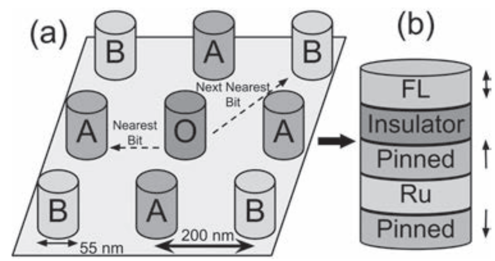

Fig. 1. (a) Schematic depicting the rowhammer configuration used to simulate the magnetic field at the unselected O bit. Both the nearest neighbour (A bits) and the next nearest neighbour (B bits) are assumed to have the Free Layer of the STT-RAM stack pointing in the same direction so as to maximize the magnetic field experienced at the central O bit. The centre to centre bit spacing is 200 nm while the diameter of a bit is 55nm. (b) The individual layers in the MRAM stack have been indicated where the FL and the two pinned layers are magnetic while the Insulator and Ru layers are not magnetic. The direction of magnetization is indicated with arrows.

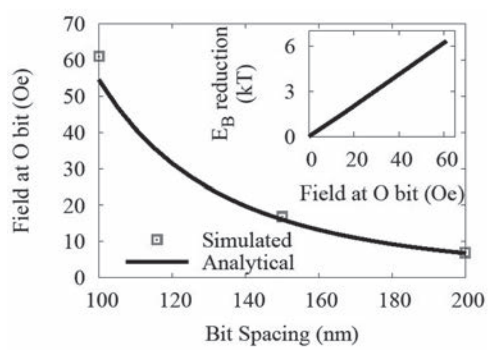

Fig. 2. Simulated and analytical fields observed at the unselected O bit are shown as a function of bit spacing. Simulated fields are computed using magnetostatic calculations. Analytical results are arrived at assuming each layer of the STT-RAM stack to be a point with a given magnetization. The inset shows how much the thermal energy barrier of the FL layer reduces as the magnetic field experienced by it from the surrounding bits is increased.

AI-08. Artificial neural network based on spin-wave coupled spin torque oscillators.

H. Arai[1,2] and H. Imamura[1]
1. Spintronics RC, National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Ibaraki, Japan; 2. JST-PRESTO, Kawaguchi, Saitama, Japan

Artificial neural networks (ANNs) are the key technology for machine learning involving deep learning, which can be applied in the fields such as object detection and recognition. Artificial neurons are constructed on the model focusing on biological behaviors of a neuron in brain. The integrate-and-fire model reproduces simple spiking behavior caused by external stimulations, and develops integrated circuits based on simple electronic devices [1]. The oscillation model is other neural model using periodic spiking behaviors of the biological neuron. In order to obtain highly integrated oscillators as processing units for ANNs, the size of the oscillator should desirably be of a nano-order scale. The important property required for artificial neurons in ANNs is to show nonlinear relation between input and output signals. The relation is called as activation function. The typical activation function in deep learning is the sigmoid function [2]. If a processing unit provides a sigmoid-like nonlinear relation between input-output signals, one can easily utilize the framework of computation of ANNs. In this study, we propose an ANN based on spin-wave coupled spin torque oscillators (STOs), providing sigmoid function-like input-output relation. We also perform a task-solving demonstration to recognize handwriting digits using ANN. Figure 1(a) shows a schematic illustration of an STO unit we propose, which is a laterally-long magnetic resistant device with double point contacts. The dc current induces the dynamics of the magnetization underneath the point contacts, m^L and m^R. The dynamics propagates spin waves between both point contacts which couples the dynamics of m^L and m^R. We propose in the following, the operation method of STO-based ANN processing unit. The STO receives an oscillating magnetic field (H_{ac}) as an input signal. The output signal from the STO is ac current, which produces the Oersted field (H_{Oe}) which is applied to the next STO unit. In order to yield the sigmoid-like input-output (H_{ac}-H_{Oe}) relation, we utilize out-of-phase oscillation for H_{ac}=0. By applying H_{ac} field to the out-of-phase oscillation state, the phase difference between m^L and m^R is varied. This result indicates the control of output ac signal from the STO unit, or H_{Oe} via H_{ac}. The out-of-phase oscillation appears by taking the Dzyaloshinskii-Moriya interaction (DMI) [3] on the free layer of the STO, as shown below. The magnetization dynamics is obtained by solving Landau-Lifshitz-Gilbert equation with the DMI being incorporated. We used micromagnetic numerical simulator, mumax3 [4]. The shape of a free layer is assumed as 2 nm wide, 40 nm long, and 1nm thick, with an one-dimensional magnetization chain. The effective field is the sum of exchange field and DMI, designated as A and D, respectively. The positive current is defined as the electrons flowing from the free layer to the reference layer. The magnetization of the reference layer (p) is fixed to the positive x-direction. Figure 1(b) shows the time development of the magnetization x-components of the contacts, m_x^L and m_x^R, with A=7 pJ/m, and D=0.8 mJ/m^2. As mentioned above, the out-of-phase oscillation is obtained where output signal from the STO is small. The oscillation frequency is about 4 GHz. Next, the oscillating magnetic field (H_{ac}) with 4 GHz frequency is applied to the free layer along y-direction. The phase difference is varied between m_x^L and m_x^R, which accordingly leads to obtaining output signal from the STO, m_x^{out}, as plotted in Fig. 1(c). The m_x^{out} is calculated by summing up m'^L_x and m'^R_x, where m'_x corresponds to an oscillating component obtained through a bias tee (BT) shown in Fig. 1(a). The phase difference depends on the intensity of H_{ac}. The amplitude of m_x^{out} after reaching a stable oscillation is plotted as a function of H_{ac} in Fig. 1(d). The curve looks similar to a shifted sigmoid function. We assumed H_{Oe}=c m_x^{out}, where c is constant, and found that the best performance was obtained for the following recognition task when c=90 Oe. We performed typical recognition task for ANN, using the handwriting digits recognition for MNIST database [5]. Figure 2 shows the structure of ANN with three layers. The first layer is the input layer with 784 nodes, receiving signals from normalized gray-scaled pictures with 28 pixels each side. The second (hidden) layer has 50 nodes. The last layer is the output layer with 10 nodes, corresponding to numbers from 0 to 9 digits. The back propagation is used for the learning algorithm. After learning, STO-based ANN with the activation function shown in Fig. 1(d), provides recognition accuracy of 75% on average.

2. Laboratoire Pierre Aigrain, ENS, Equipe THZ & Infrarouge, PARIS, France; 3. INAC/SP2M, CEA-Université Grenoble-Alpes, Grenoble, France; 4. Thales Research & Technology, Palaiseau, France

It was recently reported that THz emission can be realized in heterostructures composed of ferromagnetic (FM) and non-FM metal films *via* dynamical spin-to charge conversion originating from interfacial spin-orbit coupling or inverted spin-Hall effect (ISHE). Those phenomena are generally investigated through time-dependent spectroscopy (TDS) [1-3]. In that mind, we will present our last lattest results of THz emission provided by optimized grownth bilayers composed of a high-spin orbit material (Pt, Au :W) in contact with a thin ferromagnetic layer Co/Pt, NiFe/Au:W, NiFe/Au:Ta (Fig.1). Those bilayers state-to-the art bilayers model systems are also used in experiments combining RF-spin pumping and spin-to-charge conversion by ISHE [4-5]. Here These kind of experiments consist in exciting magnetization and spin-currents within the FM layer via femtosecond laser excitation and measuring, in the picosecond timescale, the relaxation of the correlated oscillating spin and charge currents or dipoles responsible for THz dipolar emission. According to the resutl results presented in Fig. 1, we see acn observe that the amplitude of TDS of our Co/Pt sample has the oder compete with the standard electro-optic (EO) delivered from ZnTe crystals, as known as « traditional conventional » material for THz [2-3]. It is very point because For potential applications, the main advantages of the THz spintronic emitters THz emitter based on magnetic hetrostructures are low-cost and the controle of the polarization of the emitted THz wave being easily tuned with an external magnetic field. In comparaison with Co/Pt systems, In NiFe/Au:Ta and NiFe/Au:W bilayers, the provide a smaller signalsignals is very small even though the spin Hall angles for Au:Ta and Au:W are larger than for Pt [6]. This is mainly due to their smaller spin-mixing conductance in comparaison with the optimized Co/Pt one. To understand this point, we will discuss the role of the generalized spin-mixing conductance on the spin-transport properties and spin-orbit torques involved in the time-dependent diffusion and relaxation phenomena. In Fig.2, we demonstrate that the THz signals strongly depend on the spin Hall angle of non-FM metal, spin diffusion length, and spin-mixing conductance. In the structures with large spin-mixing conductance and spin length diffusion, *e.g.,* Co/Pt, the THz signal is comparable to ZnTe signal. It should be a rapid method to know the characteristic of spintronics samples. Moreover, in order to study the SHE spin-current profiles in those $[Co,Ni]_N$/Pt and $[Co,Ni]_N$/Au:W multilayers, we have studied in the static regime, their the unconventional Anomalous Hall effect (AHE) properties showing up a characteristic AHE spin-inversion from Pt to Au:W samples by proximity effect. We analyze our results in the series of samples: the exact conductivity profile across the multilayers via the 'extended' Camley-Barnas approach [7] and the spin current profile generated by SHE. The values of spin Hall angles in layers are found: -0.2 for Pt (enhanced compared to CIP geometry), 0.01 for CoNi, and 0.1 for Au:W (resistivity). In $[Co,Ni]_N$/Pt sample, we show that the transverse current changes from negative (N<20) to positive (N>20) values.

1. National Institute for Materials Science (NIMS), Tsukuba, Japan; 2. JST-PRESTO, Saitama, Japan; 3. Tohoku University, Sendai, Japan

Introduction: Developing energy harvesting technologies is an urgent task for coming IoT to supply electric energy (μW-mW level) to the numerous sensors network independently. Thermoelectric power generation (TEG) is one of the important technologies to obtain electricity from various types of heat surrounding us, i.e. environmental heat, exhaust heat, body heat etc. In previous studies, it was proposed that there are many advantages to use anomalous Nernst effect (ANE) in magnetic materials for novel thermoelectric applications in comparison with conventional TEG using Seebeck effect.[1-4]. Because ANE generates the electric field to the outer product direction between magnetization and temperature gradient, we can expect to realize different types of TEG having high flexibility, cost-effectiveness, and expandability to large area heat source. However, because the reported anomalous Nernst coefficient S_{ANE} that determines the thermopower of ANE is less than 1-2 μV/K, it is necessary to explore magnetic materials showing one order of larger thermopower of ANE (few tenth μV/K) for realizing practical applications for energy harvest.[3] From the linear response expression of the electric field under temperature gradient, anomalous Nernst coefficient S_{ANE} can be expressed by the following equation, using diagonal and off-diagonal parts of resistivity tensor and Peltier tensor, suggesting that materials having the large Seebeck effect(α_{xx}), electric resistivity(ρ_{xx}) and anomalous Hall effect (AHE) (ρ_{xy}) are promising to obtain large S_{ANE}. It has been recently reported that antiferromagnetic material Mn_3Sn shows large anomalous Nernst effect because of its predicted large anomalous Hall effect due to significantly large Berry curvature[5], which is the result indicating the importance of large intrinsic anomalous Hall effect for large S_{ANE}. On the other hand, large intrinsic AHE has been also predicted in ferromagnetic Co-based Heusler compounds such as Co_2MnAl[6,7]. However, ANE in these compounds has not been ever systematically investigated. Because Fermi level of Co_2YZ Heusler can be controlled by changing Z element having different valence electron number, this group of materials is interesting to understand how Fermi level position affect the response of ANE. Therefore, in this study, we systematically investigated AHE, ANE, and Seebeck effect in $Co_2MnAl_{1-x}Si_x$ epitaxial thin films to observe large intrinsic ANE and also investigate the Fermi level position dependence of ANE. Experimental procedure : 30nm-thick $Co_2MnAl_{1-x}Si_x$ (CMAS) epitaxial thin films were deposited by a UHV magnetron sputtering system on (001)-oriented MgO single crystalline substrate at ambient temperature and then annealed at 500-700°C. CMAS films having a different composition ratio of Al:Si, x = 0 to 1, were prepared. ANE were characterized by giving the temperature gradient to in-plane direction and applying magnetic field to out-of-plane direction of the films (shown in the inset of Fig.1). Given temperature gradient ∇T was evaluated by IR camera with black body coating strictly. Experimental result : The structural analysis using XRD confirmed all CMAS films have epitaxial single phase. Monotonic increase of lattice constant was also observed with increasing Si composition ratio x. Figure 1 shows perpendicular magnetic field dependence of ANE signals normalized by temperature gradient ∇T and the sample width in the CMAS films annealed at 600°C. Interestingly, although Co_2MnAl shows the largest AHE as theoretically predicted[6], we found the largest ANE signal ever reported 4.2μV/K in $Co_2MnAl_{0.63}Si_{0.37}$. The systematical analysis by measuring AHE, ANE and Seebeck effect confirmed that large ANE in $Co_2MnAl_{0.63}Si_{0.37}$ originates from both large intrinsic AHE (not only large ρ_{xy} but also large α_{xy}) and large Seebeck effect. By increasing annealing temperature over 600°C, we found further enhancement of S_{ANE} in $Co_2MnAl_{0.63}Si_{0.37}$ film up to 6.2 μV/K at 650°C together with the improvement of $L2_1$ atomic ordering.(Fig.2) Our first principle calculations for the off-diagonal part of electric and Peltier tensors (σ_{xy} and α_{xy}) qualitatively well explained the enhancement of ANE from disordered B2 structure to ordered $L2_1$ structure in experiment. This result suggests a possibility to realize giant ANE due to intrinsic large Berry curvature, which opens up a way for realizing practical thermoelectric energy harvesting applications using magnetic materials.

Abstract Mutual synchronization of spin current driven nano-oscillators can both increase their output power and reduce their linewidth and is therefore a critical mechanism to reach sufficient microwave signal quality for actual applications. Here, we, for the first time, demonstrate two-dimensional *N* x *N* SHNO arrays (*N* = 2 – 10) of Pt/Hf/NiFe nano-constrictions, and observe robust mutual synchronization for *N* = 2 – 8 and partial synchronization in the larger arrays. Our results indicate that each nano-constriction interacts with its neighbors via both dipolar and exchange coupling. For the smaller arrays, the net coupling is strong enough to have robust mutual synchronization for nano-constrictions separated by up to 300 nm (pitch). However, to achieve robust synchronization in the larger arrays, the pitch size must be reduced to increase the coupling strength. Our results also indicate that neighboring nano-constrictions synchronize with a net relative phase shift, such that the initial rapid improvement of power and linewidth with increasing *N*, levels off for larger N and even deteriorates for of the largest arrays. Spin Hall nano oscillators (SHNOs) operate via the injection of a pure spin current into a ferromagnetic (FM) layer by passing a direct current through a non-magnetic (NM) heavy metal layer (e.g. Pt, W, Ta). The spin current exerts a torque on the local magnetization of the FM and can fully compensate the intrinsic damping to sustain a steady state precession of the magnetization around the local effective magnetic field. Some of us recently demonstrated robust mutual synchronization of chains of up to nine Pt/NiFe SHNOs [1]. Such chains can resemble the human brain where neurons interact with neighboring neurons through synaptic couplings resulting in a synchronization of their action potential activity. Synchronized networks have also been proposed for non-Boolean computing approaches such as bio-inspired neuromorphic computing with coupled oscillators [2-3] in which the synchronization frequency, the integrated output power, and/or the phase can be considered as the computation output. In this digest, we demonstrate 2D arrays of SHNOs fabricated in $Ni_{80}Fe_{20}$(30)/Hf(5)/Pt50) tri-layers (numbers in parenthesis indicate thickness in Å). Figure 1 shows a schematic of a typical device and a scanning electron microscopy (SEM) image of a 8 x 8 SHNOs array. An external magnetic field (H) was applied during the microwave measurements with an out of plane (OOP) angle θ and an in-plane (IP) angle ϕ as shown in Fig.1. The nano-constriction width was varied from *w* = 80 to 120 nm while the pitch size (*p*) in both the *x* and the *y* directions was set to 140, 200 and 300nm, to modify the dipolar and exchange coupling. Fig.2 shows auto-oscillation measurements for 2 x 2 and 4 x 4 SHNOs array (*w* = 300 nm and *p* = 300 nm). As can be seen, the oscillators within the array synchronize with increasing current and the integrated power increases while the linewidth decreases. However, for larger arrays with the same *w* and *p*, we could not observe complete synchronization (not shown). By reducing both the nano-constriction width and array pitch to *w* = 80 nm and *p* = 140 nm we are able to increase the nearest neighbor coupling in the arrays and demonstrate complete synchronization in arrays as large as 8 x 8 (Fig.2 (c)). It is however quite interesting that these large fully synchronized arrays do not demonstrate the same beneficial improvement in their power and linewidth as smaller arrays. We believe this is a result of a non-zero relative phase shift between neighboring nano-constrictions. While the total cumulative phase shift can remain small within the smaller arrays, it will eventually grow important as *N* increases, potentially leading to non-constructive addition of the individual nano-constriction signals. To benefit from very large fully synchronized SHNO arrays it will hence be important to reduce the relative phase shift between neighboring nano-constrictions. Our demonstrated SHNO array architecture imitates artificial neural networks in which neurons (individual construction within the array) communicate with neighboring neurons via synaptic connections. We believe that the synaptic coupling can be tailored through both the dipolar coupling and the direct exchange interactions between the array elements in the 2D SHNO arrays, where both can be tunable by the applied current, and the magnitude and angle of the applied field.

Histamine is a biogenic amine produced by microorganisms during the fermentation process of several food products such as fish, meat, cheese, vegetables, chocolate, beer, or wine. These amines are produced by bacteria during amino acids decarboxylation. The ingestion of high levels of histamine may cause serious toxicological problems on humans. In addition, 1% of the population is intolerant to it, displaying gastrointestinal symptoms, rhinitis or urticaria. For these reasons, it is important to set up a rapid method for the detection and quantification of histamine in food where fermentation takes place. Analytical techniques for its determination include liquid chromatography, enzymatic methods and ELISA immunoassays [1, 2]. These are efficient but expensive to be used at large scale, requiring centralized facilities and qualified analysts. An inexpensive quantification method that can be used by untrained individuals in non-laboratory environments would be very useful for industrial or personal usage. This work aims to develop a rapid, cheap, and simple test for the detection and quantification of histamine in wine. Competitive lateral flow immunoassays (CLFI) have been developed by using magnetic (iron oxide) and non-magnetic (gold) nanoparticles as labels. The CLFI signal read out is performed by a magnetic sensor sensitive to superparamagnetic particles [3,4] in the first case, and a commercial optical strip reader (ESE-Quant LR3 lateral flow system, QIAGEN) that quantifies the colour intensity of the gold line by reflectance measurements in the second one. Figure 1 schematises the design of the CLFI: the sample to be analysed flows by capillary along a nitrocellulose membrane across which two lines of bioreagents have been previously deposited. One of them is the test line on which a dense band of BSA-histamine complexes has been immobilised. The other one is the control line, composed by anti-IgG antibodies. At the beginning of the strip (left in the figure) there is a sample pad to absorb the sample and transfer it to the paper; at the right end there is a wicking pad with the role of drawing the sample off and prevent the backflow. The sample to be analysed is mixed with a monoclonal anti-histamine antibody in a test tube. The assay is as follows: 1. The sample is mixed with a fixed and known concentration of a monoclonal anti-histamine antibody. Binding of the histamine to those antibodies occurs. If the sample has no histamine (blank), the antibodies remain free. If the analyte concentration is high, all of them are bound. 2. The sample pad is introduced in the liquid sample (or a sample aliquot is deposited on it). The fluid flows along the strip and crosses the test line. At that point, only the anti-histamine circulating antibodies which are free (not bounded to histamine in the sample) attach to the immobilised complexes. In the blank sample, all of them are free. The larger the concentration of histamine in the sample, the smaller the fraction of retained antibodies. 3. To develop the assay the strip is immersed in a solution of protein G conjugated to the nanoparticles. This protein has a strong affinity for the Fc fragments of antibodies. Therefore, it specifically binds to the antibodies that had been captured in the test line. The labels reveal a signal (either coloured or magnetic) whose intensity is inversely proportional to the concentration of histamine in the sample. 4. The surplus of protein G-nanoparticle conjugates proceeds along the strip until it is trapped in the control line. This serves as verification of the correct performance of the test. Histamine was determined in the concentration range 10^{-6} to 10^{-1} mg/mL. The tests were applied to histamine detection in wine, and results were validated by comparison with those obtained by a liquid chromatography method. This concentration range is suitable for control of histamine in foods, and particularly in wine.

Magnetophoresis, which refers to the motion of an object in a magnetic field gradient, permits to address numerous biomedical applications when implemented in microfluidic devices [1-3]. The implementation of micrometer-sized soft magnetic structures is particularly beneficial in this context as it permits (i) to create large magnetic field gradients, and (ii) to modulate or even cancel the magnetic forces in order to release the trapped objects on demand. In order to achieve high concentration of magnetic flux, the soft magnetic material should combine a large magnetization and preferentially a high effective magnetic susceptibility χ_{eff}, to operate at relatively low magnetic fields, while maintaining no hysteresis loss. To overcome the technological challenges owing to heterogeneous integration of metallic material with polymers such as PolyDiMethylSiloxane (PDMS), as well as limitations related to pure metals micropatterning using time consuming, costly and complex UV-LIGA process, the approach of polymer-based composites is promising [4-6]. Here we focus on I-PDMS composites, made of the widespread PDMS polymer as a matrix and carbonyl iron particles as magnetic loads. PDMS properties are preserved such as soft-lithography micropatterning and O_2 surface activation for plasma bonding with glass and PDMS. Mass fractions of carbonyl iron particles as high as 83 wt% were achieved, which leads to saturation magnetization in the excess of 600 kA/m, which is comparable to benchmark soft magnetic metallic alloys such as Mumetal or Permalloy. In addition, the relatively easy microstructure engineering enables ones to tune magnetic properties. We recently reported on the effect of applying a magnetic field during the polymer reticulation in order to self-order particles in the polymer matrix [7]. High aspect ratio particle-agglomerates create a uniaxial magnetic anisotropy over the whole range of investigated compositions. Such composites can be exploited in different ways in microsystems: (i) at high concentration as a cost effective alternative to purely metallic micro-patterns or (ii) at low concentration, as arrays of individual magnetic flux micrometer sized concentrators. In highly concentrated I-PDMS the particles form ramificated chains oriented along the flux lines. It gives rise to 20% increase in the susceptibility as compared to composites with isotropic particle distribution. To study the impact on the generated magnetophoretic force, we developed a microfluidic channels with a wall made of I-PDMS. For one batch of devices we implemented isotropic I-PDMS and for the second batch anisotropic I-PDMS (see Fig. 1a). Microbeads flowing in the channel were submitted to different forces: magnetophoretic forces, fluidic drag force, gravitational force, and buoyancy forces. The motion of a magnetic bead in a laminar flow can be then described by the balance of forces. To measure the magnetophoretic force experienced by the beads for each batch of devices we used the following protocol. The channel was first filled up with beads. By stopping the flow rate, the initial position of the beads in the channel was defined. An external magnetic field was applied. The superparamagnetic beads were then attracted toward the I-PDMS composite wall of the channel. Fig. 1b displays a stacking of video frames revealing microbeads trajectories. From beads velocities measurements, we could map the magnetophoretic force in the channel. Fig. 1c shows the deduced force at different distances from the composite wall. At a distance of 150 µm from the microconcentrator, we measured a force reaching 60 pN using the anisotropic I-PDMS, a force twice as large as the one measured using isotropic composite. Based on the measured variation of the magnetophoretic force and on finite element simulations, we highlighted that the benefit of using anisotropic composite does not only rely on the global susceptibility increase, but also on local magnetic field gradients originating from its fine periodic microstructure [8]. In contrast, at low particle concentrations (1 and 5 wt%), the obtained microstructure is made of well-defined and isolated chains, as revealed by X-Ray Tomography (see Fig 2a). We observed two types of organizations: chain-like agglomerates and isolated clusters of particles concentrated at the bottom surface of the composite membrane. This leads to two populations of micrometer sized traps with average diameter of 1.5 and 6.7 µm, larger ones mostly corresponds to particle chains. We integrated 1 wt% and 5 wt% I-PDMS membranes in microfluidic systems and studied their magnetic trapping performances. Micrometer trap enabled to isolate magnetic beads and to organize them on large surfaces. Fig. 2b reports microscopic images of microfluidic channel integrating a trapping membrane (1 wt%), before and after beads injection at 250 µL/h. We tested the persistence of trapping when increasing the flow rate. Using 5 wt% composite, 50 % of beads remain trapped at 2 mL/h. We have also shown that these dense arrays of traps permit to create a monolayer of beads, with a density of 1200 beads/mm^2, 89 % of large traps being occupied. This original array of magnetic flux concentrator is promising as the implementation is quite simple while it permits to address biological characterization that require the controlled immobilization of a target population, such as drug assays.

3. Faculty of Mathematics and Physics, Charles University, Praha, Czechia

The transverse relaxivity r_2 of contrast agents for MRI describes their efficiency to shorten transverse relaxation times T_2 of ^{1}H nuclear spins of nearby water molecules, and thus the contrast media with high r_2, typically magnetic nanoparticles, are used as so-called negative contrast agents for T_2-weighted images. The role of magnetic particles consists in creating of inhomogeneities in the applied magnetic field, which leads to a loss of phase coherence of precessing ^{1}H spins. The magnitude of this effect is treated by theoretical models (see, e.g. [1]) that take into account both the fundamental properties of magnetic particles and self-diffusion of water, suggesting several distinct regimes of relaxation. In the present contribution, several distinct types of magnetic particles are prepared, and temperature dependences of the transverse relaxivity are analysed and compared with the theory. Four types of magnetic nanoparticles were synthesized, namely $La_{0.65}Sr_{0.35}MnO_3$ (LSMO) and $La_{0.80}Na_{0.20}MnO_3$ (LNMO) manganites with perovskite lattice (R-3c) and $Mn_{0.61}Zn_{0.42}Fe_{1.97}O_3$ (MZFO) and $Co_{0.44}Zn_{0.70}Fe_{1.86}O_4$ (CZFO) ferrites with spinel structure (Fd-3m). The manganites were prepared by a sol-gel process followed by thermal treatment and mechanical processing (for LSMO see [2]). Ferrite particles were synthesized under hydrothermal conditions (for MZFO see [3]). All four materials were coated with silica (denoted by @ silica) by using tetraethoxysilane. In addition, two other surface modifications were employed for MZFO particles. Titania-coated nanoparticles (MZFO@TiO_2) were achieved by a procedure similar to encapsulation into silica but titanium tetrabutoxide was used as a precursor. Further, citrate-stabilized nanoparticles (MZFO@cit) were obtained by chemisorption of citric acid and subsequent ionization by ammonia. XRD measurements of bare particles evidenced single-phase character of all products. The Rietveld analysis of peak broadening provided the mean crystallite size of 23-31 nm for manganite nanoparticles, and 11 nm for both the ferrite samples. TEM study confirmed typical core-shell structure of silica-coated particles and uniform thickness of the shell with the mean of ≈15-20 nm. The magnetic cores of silica-coated particles were formed by small clusters of crystallites, the mean core size was ≈50 nm for manganites and 26-31 nm for ferrites (i.e. several crystallites were present in an average magnetic core). The image analysis of MZFO@TiO_2 was not straightforward but TEM analysis evidenced larger particles. And DLS measurements provided comparable data (z-average hydrodynamic size 1.8 × larger for MZFO@TiO_2 than for MZFO@ silica). Magnetic behaviour was analysed based on hysteresis loops at 5 K and 300 K (see Fig. 1), ZFC-FC susceptibility studies and temperature scans of magnetization at 0.5 T (see Fig. 2). Shortly, the manganite systems showed ferromagnetic ground state with magnetic moments of spontaneous ordering of 2.28 μ_B and 1.63 μ_B per f.u. at 5 K and Curie temperatures T_C of 352 K and 309 K for LSMO and LNMO, respectively. The ferrimagnetic arrangement of MZFO and CZFO was characterized by 4.55 μ_B and 2.64 μ_B at 5 K and T_C of ≈425 K and 345 K, respectively. Aqueous suspensions of coated samples with concentrations determined by chemical analysis were subjected to relaxometric study at 0.5 T (Fig. 1b). The relaxivities of silica-coated particles correlated well with the magnetization of cores at a given temperature (see magnetization data at 300 K in Fig 1a), and high relaxivites were observed especially for particles based on MZFO and LSMO. The role of different relaxation regimes was analysed based on the temperature dependences $r_2(t)$, normalized using the values of r_2(6°C). The data were compared with similarly normalized dependences of certain quantities, namely the self-diffusion coefficient of water $D(H_2O)$ according to [4], the magnetization M of bare particles at 0.5 T, and the expression $M^2/D(H_2O)$ (Fig. 2). The last quantity describes the temperature dependence of r_2 in the motional averaging regime (MAR), whereas the temperature dependence in static dephasing limit (SDL) is shaped only by $M(t)$ [1]. Generally, the observed dependences were found within the limits given by MAR and SDL. The behaviour of silica-coated ferrite samples was closer to MAR, whereas CZFO@TiO_2, containing larger clusters, seemingly approached SDL. The LNMO@silica exhibited the most pronounced dependence of $r_2(t)$ due to a rather sharp FM-PM transition. Nevertheless, more thorough analysis revealed considerable limits of the traditional model and indicated a possible role of thermally activated processes related to chemical exchange of ^{1}H.

Abstract: In the development of noble gas MRI in humans, the traditional single-tuned transmit coil does not suitable for imaging acquisitions. This paper presents a novel radio frequency(RF) coil design method for applications of 1H/3He MRI system at the ultra-low field of 0.06mT.For the complex model of the dual-tuned 1H/3He coil, the traditional Electromagnetic(EM) simulation is not applicable due to its long computing time, the EM field and radio frequency (RF) circuit co-simulation method thus is implemented to accelerate the analysis, which results in an effective evaluation. The simulation results show that the proposed model has the potential for imaging of lung with 1H/3He MRI system at the ultra-low field. 1 Introduction : MRI as a non-invasive imaging method plays an important role in medical imaging for diagnosis of various diseases. Conventional clinical MRI is mainly based on proton imaging, which shows limited MRI signals in lung imaging due to its specific tissue structures. With the development of the noble gases polarized technique, some gases such as 3He and 129Xe can be applied in MRI and fMRI for diagnosis of lung disease at low field[1-2]. In the conventional MRI system, the transmit coil is usually designed with single frequency for proton imaging[3-5].Currently, the development of dual- tuned transmit coils are mainly for 1H/31P/19F/13C nucleus[6-7].The 1H/3He dual-tuned coil at low field for MRI imaging of different organs has not been intensively studied. For the construction of RF coils in MRI, the traditional electromagnetic(EM) simulation is usually implemented with advanced numerical algorithms such as the boundary-element method (BEM)and finite-element method(FEM) to get the distributions of magnetic field and the component values in the circuit of the coils[8-11].However, the simulation speed is really slow for the complex coils with multiple ports. In order to reduce the simulation time, the EM field method and RF circuit co-simulation method is applied[12-13]. To implement noble gas 3He lung MRI on a permanent magnet open MRI system at 0.06mT, a novel 1H/3He dual-tuned quadrature transmit coil has been designed and simulated by EM field method and RF circuit co-simulation method. The performance of the proposed coil was evaluated in the aspects of the homogeneity of the transmit magnetic field and the Specific Absorption Rate(SAR) of energy in human body[14]. 2 Materials and methods : The coil system consists of four butterfly-shaped elements[7].The coils 1,3 excite 3He(coils 2,4 excite 1H). The working frequency is 1.94 MHz for 3He(2.5548 MHz for 1H)corresponding to 0.06 mT.Fig.1(a) shows the structure of coil (d1=80 mm, d2=220 mm,l1=490 mm,l2=830 mm). The distance between each two coils is 20 mm(coils 1,2;coils 3,4), and 420 mm for the opposite coils(coils 1,3;coils 2,4)(See Fig.1(b)(c)). All coil elements are made of copper with thickness of 0.1 mm. A cubic phantom(400×770×300 mm^3)was selected to simulate human body, it was placed in the center region. The co-simulation approach was conducted by using the commercial CST(Computer Simulation Technology Darmstadt, Germany) software. In the simulation, the boundaries of RF coil model were set to "open". The distance between phantom and background was 500 mm, the bandwidth was 1~50MHz, and the total number of mesh cells was 6438700.Each coil had an independent tuning/matching/detuning circuit. The Lamour frequency of 1H and 3He at the ultra-low field of 0.06mT was tuned by adjusting capacitors C1,C2. The input impedance of coils was matched to 50 Ω through the matching capacitor Cm. The ports were excited with Gaussian pulses. The coils were tuned by changing the capacitance in RF circuit and combining the individual EM field based on the tuned data of the external ports in order to obtain the EM field. The B_1+ is denoted as transmit magnetic field was calculated as: B_1+=u(Hx+ iHy)/2; The homogeneity of B1+ field was calculated as: $B_1{}^+{}_{homogeneity}=(B_1{}^+{}_{max}- B_1{}^+{}_{min})/(2B_1{}^+{}_{mean})$; The transmit efficiency in ROI was calculated by: Transmit Efficiency=$B_1{}^+{}_{mean}$/Total SAR; 3 Result After decoupling, both S11 and S22 reached −30dB or higher, S13 and S24 also measured about−30dB.According to B1+ field distribution and the part of thoracic cavity located in body, the ROI was selected as cuboid area (See Figure 2). At the same scale, the B1+ field is strongest when signal source of the coils 1 and 3(the coils 2,4) have the same phase. With the increasing of phase difference, the field strength is gradually weak, but the $B_1{}^+{}_{homogeneity}$ in the ROI is basically unchangeable(See Fig.2). As phase difference is increasing, the transmission efficiency is increasing for 3He, while it is decreasing for 1H. 4.Conclusion In this paper, EM field and RF circuit co-simulation method was applied in designing of a novel 3He/1H dual-tuned quadrature transmit coil for noble gas 3He lung MRI applications at ultra-low Fields. Simulation work has been conducted to validate the proposed coil design. The results showed that phase delay of both 3He and 1H is chosen as 90° to ensure a high strength of B1+ field, a great field homogeneity and a relatively large transmission efficiency. The homogeneity in the ROI was well under various phase delays, which shows the applicable of the dual-tuned transmit coil.

AP-05. Peak to Peak Voltage Detector Type MI Gradiometer for Real Time Alpha Rhythm Measurement.

J. Ma[1] and T. Uchiyama[1]
1. Graduate School of Engineering, Nagoya University, Nagoya, Japan

1. Introduction As the source of all our thoughts, emotions and behaviors, the brain activities play a very important role in our life. The brain activities have attracted considerable attentions in medical & healthcare area, and engineering application. Some disease and injuries can be diagnosed by analyzing the brain activities, such as tumors, epilepsy, and neural damage [1]. Magnetoencephalogram (MEG) is a non-invasive technique for mapping and evaluating the functional activity of brain. According to the previous studies, the MEG has been demonstrated to have better spatial resolution than EEG, as the skull and scalp are not very good conductors, magnetic field change is less distorted than voltage change. On the other hand, the magnetic field produced by neurons of brain is extremely weak. It is commonly measured by Superconducting Quantum Interference Devices (SQUIDs) which is the most reliable sensitive magnetometer for MEG measurement. However, the SQUIDs are still threatened by the need of cryogenic cooling liquids and a shielding room. The high-cost and large-scale of SQUIDs result in pressure to develop some miniature, low-cost, and highly sensitive magnetic sensor systems for MEG measurement [2, 3]. As one of the spontaneous neural oscillations in the frequency range of 8-13 Hz, the alpha rhythm is generally associated with relaxed wakefulness, drowsiness period and REM sleep stage, whose amplitude is stronger when one is relaxed but alert. Meanwhile alpha rhythm can be identified at a maximum amplitude when the eyes are close, over the occipital region [2, 4]. In this study, we have developed a peak to peak voltage detector type MI gradiometer (shortened: Pk-pk VD-type MI gradiometer) for real time MEG measurement. Meanwhile, we have demonstrated the real time alpha rhythm measurement, with simultaneous measurement of EEG. 2. Pk-pk VD-type MI gradiometer For measuring extremely weak magnetic field such as a bio-magnetic field, we have to cancel the background uniform noises such as geomagnetic field. We have developed the Pk-pk VD-type MI gradiometer based on the pk-pk VD-type MI magnetometer reported recently [5]. The new MI gradiometer is composed of a pair of MI elements: a sensing element and a reference element with distance between elements of 3 cm. we have achieved a high sensitivity of 1.4×10^{7} V/T with good linearity and a low noise level of 2 $pT/Hz^{1/2}$ in 1-100 Hz range, 3. Alpha rhythm measurement In this study, MEG measurements of spontaneous brain activity (Alpha rhythm) are carried out on a female subject (aged 24), by using the Pk-pk VD-type MI gradiometer. We set up the Pk-pk VD-type MI gradiometer system in a shielded room, with the simultaneous measurement of EEG. We study the visual alpha rhythm, which presents in the 8-12 Hz range. The subject lies on a comfy bed in a state of relaxed wakefulness, in a shielded room. The sensor head is placed 5 mm apart from the scalp of the subject, on the occipital region, at the point between O1 and O2 of the international 10-20 system. We record the MEG and EEG signals from 44 s to 60 s, by the Pk-pk VD-type MI gradiometer and EEG device, with a 7-15 Hz bandpass filter. The subject lies with eyes open during the first 8 s of the recording (44s-52s). Then, the subject is instructed to close her eyes for the remaining 8 s of the recording (52s-60s). As illustrated in Fig. 1, the time-frequency analysis is applied to both raw recordings (MEG and EEG recordings). The time-frequency spectrograms of EEG recording and un-averaged Pk-pk VD-type MI gradiometer recording are shown in Fig. 1(a) and (b). Of note is that both the Fig. 1(a) and Fig. 1(b) show a marked enhancement of alpha rhythm between first 8 s and remaining 8 s. As expected, the alpha rhythm signals simultaneously measured by EEG and MI sensor are significantly attenuated when the subject opens eyes, and intensified with eyes close. As shown in Fig.1 (b), the MEG signal of alpha rhythm for this subject has main frequency components at 10-11 Hz with a maximum amplitude of approximately 25 $pT/Hz^{1/2}$. For further demonstrating alpha rhythm measurement by MI sensor, we investigate the spectral density of alpha rhythm signals simultaneously measured by EEG and MI sensor in eyes opening and closing. As illustrated in Fig. 2(a) and (b), the spectral density of both MEG and EEG alpha rhythm recording significantly decrease with the subject's eyes open, in 8-12 Hz range. Furthermore, the Fig. 2(c) illustrates the sum power spectrum level of MI sensor recording with the subject's eyes open and close. According to the results shown in Fig.1 & 2, the considerable enhancement of alpha rhythm in the 52-60 s range further evidences the signals recorded are emanating from spontaneous brain activity. In this paper, we have developed a Pk-pk VD-type MI gradiometer for real time alpha rhythm measurement. We have achieved a clear sensitivity for spontaneous brain activity with SNR of about 8.

AP-06. A Theoritical and Simulational Study on the Chemical Shift Effects on the Magnetic Susceptibility of Iron at Ultra-Short Echo Times.

X. Lu[1], J. Zhu[1], Z. Wang[1], S. Wei[1], H. Wang[1] and W. Yang[1]
1. Institute of Electrical Engineering, Chinese Academy of Science, Beijing, China

1. Introduction Magnetic Resonance Imaging(MRI) has been proven to be important for in vivo quantitative characterization of iron deposition, either endogenous or exogenous(Iron Nanoparticles, IONPs). Iron has endogenous paramagnetic characteristics, and causes shortened T1, T2, and T2* relaxation times as well as phase and susceptibility changes by affecting the magnetic environment of water protons [1-2]. Among all the quantitative MRI methods, quantitative susceptibility mapping (QSM) has gained increased interest as iron is paramagnetic, leading to a linear increase in susceptibility with iron concentration. 2017, it has been shown that the iron could be quantified by both QSM and R2* to a range as high as 22 mM by using ultra-short TE(UTE) technics[3]. However, for in vivo study environment, as fat is an essential contents exists everywhere in human body, the chemical shift effects caused by fat will cause severe streaking artifacts in the QSM results and make the quantification failure[4].The H protons of fat, are nestled within long-chain triglycerides and covered by electron clouds. These clouds partially shield the fat protons from the full effects of an externally applied magnetic field. It is still unknown how much the fat will effects the MRI phase signals with UTE acquisitions, as at a very short TE, the chemical shift effects caused phase shift could not be very obvious. In this study, simulation study was performed to evaluate the chemical shift effect on the quantification of the magnetic susceptibility with UTE sequences based on a fat combined susceptibility-phase change model. 2. Method and Results To study the magnetic susceptibility changes that comes from fat, a relationship between the chemical shift from fat and the frequency changes caused from the background magnetic susceptibility(x) is established as shown in Equ 1. $S_{fat}(t) = m((1\text{-}ff)+ff^{*}\sum\alpha_n exp(\text{-}i2\pi f_n t))exp(\text{-}t/t_2{}^{*})exp(\text{-}i\gamma\delta Bt)$, $\delta B = conv(\chi,D)$ *(1)* Where, $t_2{}^{*}$ is the transverse relaxation time and χ is the magnetic susceptibility of the irons. The phase change of the MRI signal is come from the background field change δB, which is the convolution between the susceptibility χ and magnetic dipole D. For MRI signals with fat, a multi-peak fat model were used in this study by adding a frequency shift with different fat comports, as shown in equ 1, ff means fat fraction. A numerical phantom for simulation was designed. For each study, six spheres in a ring have different magnetic susceptibility (2, 4,6,8,10,12 ppm) but the same fat fraction. By changing different fat fraction and then the QSM performance are different as shown in fig 1, where fat fraction are 0, 0.1,0.2,0.3,0.4,0.5,0.6,0.8 correspondingly. Signal were obtained at a ultra-short TE combination(TE1= 0.032ms, dTE = 0.1ms). As can be seen in fig 1, the streaking artifacts become more severe when the fat fraction increases even at UTE. Fig 2 shows the phase of different fat fraction when acquisition time is 0.332 ms. For the first row images, the phase differences between different fat fraction is not obvious, but for the second row, where all the phases are subtracted by the first one that without fat(ff=0), it could be easily observed that the phase increases when the fat fraction increases. 3. Discussion and Conclusion In this study, simulation studies were performed to verify the chemical shift effects on the UTE QSM. Several factors were considered, such as the TE times, fat fractions, etc. It could be concluded from the simulation results that the streaking artifacts becomes more and more severe when the fat fraction becomes greater, even when TEs are very short. Furthermore, the streaking artifacts should be the phase difference caused by the chemical shift of fat. This study issued a huge challenge for the quantification of high concentrated iron with QSM especially for irons that is adjected to fat. Because at the very short echo times(<0.5ms), the fat effects cannot be easily removed by traditional method, such as IDEAL, which has requirement on the TE interleaves(>0.8 ms). In the future studies, we will take efforts to find ways to eliminate the chemical shift problems when using UTE. *Acknowledgement* This work is supported by National Natural Science Fundation(NSFC 51607169).

AP-07. Magnetic-Fluorescent Fe_3O_4@Chitosan-Graphene Quantum Dots Nanocomposites for Dual-Modal nanoprobes of Fluorescence and Magnetic Resonance Imaging.

Y. Li[1], K. Wang[1], X. Xu[1] and Y. Jiang[1]
1. University of Science and Technology Beijing, Beijing, China

The recent development of nanoprobes with multiple functionalities has attracted considerable interests for various biomedical applications.[1] The Fe_3O_4 Nanoparticles (NPs) are superparamagnetic and usually used as magnetic resonance imaging (MRI) contrast agents. The graphene quantum dots (GQDs), a new zero dimensional graphene nanomaterial, exhibit tunable photoluminescence property, excellent stability and biocompatibility. If the Fe_3O_4 NPs and GQDs can combine together, the composites are expected to be dual-modal nanoprobes of fluorescence and MRI. In this work, we study on the Fe_3O_4@chitosan-graphene quantum dots (Fe_3O_4@CS-GQDs) NPs which are demonstrated to be a fluorescence and MRI contrast agent. The Fe_3O_4 NPs were fabricated by hydrothermal synthesis and had an average diameter of 9 nm. Next, the Fe_3O_4 NPs were dispersed in chitosan solution to obtain the Fe_3O_4@CS NPs. Then, the Fe_3O_4@CS-GQDs NPs were synthesized by crosslinking between carboxyl groups of GQDs and amine groups of Fe_3O_4@CS.[2] The magnetic property and fluorescence of Fe_3O_4@CS-GQDs NPs were characterized by vibrating sample magnetometer measurements and photoluminescence (PL) spectroscopy. As shown in Figure 1a, the magnetization hysteresis loop shows a near zero coercivity, indicating the superparamagnetic property of Fe_3O_4@CS-GQDs NPs. The PL spectrum of Fe_3O_4@CS-GQDs NPs shown in Figure 1b exhibits a emission peak at 434 nm, which is under the excitation of ultraviolet 350nm. These results show that the Fe_3O_4@CS-GQDs NPs have both fluorescent emission and superparamagnetic properties. The T_2-weighted MRI of Fe_3O_4@CS-GQDs NPs were taken on a 3 T clinic MRI scanner. As shown in Figure 2a, the T_2 signal intensity decreased significantly with increasing Fe concentration, which indicates the Fe_3O_4@CS-GQDs NPs to be a promising contrast agents for MRI applications. To investigate the biocompatibility of the nanoprobes, the cytotoxicity of Fe_3O_4@CS NPs and Fe_3O_4@CS-GQDs NPs on Hela cells were studied with an MTT assay. According to Figure 2b, the viability of Hela cells is higher than 80% after 48 h of incubation with 50 μg/mL Fe_3O_4@CS NPs and Fe_3O_4@CS-GQDs NPs. Therefore, the Fe_3O_4@CS-GQDs NPs were demonstrated to be a potential dual-modal MRI contrast agent and fluorescence probes with high biocompatibility.

Abstract In this paper, an asymmetric gradiometer system is designed to measure the magnetocardiograms without magnetic shielding environment. The gradiometer mainly included three-dimensional second-order gradient coils, and a three-dimensional SQUID magnetometer, which can configurate a 4-channel magnetocardiography measurement system. The asymmetric second-order gradient coil can be used to eliminate different gradient magnetic noise in the environment. The design of a 3D gradient coil can not only measure magnetic field information in the Z direction but also the X-Y direction. The 3D SQUID magnetometer can be used to compensate the additional noise caused by the area and parallel error because of the process of winding gradient coil. The measurement system contained nine low-temperature dc SQUID sensors and can measure the human magnetocardiograms signal without shielding. I. INTRODUCTION The magnetocardiograms which is only about 10^{-12} Tesla is much weaker than environmental magnetic field[1]. So how to curb environmental noise is a key technology problem in magnetocardiograms measuring. The mainly method is to build a high performance magnetic shielding room which can reduce the environmental field value into an acceptable range[2]. On the one hand, such magnetic shielding room is expensive, about $1 million or so. On the other hand, the shielding chamber limits the mobility of the magnetograph. Therefore, this method greatly restricts the development of magnetocardiograph[3]. So, it is very important to carry out the magnetocardiograms measurement technology without shielding environment magnetic. At present, the main method is to manually winding the hardware gradiometer on the coil rack with high machining accuracy, or using SQUID magnetometer and digital signal processing technology to build software gradiometer[4]. However, the manually winding gradiometer must generate area and parallel errors which increase the additional environmental noise. Therefore, it is necessary to combine the triaxial magnetometer measuring environmental noise to compensate the analysis and eliminate the errors[5]. Finally, the magnetocardiograms measuring is realized in the environmental magnetic field. II. DESIGN OF THE GRADIOMETER SYSTEM If the environmental magnetic field is homogeneity, such as the geomagnetic field or the far radio-frequency field, it can be eliminated by a first-order gradiometer. But the electromagnetic environment of the laboratory is relatively complex, and there are a lot of first-order gradient fields[6]. It is necessary to use the second-order gradient to suppress both of the uniform and first-order fields. On the other hand, the Z direction measurement of the magnetocardiograms that are perpendicular to the chest does not reflect all the information of the heart activity, sometimes we have to separate multiple sources overlapping time when cardiac tissues are active[7]. Therefore, a 3D second-order gradient coil is designed in this paper. By measuring the magnetic field information in the X-Y direction, it can help to locate the overlap sources of the heart in Z direction. The coil is shown in figure 1 with a size of 29mm x 29mm x 58mm. The dotted line arrow in the Z axis points to is the asymmetric second-order gradient coils we designed. By trial and error, the optimal baseline proportionis adjusted at 50%, 62.5%, 75% or 87.5% to better eliminate different gradient environmental magnetic fields and improve system sensitivity. Let's suppose that the magnetic field at the bottom of the gradient coil is T(x,y,z). The bottom half of the baseline is the length of the Δz and the upper half of the baseline is 58-Δz, so the gradient value T_g of the asymmetric gradient coils in the Z direction is, $T_g= T(x,y,z)-2T(x,y,z+\Delta z)+T(x,y,z+58)$. (1) Where the Δz can chose 29mm, 36.25mm, 43.5mm and 50.75mm. In order to improve the detection efficiency, three 2th-order gradient coils are also made, and the 4-channel magnetocardiography system is realized. All parts of the gradiometer system are shown in figure 2. The bottom layer is the four gradient coils which are winding on the polyimide coil rack by 200μm diameter titanium superconducting wires. In the middle layer is cryogenic SQUID sensors, the top layer is a 3D SQUID magnetometer. All of the sensors were made by Supracon AG, GERMANY. Suppose the output of the 3D magnetometer are B_x,B_y and B_z, and the gradiometer output in the Z direction is T_z. We can get that, $T_g=T_z-\alpha B_x-\beta B_y-\gamma B_z$ (2) Through the theoretical calibration value T_g and the actual measured value T_z, the regulation coefficient α,β and γ can be obtained. By formula (2), we can calculate the ideal magnetic signal, and finally get the magnetocardiograms. III. CONCLUSION The gradiometer system designed in this paper has the following characteristics. a. 3D gradiometer design can isolate multiple source overlaps in Z direction. b. Asymmetric second-order gradient coil design can more accurately suppress the environmental magnetic field gradient. c. By using the 3D SQUID magnetometer, it can be compensated the additional noise caused by the area and parallel error because of the process of winding gradient coil. Nuclear magnetic resonance (NMR) measurements in low-fields (0.01-0.1 T) brings the challenge of low signal to noise ratio caused due to fewer spin transitions [1,2]. Despite this challenge, earlier NMR measurements have been performed in the Earth's magnetic field [3], using stray fields [4] and using unilateral magnet geometries [5,6]. In this work, an alternative method of low-field unilateral NMR measurements will be demonstrated. Experimental measurements using a ring magnet, as a unilateral field source and a pulsed field excitation system [7] will be presented. As in conventional NMR instruments, uniform bias fields are first used to pre-align the spins within the sample and pulsed fields are then used to initiate the conditions of magnetic resonance. The pre-alignment field dictates the precession frequency of the magnetic spins [2] and a spatially larger region can be detected with ease if all the magnetic moments in the region are precessing at the required resonant frequency. In this work, finite element simulations were used to initially estimate the pre-alignment magnetic field in the vicinity of a cylindrical ring magnet. A small region of uniform magnetic field forms away from the magnet surface. This region, commonly termed as the "saddle point", was found to be located at a distance equal to the inner radius of the ring magnet. Saddle points will occur at locations where the field is maximal in one direction and minimal in another. For cylindrical ring magnets, the saddle point occurs when the field is maximum in the z direction and minimal in the r (radial) direction (Figure 1, saddle point is the peak), thus, at a point exterior to the magnet. All test samples can be placed at this location. On identification of the saddle point, different simulations were then performed to verify the effect of varying the magnet geometry such as the height, inner and outer radii on the saddle point's location. The simulation results show that the inner radius greatly affected the location of the saddle point (Figure 2). The outer radius contributed to an increased magnetic flux density at the saddle point. In our experiment, an outer radius of 0.5-1 inch was selected to achieve increased portability of the designed system. Finally, it was found that beyond a certain height, the improvement in static flux density at the saddle point was minimal. The static flux density at the saddle point was further used to obtain an estimate of the NMR voltage signal based on the precession frequency of protons (H). The estimated NMR voltage is directly proportional to the square of the static field strength and the coil sensitivity that depends on the pulsed field strength [8]. Therefore, an efficient combination of the two interacting fields is required to achieve the highest NMR voltage at the saddle point. Through this work, a systematic analysis and development towards designing portable NMR systems based for examining localized targets will be achieved. Incorporating the estimations from the simulation results, NMR measurement results and design considerations for the magnet and the coil will be presented.

AP-10. Noise reduction in magnetocardiograph based on time-shift PCA just using measurement data.

M. Iwai[1] and K. Kobayashi[1]
1. Science and engineering, Iwate University, Morioka, Japan

Background Magnetocardiograms (MCGs) have become increasingly relevant for clinical research, due to its potential to detect early stages of heart disease. However, it is difficult to assess heart activity precisely without some form of noise reduction, because MCG measurements are extremely small compared to environmental magnetic noise. One of solutions that can suppress the noise is the use of a digital signal processing (DSP) method. The finite impulse response (FIR) filter is a well-known method in reducing noise via DSP. However, FIR filters have various issues such as distorted waveforms, generation of phase differences, and reduced signal peaks. Hence, a noise reduction method using a time-shift principal component analysis (PCA) [1], [2], [3] is considered. This method reduces noise by subtracting reconstructed noise by reference data from measurement data. This method has to need reference sensor, so this method cannot use without reference sensor system. We propose a new time-shift PCA method without reference sensor in order to apply the time-shift PCA without reference sensor systems. *Methods* The proposed method has same basic process as the conventional time-shift PCA [1]. Difference from the conventional method is adding the process to reconstruct reference data from measurement data. The method to reconstruct reference data can be summarized as follows. First, apply PCA to measurement data. Second, sort the principal components according to the ordering provided by kurtosis order. Third, select the principal components with lower values of kurtosis (Selected number is arbitrarily). Fourth, apply inverse PCA to selected principal components for reconstructing reference data. The reason why we use kurtosis order in this method is that the principal components represent the noise have low values of kurtosis [4]. After this process, we apply the conventional time-shift PCA by using reconstructed reference data. *Simulation* Simulations were carried out in this study with considering time-shift point and that noise reduction accuracy. In this simulation has used the simulation data that were mixed with the MCG signal data and the noise data with signal-to-noise ratios (SNRs) of 0 dB, -10 dB and -20 dB [4]. In this simulation, the reference data was reconstructed from measurement data, and then we assumed that reference sensors are at the four corners in measurement positions and we evaluated the noise reduction accuracy with correlation coefficient between the MCG signal data and the signal processed data. *Simulation Results* The noise reduction accuracy at each time-shift points is shown in Fig. 1. The leftmost data shows correlation coefficients between the MCG signal data and the simulation data at each SNR (0 dB, -10 dB and -20dB). And the waveform of the simulation data, the MCG signal data and the signal processed data at -20 dB simulation are shown in Fig. 2. Fig. 2 (a) shows waveform of the simulation data with -20dB SNR, Fig. 2 (b) shows that of the MCG signal data and Fig. 2 (c) shows that of the signal processed data. As shown in Fig.1, improvement of the noise reduction accuracy were seen in all sift points. Among them, best shift point was 1 (0.002 [s]) at all SNRs. Machine time was 0.18 s in this case. In addition, improvements of correlation coefficient were 0.49, 0.68, 0.49 and improvements of SNR were 31.29 dB, 40.37 dB, 40.83 dB at each SNR. *Summary* We proposed a new time-shift PCA method without reference sensor. We carried out the simulation with considering time-shift point and that noise reduction accuracy. As a result of simulation, we found that the method can reduce the noise about 40 [dB] and that best shift point that has the highest noise reduction accuracy is 1.

AP-11. Quantitative component selection method using attractor analysis for noise reduction by ICA of magnetocardiogram.

K. Kobayashi[1] and M. Iwai[1]
1. Faculty of Science and Engineering, Iwate University, Morioka, Iwate, Japan

Introduction Magnetocardiogram (MCG) is a noninvasive technique that detects the magnetic field generated by the electrical activity in the heart. Recently, MCG has been attracting a lot of attention in relation to the early detection of heart diseases [1]. As MCG is a multichannel measurement technique and as the signals are not affected by the shape of the lungs and torso, it has high potential for clinical applications [2]. On the other hand, MCG is very weak signal less than 100 pT, and then signal-to-noise ratio (SNR) is very low. Many noise reduction methods are proposed for biomagnetic measurements, particularly independent component analysis (ICA) for separating the signal and noise. However, ICA has the problem that is to distinguish signal or noise components from separated components. In many cases, these is decided by personal qualitative evaluations (knowledge and sense). We have studied a method of environmental magnetic noise reduction using ICA for MCGs. The purpose of this study is to establish quantitative component selection method of the cardiac magnetic field component and the noise component separated by ICA. Therefore, we proposed the method to use attractor analysis and the multiple coefficient of determination. Method Fig.1 shows examples of attractor analysis. Attractor analysis is a kind of chaos analysis, it is a method to express periodic features of waveforms by using time and amplitude, and is effective for discriminating independent signals. As shown in Fig. 1 (a) right side, measurement signal x(t+1) is plotted on the x-axis and measurement signal x(t) is plotted on the y-axis. Then discrimination between the cardiac magnetic field component and the noise component is performed by utilizing the property that each component has a different waveform. In order to quantitative component selection of the signal and the noise, the multiple coefficient of determination is used. The multiple coefficient of determination is calculated as the correlation coefficient with the waveform after the attractor analysis and the regression line from the least squares method in the waveform after attractor analysis. The multiple coefficients of determination for the components shown in Fig. 1 became about 0.9 for the cardiac magnetic field component in (b), about 0.6 for the sine wave in (c), about 0.001 for random noise in (d). It is found that the magnetocardiogram component is a high multiple coefficient of determination and the noise component is a low multiple coefficient of determination. Simulation studies Simulation studies were performed using MCG. The MCG data was measured with a 64-channel (8 x 8) SQUID magnetometer in a magnetically shielded room (MSR) [3]. To reduce noise, the data were averaged 150 times. The averaged data represent here the ideal signal data. Noise data was also measured with the same SQUID magnetometer while applying environmental magnetic noise with a coil in the MSR. For the simulations, the ideal signal data and noise data were mixed with the SNRs of 0 and −10 dB. Fig.2 shows the example waveform of 0dB simulation data, ideal signal data, and after noise reduction data. It is found that the noise is eliminated in 0 dB simulation data, and the waveforms of the magnetocardiogram are restored. The correlation coefficient of after noise reduction data and ideal signals data is 0.97. And the correlation coefficient of -10 dB simulation data is 0.88. Conclusion We proposed the noise reduction method by ICA using attractor analysis and the multiple coefficient of determination as quantitative component selection. The simulation data with SNRs of 0 dB and -10 dB were examined and evaluated. As the result, high noise reduction accuracies were obtained.

Abstract : The theoretical analysis of co-simulation in the conditions of strongly coupled RF coils is proposed in this paper. The proposed co-simulation method is evaluated through the comparison with the conventional simulation methods in terms of the efficency, electromagnetic field (EM) and specific absorption rate (SAR) of a 2-channel strongly coupled coil array. The results demonstrate the proposed co-simulation method saves approximately 94.5% of total simulation time for strongly coupled coil arrays while the EM field and SAR variation is less than 4%. *Index Terms*—magnetic resonance imaging, numerical analysis, radio frequency coil. Introduction: In magnetic resonance imaging (MRI), the performance of radio frequency (RF) coil arrays is critical, determining the imaging quality and safety [1]. Coupling between coil elements is a common cause of performance degradation and must be sufficiantly reduced in design of multi-channel RF coil arrays to maintain the array performance [2]. The EM field simulation is the main tool to analyze the coupling condition and optimize the decoupling method [3]. The conventional EM field simulation methods are often time-consuming, sometimes even not practical because of the unacceptibly long computing time. In previous studies, fast MRI coil analysis based on 3-D electromagnetic and RF circuit Co-simulation has been uesd to improve coil performance [4]. However, current analysis is based on the assumption that the interaction between ports can be negligible [5] and there is no theoretical analysis of strong coupled condition. In this paper, an extended theoretical analysis of strongly coupled coil arrays is proposed. Through the numerical study of a 2-channel strongly copuled coil array model, the efficency, the scattering parameter, electromagnetic field (EM) and specific absorption rate (SAR) [6] are compared using the propsoed co-simulation method and the conventional simulation methods. Theory: The power of incident wave and reflected wave is deduced of a 2-port network model as shown in Fig. 1. The power of incident wave and reflected wave of each port are a_1^1, b_1^1, a_1^2, b_1^2, i=1,2,respectively. The input power of the 2-port network $x_{circuit}(w) = [a_1^1, b_1^1, a_1^2, b_1^2]$, S^1, S^2 of sub-network represent the tuning and matching circuit [5]. $_S{}^{coi}$ represents the scattering matrix of coils. While coupling is not neglectable, the non-diagonal elements in the matrix $_S{}^{coi}$ will become non-zero numbers. H^i_{field} (ω) signifies the transfer function of field distribution. Since $a_2^1= b_1^{coil}$, $b_2^1= a_1^{coil}$ and $a_2^2= b_2^{coil}$, $b_2^2= a_2^{coil}$, the interaction between different ports is redefined as shown in Fig. 1 (1)-(3), The EM field distribution Y(w) based on the above equations, in strongly coupled coil array is expressed as shown in Fig. 1(3). Method: As an example, a 2-channel phased array coil which was comprised of two square coils, each with dimensions 80×80 mm^2 and 5 mm in conductor width. The adjacent distance was only 4 mm so the coupling between the two coils was very strong with S_{12}=S_{21}=-4.8dB. Commercial software (Computer Simulation Technology, Darmstadt, Germany) was used to validate the co-simulation method in the strongly coupled case. A cubic phantom measuring 300×300×200 mm^3 was placed 10 mm above the RF coil model. The material property of the phantom was set as conductivity = 0.6 S/m, relative permittivity εr = 78 and relative permeability μr = 0.99. The two simulation methods are modeled as shown in Fig. 2. (a). The red and blue components in Fig. 2(a) denote ports and lumped elements, respectively. In the proposed simulation, all the lumped elements were replaced by ports with 50 W. The linear equation system solver accuracy was set to -40 dB.The boundary condition of the RF coils were set to open and the bandwidth was set to 50 MHz ~ 200 MHz. The mesh cells of the two simulations were all 7126140. The coils was resonant by adjusting the capacitance without any decoupling and the coupling condition was evaluated by analyzing the S parameters. It was compared with the conventional simulation by analyzing the results of simulation time, the EM field, SAR and time of simulation [2]. Results : S-parameters of the strongly coupled coil array are obtained and agree well in both methods with S_{12}=S_{21}=-4.8dB. The EM field and SAR distribution of the YZ plane in the phantom is compared as shown in Fig. 2(a)-(d). The field distribution data for the two simulation procedures was below 4%. The total simulation time of the conventional simulation methods and the proposed co-simulation methods is 729 hous and 40.7hous, respectively. A total of 27 iterations for both methods are required to optimized S parameters and the proposed co-simulation method saves about 94.5% of total simulation time. Conclusion : A systematical theoretical analysis of EM and RF circuit co-simulation approach for strongly coupled coil arrays in MRI applications was proposed in this paper. Through the simulation study of a 2-channel coil array model, the co-simulation method demonstrates the advantages of high efficiency and accuracy over the conventional EM simulation method.

AP-13. Improving Tip Position Estimation Accuracy of Gastric Tube by Compensating Geomagnetic Field with Offset Coils.

T. Sasayama[1], Y. Gotoh[2] and K. Enpuku[1]
1. Kyushu University, Fukuoka, Japan; 2. Oita University, Oita, Japan

Introduction Naso- or oro-gastric tubes are used for patients who have difficulty swallowing, to deliver nutrients or medicines to the stomach. To observe whether the tube is inserted into the stomach correctly, we have proposed a method that estimates the position of the permanent magnet attached to the tip of the tube using several magnetic sensors placed outside the patient's body [1], [2]. The mean of the tip position estimation error is less than 10 mm when the distance between the sensor plane and the permanent magnet is 150 mm [2]. However, if the system is used on pregnant or fat patients, the system needs to perform accurately even for distances greater than 150 mm. To achieve the requirement mentioned above, the sensitivity of the magnetic sensors should be enhanced. Although high-sensitivity magnetoimpedance (MI) and magnetoresistance (MR) sensors can detect signals of the order of nT, the performance is only achieved in a magnetically shielded room due to the limitation of the measurement range and the existence of the geomagnetic field; this creates a problem for the system's practical use in hospitals. Therefore, we propose a method to compensate the geomagnetic field using offset coils. *Methods* Figure 1 shows the proposed system. Four three-axis MR sensors (HMC2003, Honeywell International Inc.) were used for detecting magnetic flux. The MR sensors have offset coils, and the current through the coils was generated by an operational amplifier (OPA350, Texas Instruments Inc.). The output voltage of the amplifier was set using a D/A converter with a 16-bit resolution (DAC8532, Texas Instruments Inc.). The output voltages of the MR sensors were measured using an A/D converter with 32-bit resolution (ADS1262, Texas Instruments Inc.). First, the geomagnetic fields were recorded using these MR sensors. Then, the current through the coil was adjusted so that the signals from these MR sensors were zero. The permanent magnet was finally arranged, and the magnetic fields generated by the permanent magnet were recorded. The magnetic moment, m, and the position, r, of the permanent magnet were estimated using N magnetic sensors and the following equation: minimize $||b(r, m) - b_{meas}||^2$, (1) where $b(r, m) = [b_1(r, m), \ldots, b_N(r, m)]^T$ is the magnetic flux density and $b_{meas} = [b_{meas,1}(r, m), \ldots, b_{meas,N}(r, m)]^T$ is the measured magnetic flux density. $b_k(r, m)$ can be calculated using the following equation: $b_k(r, m) = m_0/4\pi \times \{3(m \bullet r_k')r'/\|r_k'\|^5 - m/\|r_k'\|^3\} \bullet u_k$, (2) where $r_k' = r - r_k$, r is the position vector of the permanent magnet, r_k is the position vector of the kth magnetic sensor, u_k is the direction vector of the sensitive direction of the kth magnetic sensor, and m_0 is the permeability of a vacuum. The nonlinear least squares expression in (1) was solved using the trust-region method provided in the Intel Math Kernel Library. *Results* Figure 2 shows the values of the tip position estimation error when the distance z between the sensor plane and the permanent magnet is 130, 150, 170, and 190 mm respectively. Figure 2 (a) and 2 (b) show the estimation error without and with the geomagnetic field compensation, respectively. As shown, the estimation error with geomagnetic field compensation is less than that without compensation. This indicates that the compensation using offset coil improves the estimation accuracy. The mean of the tip position estimation error in Fig. 2(b) is less than 10 mm even when z = 190 mm, thus meeting the requirement in the real clinical application for pregnant or fat patients.

Until now most contrast agents (CA) that are used in Magnetic Resonance Imaging (MRI) studies have been paramagnetic. However, ferromagnetic CAs are potentially more sensitive as T_2 CAs than T_1 paramagnetic compounds due to their large magnetic moments. Previous study has shown that ferromagnetic gadolinium silicide (Gd_5Si_4) nanoparticles (NP) could be useful as potential T_2 CA for MRI with significantly reduced echo time (TE) compared to Superparamagnetic Iron Oxide Nanopartilces (SPION) which are currently the most widely used T_2 CA [1]. Furthermore, the need for better MRI images without the need of upgrading to the higher magnetic field strength can be achieved using better CA such as Gd_5Si_4 NP. The quality of the image contrast in MRI is improved by shortening T_1 and T_2 relaxation times at the site or close proximity to the CA. The efficiency of a T_1 CA is defined by its relaxivity, r_1, which is field and temperature dependent. While, T_2 agents are defined by their relaxivity, r_2, which is dependent on both the saturation magnetization (Ms) value and the effective radius of the NPs [1, 2]. In this study, effect of Gd_5Si_4 NP of varying sizes and with different concentrations are investigated on T_1, T_2 and T_2* (effective/observed T_2) relaxations times. Gd_5Si_4 was synthesized by arc-melting of the stoichiometric mixture of gadolinium and silicon under Ar atmosphere and then the Gd_5Si_4 NPs were prepared by high energy ball milling of the crushed ingot. The synthesis process is described in detail elsewhere [3,4]. Ferromagnetic Gd_5Si_4 is extracted with NdFeB grade N52 permanent magnets placed below the beaker containing the ball milled powder in ethyl alcohol before size separating the NPs through time sedimentation process that provided three fractions (named S1, S2 and S3) with average sizes of 586 nm, 287 nm and 135 nm respectively as analyzed from SEM images (Fig. 1). XRD analysis on pre-separated sample show that Gd_5Si_4 is the major phase while GdSi and Gd_5Si_3 is the minor phases present in all fractions (Fig. 1). Magnetic properties measured in VSM reveal that the Curie temperature (Tc) decreases for Gd_5Si_4 phase from 312 K for S1 to 304 K for S2 and is undetectable in S3. Another Tc observed at 105 K can be attributed to Gd_5Si_3 phase. The M-H curves at 300 K exhibits ferromagnetic behavior descending to paramagnetic as we move from S1 to S3 fraction (Fig. 1). Prior to MRI measurements, NPs are diluted in solution with low-temperature 2% agarose with the following dilutions - 1:20, 1:200, 1:2000 and 1:20000. The high dilution factors were chosen based on solution MRI with lower dilution factors (data not shown) that exhibited extremely strong contrast at 21.1 T and unquantifiable results. Each nanoparticle layer was separated with a 1% agarose layer. MR images were acquired on the 21.1 T (900 MHz) magnet at the National High Magnetic Field Laboratory (NHMFL) in Tallahassee, FL. The magnet is equipped with Bruker Avance III console and Paravision 6.0.1 (Bruker, Ettlingen Germany). For all acquisition a 10-mm birdcage coil was used. Measurements were performed to quantify T_1, T_2 and T_2* relaxation times for each sample and dilution. For T_1 measurements, a turbo spin echo (TSE) sequence was used with two rare factors. The echo time (TE) was 8.8 ms and ten incrementing (12000 - 26 ms) repetition times (TR) were used. T_2 relaxation were acquired with a multi slice multi echo (MSME) sequence using a TR=5000 ms and 20 incrementing echo time (7.5 – 150 ms). For T_2*, a 2D gradient echo (GRE) sequence were used with TR=5000ms and eight incrementing TE (1.5 – 28.5 ms). Common acquisition parameters for T_1 and T_2 sequences were 2 averages, matrix = 110x200, FOV = 1.1x 2.0 cm resulting in a 100x100 mm in plane resolution using a 1-mm slice while the 2D T_2* sequence were acquired with 2 averages and a matrix of 100x55 resulting in a 200x200 mm in-plane resolution. Magnitude images were analyzed in Paravision using region-of-interest (ROIs) to cover each agarose layer as well as spacing layers. The average signal intensities were extracted and analyzed in Matlab using the Levenberg-Marquardt algorithm. For T_1 a three-parameter exponential growth function were used while for T_2 and T_2* a three-parameter exponential decay function were employed. The results shown in Table 1 indicate higher concentrations of NPs shortens the T_2 and T_2* relaxation times and the contrast disappears rapidly with any higher dilutions. Fraction S2 at 1/20 dilution show notable shortened T_1 and T_2 relaxation times compared to the other two fractions. Although S1 has more Gd_5Si_4 phase volume fraction and larger average particle size compared to S2, further investigation is needed inorder to establish the cause in shortened relaxation times compared to S1 fraction. *Acknowledgements* Synthesis and materials processing at the Ames Lab was supported by DOE (contract No. DE-AC02-07CH11358). Work at VCU was partially funded by NSF, Award Number: 1610967. AQ-01. Analysis and Optimization of a New Structure for Wireless Charging System of Electric Vehicles.

Z. Li[1] and *J. Yi*[1]
1. College of Traffic Engineering, Hunan University of Technology, Zhuzhou, China

INTRODUCTION Magnetic resonant wireless power transfer (WPT) is an emerging technology that may create new applications for wireless power charging[1]. However, the output voltage fluctuations and reduced efficiency resulting from lateral are main obstructing factors for promoting this technology. In this paper, a new WPT topology for electric vehicles is proposed. The mathematical model of the proposed topology with lateral misalignments is built based on equivalent circuit method. A method of optimizing coil parameter is proposed, the sum of mutual inductance between each receiving coil and the transmission coil is nearly constant with lateral misalignments. The output voltage can be kept constant and the high efficiency can be obtained by using the proposed method. The WPT system via magnetic resonance coupling is designed. Simulation and experimental results validating the proposed method are given. PROPOSED STRUCTURE AND MODEL The proposed structure is composed of a transmission resonance coil (labeled as Tx_1), four receiving resonance coils (labeled as Rx_1, Rx_2, Rx_3, and Rx_4), the power source, four full-bridge rectifiers, and load resistor, as shown in Fig.1. The power source via the compensation capacitor C_1 is connected in series with the transmission coil Tx_1. The power is transferred from the transmitter to the receiver using magnetic fields. The output voltage of each receiving resonance coil is converter to DC by full-bridge rectifier. Then the output voltage of each full-bridge rectifier is connected in series. The output voltage of load is equal to the sum of the voltage of each full-bridge rectifier. SIMULATION AND EXPERIMENTAL VERIFICATON To validate the proposed method, the prototype model of the system has been built, as shown in Fig. 1(a) and Fig. 1(c). It is composed of two transmission resonant coils, four receiving resonant coils, H-bridge inverter, four full-bridge rectifiers, and the load. The transmission resonant coil is placed on the below. The receiver resonant coils are placed on the top. Two transmission resonant coils are labeled as Tx_1 and Tx_2. The parameters of Tx_1 are optimized according to the proposed method; whereas the parameters of Tx_2 are not optimized. The diameter of Tx_1 is 45cm with a pitch of 0cm for approximately 17 turns. The diameter of Tx_2 is 28cm with a pitch of 0cm for approximately 11 turns. The diameter of each receiving resonant coil is 15cm with a pitch of 0cm for approximately 9 turns according to the proposed method. All coils are made from 300-strand AWG 38Litz-wire. The ferrite plate material is PC95 from TDK. H-bridge inverter is used at the transmitter side to provide AC excitation. Four full-bridges rectifiers are used at the receiver side to convert AC to DC. An impedance analyzer TH2829 is used to extract the parameters in (1) and (2). The original resonant frequency is set to be 85.0kHz. The transmission distance is 14cm. The unload quality factors of Tx_1, Tx_2, Rx_1, Rx_2, Rx_3, Rx_4 are 160, 150, 405, 397, 397, and 390, respectively. Owing to the symmetry of coils, the lateral misalignments are only analyzed to the right (Δ is the misalignments). Fig. 2(a) shows the calculated and measured mutual inductances between transmitter and Rx_1 versus misalignments for different transmission coils. It can be seen that the mutual inductance between Tx_1 and Rx_1 is changed from 7.8μH to 3.45μH as the misalignment is varied from 0cm to 20cm; whereas the mutual inductance between Tx_2 and Rx_1 is changed from 5.05μH to 0.15μH as the misalignment is varied from 0cm to 20cm. Fig. 2(b) shows the sum of the measured mutual inductances M_{12}, M_{13}, M_{14}, and M_{15}. It can be seen that the sum of mutual inductance is nearly constant at 24μH when Tx_1 is used; whereas the sum of mutual inductance is changed from 14.0μH to 10.3μH as the misalignment is varied from 0cm to 10cm. This is because the increments of M_{12} and M_{14} (compare with mutual inductance with Δ=0) are the same as the decrements of M_{13} and M_{15} when Tx_1 is used; whereas the increments of M_{12} and M_{14} are smaller than the decrements of M_{13} and M_{15} when Tx_2 is used. CONCLUSIONS In this paper, the topology of cascaded a transmission coil to four receiving coils is proposed. The mathematical model of the proposed topology with lateral misalignments is built based on equivalent circuit method. The expressions of the output voltage and the efficiency are then derived by solving the system equivalent equations. The output voltage of the load resistor is only dependent on the mutual inductance between the transmitter and receiver when the parameters of each coil and the load are given. A method of optimizing parameter is proposed in order to optimize the mutual inductance between the transmitter and receiver. The mutual inductance between the transmitter and receiver can be kept 24.0μH, the output voltage is ranged from 26.1V to 27.9V, and the transmission efficiency is nearly equal to 90.0% as the misalignment is varied from 0cm to 10cm. The advantage of the proposed topology is that the efficiency is high and the output voltage is nearly constant. Therefore, the proposed method allows for an efficient and robust WPT system for charging of EVs.

The investigation of magnetization dynamics in magnetic film is currently attracting significant attention [1]. This interest is driven by the requirement for understanding the physics and application of magnetic microwave devices. There has been an increasing research for the soft magnetic film with ultra high ferromagnetic resonance (FMR) frequencies in recent years [2], and the films in these results are mainly resonated based on the traditional FMR, which belongs to the acoustic mode. In the acoustic mode, the magnetizations of films show the in-plane uniform precession, and the resonance frequency of the film is determined by the in-plane anisotropy field, which can be included by the preparation methods [3]. However, the results of the optic mode FMR are rarely investigated. This is due to the low permeability of optic mode FMR, and it only observes in some particular structure films. The two observable FMR modes have mainly discovered in two kinds of magnetic thin films: exchange-coupling-biased multilayer films [4] and thin films with stripe domains [5]. This attributes to the moments of the optical mode for two systems precess an out-of-phase when compared with those of the acoustic mode [6, 7]. Significantly, FeNi film will arise from both the in-plane and out-of-plane magnetizations when the film thickness is above a critical film thickness, and an array of oscillating “up and down” magnetic domains forms, which are known as the stripe domain [7]. FeNi stripe domain structure film has been widely studied for its dynamic microwave magnetic properties [8-10], and the magnetic spectra exhibit multiple resonance modes, which are interpreted in terms of the magnetization configuration of stripe domains [8, 9]. In this work, FeNi films with different phases structure were prepared by electrodeposition method, the phase structures of films were controlled by the composition of the film. We focused the discussion on the influence of the phase structure on the acoustic and optical mode FMR of FeNi stripe domain films. The results indicated that the domain structures of films were changed by the phase structure of film, which depended on the composition of the film. The acoustic and optical mode FMR of films shows the similar laws in FeNi alloys but not in the pure Fe and Ni films. In addition, the magnetization dynamics of FeNi stripe domain films are further disscussed.

AQ-03. Indirect Permeability Measurements using a 'Strip-coil' for $Co_{0.6}Zn_{0.4}Fe_{1.7}Mn_{0.3}O_4$.

U. Chaudhuri[1], M. Kumari[1] and R. Mahendiran[1]
1. Physics, National University of Singapore, Singapore

Cobalt ferrite ($CoFe_2O_4$, CFO) is a well-known room temperature ferromagnet insulator with high magnetic anisotropy and large coercivity. It is reported in literature that an optimal substitution of Fe by Mn and Co by Zn in CFO ($Co_{0.6}Zn_{0.4}Fe_{1.7}Mn_{0.3}O_4$,CZFMO), reduces both anisotropy and coercive field along with a significant improvement in the resistivity [1]. A sample with low anisotropy, large resistivity and low eddy current losses can be an ideal candidate for high frequency devices. Keeping this in mind, we choose CZFMO to measure frequency dependence of electrical impedance, i.e., magneto-impedance (MI) in this work. Previous methods to measure MI involve passing a high frequency current through the sample and probing the permeability up to a skin depth $\delta(=\sqrt{((2\rho)/(2\pi f\mu_o\mu_r))})$ from the sample surface[2, 3]. The skin depth defines the region where electromagnetic waves propagate, perpendicular to the surface of the sample and depends on resistivity (ρ), relative permeability of the material (μ_r), AC frequency (f) and permeability in vacuum (μ_o). For insulating samples like CZFMO, we are unable to pass a current through the sample and hence indirect methods are needed to measure permeability. An indirect method using a strip-coil is used to measure MI using a single port impedance analyzer E4199A which directly measures the impedance of the coil surrounding the sample using RF-VI technique. Conventional test devices provided by impedance analyzer manufacturers use toroidal samples. However, in our setup we are not constrained to use any particular dimension or shape. This method has been altered from an experiment done on thin films [4] to incorporate bulk materials. Our sample was in the shape of a cylinder which homogenously filled a cylindrical strip-coil. An alternating current flowed through the strip-coil and an RF magnetic field was generated inside it along its axial direction. Using ohm's law, we write impedance (Z) as $Z= V_\Phi/I = -(d\Phi/dt)/I$ … (1) where Φ is the magnetic flux passing through the strip-coil given by $\Phi = \mu_o\mu_r H\bullet A$. Here, H is the magnetic field inside the strip-coil and A is the cross-sectional area of the strip-coil. On solving Eq.1 we get Z in terms of its real (Resistance 'R') and imaginary (Reactance 'X') components. Mathematically, $R=K(\omega\mu_o\mu_r'')$ and $X=K(\omega\mu_o\mu_r')$, where K is a constant depending on the geometry of the strip-coil. Since a sample contributes to the flux passing through the strip-coil the impedance of the strip-coil is affected by the material inserted in it. Thus variations in MI arises due to the changes in permeability of the sample. MI measurements were taken with the DC magnetic field (H_{DC}) perpendicular to the high frequency AC magnetic field (h_{rf}). In Fig. 1 we report $(\Delta R/R_0)\%=(\Delta\mu''/\mu_0'')\%$ and $(\Delta X/X_0)\%=(\Delta\mu'/\mu_0')\%$ for CZFMO from 500MHz to 2200MHz. Large resistivity of CZFMO ensures that most of the h_{rf} passes through the bulk of the sample and not just the surface, thus probing the bulk permeability of the sample. In Fig. 1(c) we show the presence of FMR signatures in our MI experiment as theoretically explained by Yelon et al.[5] The maximum percentage change observed at 2.2 GHz was ~108% for $\Delta\mu''/\mu_0''$ and ~2639% for $\Delta\mu'/\mu_0'$ on applying a DC magnetic field of ~1888 Oe and ~2943 Oe respectively (Fig.1.(c)). Such large changes in sub-tesla fields can be implemented for sensor applications and magnetic microwave devices.

1. Chemistry, Gangneung-Wonju National University, Gangneung city, The Republic of Korea

The need for protecting human or devices from a new kind of pollution known as electromagnetic interference(EMI) is becoming a world attention in the development of the efficient shielding methods to reduce EMI. An ideal EM wave absorber is necessary to have light weight, thin thickness, high EM wave absorption, broad width, tunable absorption frequency, and multi functionality. To date, considerable efforts have been made to design various materials to reach the ideal targets. In this study, we report a simple surface modification process that induces the ferromagnetic ferrite spheres and hexagonal plates to be functionalized with conducting polyaniline(PANI) for improved electromagnetic interference shielding materials. The aim of this study is to find out the effect of morphology on the electromagnetic properties, and also, effectiveness of EMI shielding of the nanocomposite with different weight ratios between ferromagnetic and polyaniline. The ferromagnetic nanomaterials were prepared in hydrothermal method with the formation of polyaniline coating and core ferromagnetic ferrite nanocomposite. The X-ray diffraction patterns and FE-SEM images confirmed the spherical core/shell of Fe_3O_4@PANI nanocomposite and the plate core/shell of $BaFe_{12}O_{19}$@PANI nanocomposite. The electromagnetic interference shielding effectiveness and EMI shielding mechanisms of core/shell nanocomposites with different morphology and different thickness in the 1-18 Hz range were studied. The microwave absorption property of the composites strongly depends on the intrinsic properties of core ferrite morphology in the polyaniline matrix and with the increasing of the thickness, the effective electromagnetic absorbing frequency band was shifted to the lower frequency.

AQ-05. High frequency magnetic loss in nanogranular FeCoTiO films with different history of induced uniaxial anisotropy.

Y. He[1], Y. Wang[1], Z. Zhong[1], H. Zhang[1] and *F. Bai*[1]
1. University of Electronic Science and Technology, State Key Laboratory of Electronic Thin Films and Integrated Devices, Chengdu, China

Soft magnetic films have attracted considerable attentions for high frequency applications, such as on-chip power inductors, transformers and voltage regulaters. Loss control is the most critical tasks for these applications.[1] The high frequency loss of magnetic thin films typically includes hysteresis loss, eddy current loss, and ferromagnetic resonance (FMR) damping loss. Nanogranular FeCo-X-O (N) (X denotes Si, Hf, Zr, Ti, Zn etc.) have higher resistivity and saturation magnetization than those of permalloy or amorphous alloys. Meanwhile, the critical thickness can be 500 nm or above due to the suppressed growth of columnar structures by insulating layers.[2] All these make the nanogranular films very attractive for on-chip passive devices. So far, nanogranular films are mainly grown by sputtering. The in-plane uniaxial anisotropy (H_k) required for hard-axis exited inductors and transformers can be induced through in-situ magnetic biasing field (H_{bias}) during growth or oblique sputtering, both of which are widely adopted in the fabrication of CMOS compatible magnetic devices.[4] However, the research about high frequency magnetic loss related to these two processes is still scarce. We here report our efforts to reducing the effective damping factor of nanogranular FeCoTiO films. Fig. 1(a-c) show the imaginary part of the permeability spectra of FeCoTiO films deposited at different oblique angles (β) upon applying magnetic field along the easy axis (called low-field FMR). It can be seen that the FMR frequency (f_r) increases from 3 GHz to 5 GHz upon increasing β from 17° to 32° at zero field. Therefore, the working frequency of nanogranular films can be simply tuned by adjusting β angle. Fig. 1(d) shows that full width at half maximum (Δf) of the imaginary permeability spectra. The lowest Δf about 0.76 GHz was obtained in the film with β of 17°, corresponding to a low α_{eff} of 0.013. Further increasing β angle cause significant structural inhomogeneities and larger α_{eff}. Fig.2(a-c) show the permeability spectra of FeCoTiO films deposited with in-situ H_{bias} of 15, 70 and 115 Oe, respectively. Regardless of the magnitude of H_{bias}, it is found that H_k varies in a small range between 70 Oe and 80 Oe. Our results clearly reveal that the rearrangement of Fe-Fe(Co) atom pairs almost fully completed at an external field as small as 15 Oe during sputtering. According to the two magnon theory, the extrinsic α_{eff} is generally related to the magnetic inhomogenieties.[4] The low field FMR results in Fig. 2 indicate that (i) further increasing biasing field cannot fully suppress magnetic inhomogenieties, which is true for even for H_{bias} up to 900 Oe (not shown); and (ii) Δf decreases with the increase of the external field and the minimal Δf is 0.55 at an external field of 200 Oe, as shown in Fig.2 (d). Finally, we calculated the high frequency loss μ''/μ' of FeCoTiO films. The two sets of data are from the film deposited under in-situ H_{bias} of 115 Oe and the film by oblique sputtering at β=17°. The μ''/μ' of oblique sputtered FeCoTiO film dominantly comes from FMR damping above 1.6 GHz, below which only hysteresis loss can be observed. However, for the FeCoTiO film deposited under H_{bias} of 115 Oe, the FMR damping can be observed down to 200 MHz due to a large α_{eff} of 0.026. Furthermore, the overall high frequency loss of oblique sputtered FeCoTiO film is much smaller than that of the FeCoTiO film deposited under in-situ Hbias, although the coercivity along the hard axis (H_{ch}) of the former (11 Oe) is much larger than the latter, 3 Oe. The large H_{ch} of oblique sputtered FeCoTiO films may come from the pinning effect of columnar structures. On the other hand, such columnar structure also brings the advantages of well aligned magnetic moments and reduced magnetic inhomogeneities in the FeCoTiO film.

Active ring resonators (ARRs) in the form of a feedback loop consisting of a spin-wave delay line and microwave amplifier are widely used for investigation of nonlinear dynamics in driven damped systems (see, e.g. [1-5]). Recently, generation of spectrally pure and low noise microwave (MW) signal was observed using optoelectronic feedback loops with optical delay lines [6-8]. An advantage of such schemes is due to attain an ultrahigh Q-factor, which is defined by the length of optical fiber [9]. It is physically clear that a connection in the closed-loop of a ferrite waveguide and a high-Q optical storage element opens new opportunities to investigate nonlinear effects. The aim of this work is to study the foldover effect that appears due to the spin-wave nonlinearity enhanced by the high-Q optical element in a combined spin-wave/optical ARR. The considered ARR scheme consists of a spin-wave delay line, a microwave attenuator, a microwave amplifier, an electro-optic modulator, an optical fiber, and a microwave photodetector, as it is shown in Fig. 1. In this scheme, the light from the external laser is introduced into the modulator, closing the circuit to the ring. Note that this ring, like an optoelectronic oscillator [9], may start up into MW self-generation in case a microwave amplification compensates for losses. In the regime preceding the self-generation, the amplitude of the signal circulating in the high-Q ring increases significantly at the resonant frequencies, and exceeds the nonlinear phenomena threshold, which is determined by the nonlinear properties of the spin waves. It manifests itself as a resonant frequency shift and foldover effect. The important feature of the investigated ARR in comparison with a typical spin-wave ARR is much higher Q-factor. It means that the optical delay line affects the nonlinear wave properties of the spin-wave ARR. Hence, the "hybrid nature" of the proposed ARR proves itself. To investigate the foldover effect in the spin-wave ARR with high-Q optical element the experiments were carried out. The spin-wave delay line consisted of an yttrium-iron garnet 5-μm thick film and two microstrip transducers separated by 4 mm. The YIG film was magnetized perpendicularly to its surface by a magnetic field of 2630 Oe. The optical part of the ARR consisted of the commercially available elements: a laser giving optical radiation of 1.55 μm, a 10-GHz electro-optical Mach–Zehnder modulator, a single mode fiber with length of 100 m, and a 10-GHz photodetector. It was found out that an increase in the amplifier gain resulted in a nonlinear upper-shift by 110 kHz of all resonant frequencies. Note that for a bigger nonlinear frequency shift the foldover instability occurred. In order to illustrate a development of foldover effect the resonant peak shapes measured for -9 dB and -1 dB below the self-oscillation threshold are shown in Fig. 2 by solid blue line and solid red line, respectively. To better understand the physics underlying the foldover effect in the ARR, a theoretical model was developed as follows. First, a nonlinear dispersion relation for the carrier spin waves was derived from the linear dispersion relation taking into account the dependence of the static magnetization on the amplitude of circulating signal. This amplitude was determined as the product of the amplitude of the input signal and the transmission coefficient of the investigated ARR. Then, the wave-number as a function of frequency was numerically calculated from the nonlinear dispersion relation. Its substitution into the linear transmission coefficient resulted in the nonlinear transmission characteristic (NTC) of the ARR. The obtained NTC was used for a comparison with the experimental results (see Fig. 2). One can see that the theoretical and experimental results have a good agreement. In conclusion, the theoretical model of the resonance spectra for the spin-wave optoelectronic ARR was developed taking into account both the dispersion and nonlinear properties of the ferrite film. Results of the numerical simulation have a good agreement with the transmission characteristic measured in the experiment. The developed theory gives a possibility to investigate the foldover effect evolving due to the nonlinear spin-wave properties of the ferromagnetic film included in the ARR containing the high-Q optical elements. The work was supported by the Ministry of Education and Science of Russian Federation (agreement 14.575.21.0157, unique identifier RFMEFI57517X0157).

Physics, The University of Western Australia (M013), Perth, WA, Australia

Yttrium iron garnet (YIG) or $Y_3Fe_5O_{12}$ has continued to attract attention over the years due to its low microwave loss, essential for microwave device technology [1]. Apart from microwave application, recently the nanometer (nm) thick YIG films have been used to realize spin transfer torque devices, magnetic logic devices, and frequency tunable metamaterials [2]. This has enhanced the interest in the study of physical properties of YIG thin films. The fabrication of epitaxial YIG films in micrometer thick range on Gadolinium Gallium Garnet ($Gd_3Ga_5O_{12}$ or GGG) substrates has been commonly done by liquid phase epitaxy (LPE). However, Pulsed laser deposition (PLD) and RF sputtering are known to be better suited techniques to deposit nm thick epitaxial YIG films on GGG and polycrystalline YIG films (on substrates other than GGG) [3-4]. Recently large amount of work has been reported on PLD deposited YIG thin films that are grown on different substrates [3-4]. One curious finding has been that whenever YIG films were grown on GGG substrate, effective saturation magnetization ($4\pi M_{eff}$) larger than bulk has been observed when studied using Ferromagnetic resonance (FMR). where $4\pi M_{eff} = 4\pi M_S - H_U$. Here $4\pi M_S$ is the bulk saturation magnetization and H_U is uniaxial anisotropy field. In our previous study, we performed a systematic structural, magnetic and microwave studies on PLD deposited YIG/GGG films and established that the high $4\pi M_{eff}$ value is due to the presence of negative H_U arising from the compressive stresses present in the film. The presence of this stress in YIG film was confirmed by multiple {*hkl*} stress measurements with grazing incidence X-ray diffraction performed at different depth of penetration on the YIG film. The question then arose whether this effect is only seen in YIG/GGG films deposited by PLD technique or can also be observed in thin films grown by other techniques. RF sputtering is a technique widely used for industrial application due to uniform and large area deposition. Hence, to cheek the above hypothesis of stress induced anisotropy, we further extended our study to YIG thin films deposited on GGG substrate by RF sputtering. In the present work, we report the growth and microwave studies at different frequency of ~250 nm thick YIG film deposited on GGG (111) substrates by RF magnetron sputtering. (Edward Z400) at room temperature. The YIG film is deposited at an RF power of 100 W and in an argon atmosphere of 1.6×10^{-2} mbar. The chamber was evacuated to 5×10^{-6} mbar prior to film deposition using a turbo molecular pump. The target to substrate distance was maintained at 4 cm. After the deposition, the thin films were *ex-situ* annealed in air at 700 ^{o}C for different time intervals (2, 4, 6 and 10 hours). X-ray diffraction (XRD) shows that as-grown layer is amorphous and pure YIG phase is formed with preferred (111) orientation after annealing. We observe ~ 0.4% increased lattice parameter (*a*) for 2h annealed YIG films (12.429 Å) over the YIG bulk (12.376 Å) and this difference in '*a*' is reduced with the increase in annealing time (*a*=12.410 Å for 10h annealed film). The microwave properties have been investigated using a field-modulated broadband FMR in the frequency range 2-18 GHz. The magnetic field (*H*) was applied normal to the film plane. Fig. 1(a) shows the measured FMR fields as a function of frequency for YIG/GGG films annealed for different times. The $4\pi M_{eff}$ for each film has been estimated by fitting experimental data to Kittel formula for perpendicular position [3]. Similar to our previous results on PLD deposited YIG/GGG films, all the rf sputtered annealed YIG films here show $4\pi M_{eff}$ value larger than the SQUID measured $4\pi M_S$ value (~ 1780 G). Hence the higher value of $4\pi M_{eff}$ observed in the rf sputtered case can also be explained by considering the presence of negative H_U. The $4\pi M_{eff}$ value also found to decrease with the increase in annealing time. This indicates the presence of negative H_U decreases with the increase in annealing time due to stress relaxation. These values are, however, much smaller than those observed for PLD films, where we observed $H_U = -830$ Oe. Another interesting result obtained from the present study pertains to the FMR line width (ΔH) as a function of annealing temperature. Fig. 1(b) represents variation of ΔH as a function of annealing time and is plotted for frequencies 6 GHz and 18 GHz. It is seen that, the 10h annealed film shows a minimum ΔH value, lying between 30 Oe to 54 Oe over a wide frequency range (2-18 GHz). Compared to the 2h films, the FMR ΔH was reduced by ~50 % upon annealing for 10h. Although the FMR linewidth and coercively (H_C) of rf sputtered films (H_C=18 Oe, ΔH = 30 Oe) are nearly six times larger than that of PLD deposited YIG films (H_C=3 Oe, ΔH = 5 Oe), they are still much smaller than some of the results reported in recent years [5-6]. From the present investigations it is evident that the annealing helps in YIG phase formation as well as in reducing the stress, resulting a decrease in the FMR line width. Following a detailed analysis, a correlation between the microstructure and microwave properties has been established.

In recent years, wireless capsule endoscope has attracted much attention in the test and diagnosis digestive disorders. The implantable antenna is an important component of a capsule endoscope to transmit medical image from inner body to outside body. The popularly used frequency bans in medical devices are Medical Implant Communication Service (MICS) band (403-405 MHz) and Industrial Scientific Medical (ISM) bands (433.05-434.79 MHz, 869.7-870 MHz, and 902-928 MHz) [1]-[2]. An implantable antenna is required with small size. To obtain antenna miniaturization, traditional techniques mainly focus on geometry design using folded or spiral shape [3]-[5]. In this paper, we proposed a novel flexible implantable antenna operating at ISM bands of 869.7-870 MHz and 902-928 MHz. The antenna is of a coplanar waveguide (CPW) fed antenna printed on a 20 µm thick Kapton polyimide substrate. Figure 1(a) shows the configuration of the CPW antenna. A magneto-dielectric sheet with 0.5 mm thickness is placed at the bottom layer of the antenna to tune the antenna bandwidth covering ISM bands. Figure 1(b) shows the side view of the arrangement of the antenna with magneto-dielectric sheet. The relative dielectric constant of Kapton polyimide is 3. The magneto-dielectric sheet has relative permittivity εr=13, relative permeability μr=20.7, dielectric loss tangent $\tan\delta\varepsilon$=0.17, and magnetic loss tangent $\tan\delta\mu$=0.12. The antenna was simulated and optimized by using Ansys High Frequency Structure Simulator (HFSS). To simulate the antenna inside a human body, a single-layered body phantom with box shape of 110 mm×110 mm×50mm was used as shown in Figure 1(c). The dielectric constant of human phantom is adopted of skin with εr=45.2 and σ=0.61 s/m. The antenna is fabricated and measured inside chopped meat. Figure 1(d) shows photograph of fabricated antenna. Figure 2 shows simulated and measured |S11| of the proposed antenna. The simulated -10 dB bandwidth of the proposed antenna with magneto-dielectric sheet is 1013-1063.6 MHz, the bandwidth is 930-1310 MHz for the antenna without magneto-dielectric sheet. The measured bandwidth of the antenna with magneto-dielectric sheet is 835.9-995.4 MHz(-15dB), and the bandwidth is 840-1035.6 MHz for the antenna without magneto-dielectric sheet. There is some disagreement between measurement and simulation which is caused by the difference between simulation model of body phantom and chopped meat used in measurement. The measurement and simulation both show that the adoption of magneto-dielectric sheet results in frequency bands shifting to the left The measured bandwidths of the antenna with magneto-dielectric sheet cover ISM bands of 869.7-870 MHz and 902~928 MHz.

1. New Industry Creation Hachery Center, Tohoku University, Sendai, Japan; 2. Department of Electrical Engineering, Tohoku Unviersity, Sendai, Japan

Introduction - In the early stage 5th generation mobile phone system, it is expected to use high frequencies up to the SHF band (3 to 30 GHz) [1]. Therefore new noise countermeasure material is necessary in this band [2]. In this paper, we studied M-type, Y-type and Z-type hexagonal ferrite fine particles in composite form with epoxy resin, to find candidate for this application through SEM observation, XRD, DC hysteresis loop, high frequency complex permeability, and conduction noise suppression effect on micro stripline(MSL). *Preparation and properties of fine particles* - While Sr and Ba hexagonal ferrite materials are known as permanent magnet materials, they are also useful as high frequency materials whose ferromagnetic resonance (FMR) frequency exceeds 20 GHz, which corresponds to the center frequency of noise suppression exceeds 20 GHz. Firstly we followed a known direction to reduce magneto-crystalline anisotropy by a 1 – 2 at% substitution of Fe^{3+} ions by a combination of metal ions such as Co^{2+} and Ti^{4+}. Table I shows list of test particles; Z-type $Ba_3Zn_{2-X}Co_xFe_{24}O_{41}$(x = 1.25), Y- type $Ba_2Zn_2Fe_{12}O_{22}$, and M- type $SrCo_xTi_xFe_{2-x}O_{19}$ (x = 1.4) [3]. The fired polycrystalline material was pulverized to obtain fine particles. The XRD pattern showed that the crystal structure is mainly composed of hexagonal crystals since the relative intensity and diffraction angle of the main diffraction peak agree with the values of the JCPDS database. *Fabrication and properties of composite sheet* - The fine particles were mixed with the epoxy resin at a volume ratio of about 50%. This mixed solution was dropped onto a polymer sheet and screen-printed with a metal squeegee to a certain thickness, then a composite sheet was obtained. On the premise of mounting the composite in the gap between the interposer substrate and the IC chip, the coating thickness was chosen as 50 ± 5 um in total. The Y-type fine particles were almost flat in planar state even after grinding and the Z-type and M-type fine particles were close to spherical and randomly oriented, according to the SEM observation. The coercive force obtained from the DC magnetization curve is 8 to 9 Oe in a composite sheet of Y-type and Z-type fine particles (hereinafter referred to as Y-type sheet, etc.), which is smaller by one order of magnitude than the M-type sheet (90 Oe). Correspondingly, the maximum value of the relative imaginary part permeability was the maximum of 1.8 for the Y-type sheet, and it was 0.9 for the Z-type sheet, and 0.3 for the M-type sheet. As shown in Fig. 1, measured input loss ratio [4] $P_{loss}/P_{in}=1-(|s_{11}|^2+|s_{21}|^2)$ with a network analyzer (Agilent Technologies, Model N5244A) became the larger as the relative imaginary part magnetic permeability became higher. The measured P_{loss}/P_{in} was as high as 0.21 at 6 GHz, which should correspond to more than 5 dB conduction noise suppression. This research was supported in part by the R&D program of the Radio Use, Ministry of Internal Affairs and Communications, and the Cooperative Research Project Program of the RIEC (H27-B05) Tohoku University.

Nonreciprocal metamaterials have been investigated to discover new electromagnetic phenomena and to invent state-of-the-art functional circuits and antennas [1],[2]. By using nonreciprocal metamaterials, we can have unidirectional wavenumber vectors along the wave-guiding structures regardless of the propagation directions. Transmission-line resonators based on such noneciprocal metamaterials show unique characteristics in that the resonance frequency is independent of the resonators' size and that the field profiles have uniform magnitude and linearly-varying phase distribution, referred to as pseudo-traveling-wave resonators [3]. In addition, phase gradient of the fields along the resonators can be arbitrarily varied by changing the nonreciprocity of the lines under the resonant condition, which is implemented to highly-efficient beam scanning leaky wave antennas [4], and to polarization-switchable circularly polarized antennas. However, most of phase-shifting nonreciprocal metamaterials have resulted in relatively small magnitude of nonreciprocity even with considerably large applied dc magnetic field with the help of strong permanent magnets or huge size of electromagnets, which limit the availability and applications to beam steering antennas for practical use. In order to make the steering beam angle wider for antenna applications or to reduce the magnitude of the dc magnetic field, enhanced nonreciprocity is essential. Recently, the phase-shifting nonreciprocity for the normally magnetized ferrite-based metamaterials was analytically formulated showing that this phenomenon is described by a product of two factors; the one corresponds to off-diagonal component in Polder permeability tensor determining gyro-magnetic characteristics. Another factor is the geometrical asymmetry which is realized by periodically and asymmetrically inserting stubs into the normally magnetized ferrite rod-embedded microstrip lines at the center [5], [6]. So far, shunt stubs periodically inserted in previous metamaterials were constructed on the non-magnetic dielectric substrates to avoid the influence of dc magnetic field on the stub performance. However, capacitive stubs constructed on the dielectric substrate suffer from the coupling between adjacent stubs and cause degradation of enhanced phase-shifting nonreciprocity. In this paper, we propose a new enhancement technique for the phase-shifting nonreciprocity in metamaterial lines loaded with comb-shaped periodic open stubs constructed on the normally magnetized ferrite substrate at one side of strip edges, as shown in Fig 1. In the configuration, the edge guided mode [7] is excited that caused zigzag propagation along each stub. This mechanism corresponds to longer distance for one propagation direction. This situation is realized by reducing the coupling between adjacent stubs. At the other side of strip edges, inductive stubs are periodically inserted to realize negative effective permittivity and to reduce the propagation distance in the opposite direction of propagation. Combination of capacitive and inductive stub insertion results in enhanced nonreciprocity. Polycrystalline Yttrium Iron Garnet was employed as the ferrite material. The configuration parameters for the prototype circuit are as follows; thicknesses of the ferrite and dielectric substrates are both 0.8 mm, dielectric constants of ferrite and dielectric substrates are 15 and 2.6, respectively. The width of the center strip is 2 mm. The length and width of capacitive stubs are 2 mm and 0.8 mm, respectively. The unit cell length is 1.9 mm. In Fig. 2, the simulated and measured phase shifting nonreciprocity $\Delta\beta$ are extracted from the S-parameters for five unit cells and plotted as a function of the operating frequency and externally applied dc magnetic fields. It is found from Fig. 2 that experimental results agree well with numerical simulation results. It is noted that the beam sweep of ±15 degrees in the present configuration corresponds to the nonreciprocity for the external dc magnetic field of ±26 mT only which is about a quarter compared to the typical value of 100 mT required for previous nonreciprocal metamaterials. Thus, reduction of the applied dc magnetic field required for the nonreciprocity will open up realization of tunable nonreciprocity of metamaterials and beam steering antennas for practical use.

AQ-11. Synthesis and Microwave Absorbing Property of $SrZn_xFe_{(2-x)}Fe_{16}O_{27}$ ($0.0 \le x \le 1.0$).

J. You[1], S. Choi[1], S. Lee[1] and S. Yoo[1]
1. Material science and engineering, Seoul National University, Seoul, The Republic of Korea

Strontium W-type hexaferrite ($SrFe_{18}O_{27}$, SrW) is a ferromagnetic material possessing high saturation magnetization (M_s) about 80 emu/g and high anisotropy field (H_a) about 19 kOe [1]. Due to its cost-effectiveness and suitable magnetic properties, W-type hexaferrite has attracted attention for permanent magnet application and microwave application especially for microwave absorber in the large frequency range of 8–40 GHz [2,3]. In this report, we tried to prepare Zn-substituted SrW bulk samples with the compositions of $SrZn_xFe_{(2-x)}Fe_{16}O_{27}$ ($SrZn_xFe_{(2-x)}W$) where x value was $0.0 \le x \le 2.0$ for the first time in a reduced oxygen atmosphere, and identify the effect of Zn^{2+} substitution on their magnetic properties. Furthermore, microwave absorbing properties of $SrZn_xFe_{(2-x)}W$ with varying x were investigated in the frequency range of 1-18 GHz. For these purposes, the samples with different x values were annealed at the temperature region of 1125–1350°C for 2 h in the PO_2 of 10^{-3} atm. As a result, single phase of $SrZn_xFe_{(2-x)}W$ could be obtained for x values of 0.0, 0.5, and 1.0. It was found that cell volumes of the samples increased with increasing x until $x = 1.25$ due to the larger ionic radius of Zn^{2+} than Fe^{2+}, and then remained constant with further increased x. Static magnetic property measured by vibrating sample magnetometer revealed that anisotropy field value of the samples decreased with increasing x from 0.0 to 1.0, and decreased from $x = 1.0$ to 2.0. In contrast, saturation magnetization value increased with increasing x value. And also, the complex permeability and permittivity values for the $SrZn_xFe_{(2-x)}W$-epoxy resin composites with ferrite filling ratios of 30, 50, 70, 90 vol% were measured by vector network analyzer. The measurement revealed that real permeability value increased and ferromagnetic resonance frequency decreased with increasing x value which is attributable to increase in saturation magnetization and decrease in anisotropy field. The reflection loss values were calculated based on the obtained complex permeability and permittivity values. It was found that the reflection loss values larger than -20 dB (90% absorption) could be obtained with absorber thickness less than 1.5mm. Detailed properties of $SrZn_xFe_{(2-x)}W$ will be presented for a discussion.

AQ-12. Transport, magneto-optical and micromagnetic characterization of domain-wall resonance (DWR) in giant magnetoimpedance strain and magnetic field sensors.

G. Büttel[1] and U. Hartmann[1]
1. Institute of Experimental Physics, University of Saarland, Saabrücken, Germany

Recently, very high strain-gauge factors have been determined on micromachined thin-film and multilayer giant magnetoimpedance sensors [1]. The observed domains walls and different magnetization reversal mechanisms are complex and difficult to predict in advance in such sensors, but strongly determine the high-frequency transport characteristics and are critical for strain and magnetic field sensitivity in the low-field regime. In this contribution we report on observed domain walls emerging during sweeping of the external field. Domains were imaged and distinguished by longitudinal magneto-optical widefield Kerr and magnetic force microscopy. The main goal of this study was to obtain a match with micromagnetic simulations carried out by the MUMAX framework. While typically a double peak GMI response has been reported in mm-sized NiFe multilayer thin-film and ribbon GMI sensors with a Cu core layer and surrounding NiFe layers [2], we show that in microstructured and -machined multilayers a well-pronounced fourfold peak behavior can occur. Measurements were performed by a VNA in distinct frequency regimes below the FMR frequency of the Kittel mode. Similar multi-peak effects were also reported for GMI thin-film sensors with CoNbZr in the low-MHz regime, but no explanation could be found so far [3]. The DWR depends on the actual structure of the multilayer system, on materials, post-deposition annealing processes, ac current amplitude and domain-wall types and density. The implications of DWR in GMI sensors may be dis-/advantageous in future GMI sensor applications for magnetic field/particle or strain detection. Therefore, a thorough understanding and prediction of such processes by micromagnetic simulations is very helpful. A careful/thorough set-up of the exciting-field geometries has to be defined in the simulations to understand and verify the more or less pronounced occurrence of DWR in the MHz regime for different multilayer designs. The Oersted field that is generated by the ac current in the Cu core layer has antiparallel orientations in the surrounding bottom and top NiFe layers. For a single layer system, the dipolar coupling between the top and bottom layers adjacent to the Cu core leads to an antiparallel orientation of domain walls and opposing oscillations of the Oersted field and of vortices and anti-vortices in the single layers (Fig. 1). For a double layer system, experimentally and in micromagnetic simulations, the amount of vortex structures is strongly reduced and the DWR peaks in the GMI curve are less pronounced (Fig. 2). This can be qualitatively understood by a very weak antiparallel dipolar coupling of bottom and top double layers and by the antiparallel coupling of the single NiFe layers in each surrounding double layer. This leads to a damping of strong oscillations/DWR as the Oersted field is parallel and antiparallel to the single layers below and on top of the Cu core. In addition, the domain walls of the individual layers of the double-layer system are much stronger coupled by dipolar interactions. Both aspects can be experimentally verified by an identical shape of MOKE-recorded hysteresis curves from the top of the double layer and VSM hysteresis curves of the whole multilayer stack. By applying tensile strain to such double layer GMI sensors, the field regime exhibiting DWR increases as well as the number of domain wall annihilations/nucleations in the low-field regime before the magnetization rotates towards the saturated state. This further proves that a high density of domain walls in microscaled GMI sensors strongly influences or dominates the change of permeability and impedance in the skin-effect regime far below the FMR frequency regime. This may lead to fundamental scaling limits for GMI sensors or it may stimulate new design and materials concepts, when a rotation of magnetization in the low-field regime cannot be established. In conclusion, we show that micromagnetic simulations, not presented so far for GMI devices, are a powerful tool for the prediction of DWR in relatively large GMI devices with odd and even numbers of NiFe layers and alternating changes of dipolar coupling and occurring domain walls. Thereby, optimal strain and field sensitivities can further be explored and optimized for future smaller GMI sensors.

Fig. 1. Longitudinal Kerr-microscopy image of a single system (400µm x 40µm) at 4 Oe. For zero field no vortices/anti-vortices occur in the films and no DWR in the corresponding GMI curves. The density of the vortices strongly depends on the thickness of the Cu core layer

Fig. 2. Longitudinal Kerr-microscopy image for two double (NiFe/Ti/NiFe) layers (400µm x 20µm) surrounding the Cu Core layer at an external field of 4 Oe. Due to the large size and soft magnetic properties of NiFe only a qualitative match (shape, density) to the micromagnetic simulations can be reached. Vortices/anti-vortices do not occur in the double layer system as well as flux closure domains parallel to the longitudinal axis of the GMI structures in comparison to single layers.

AQ-13. New Measurement Method of Broadband Permittivity and Permeability of Non-Solid Materials in Small Quantity.

Evaluation of permittivity (ε) and permeability (μ) of magnetic/dielectric material in microwave band becomes more important with the rapid expansion of microwave technologies. Transmission/reflection line method is well known as a simultaneous measurement method of ε and μ in the band. However in this method material under test (MUT) is limited to solid state. On the other hand, for measuring liquid material open ended coaxial probe method was proposed. The method is disadvantageous in terms of requiring deciliter volumes of MUT for approximating a semi-space filled by MUT. We propose a new measurement method with the aim of simultaneous measuring both of permittivity and permeability of not only solid material but also a small amount of liquid, powder, and gel state material. A plastic toroidal case was utilized to encapsulate non-solid state MUT and whole the case was evaluated by coaxial line method. In this study the cases were modeled using Acrylic 3-D printer (Stratasys, Objet 260 Connex). An example of the plastic case with a cap fabricated is shown in Fig. 1. Outer and inner diameter (7.00 and 3.00 mm) of the case was designed to fit to a coaxial sample holder (KEAD Inc., CSH2-APC7). The length of the case including a cap thickness measured by digital vernier caliper was 5.00 mm. In the same way, thickness of wall, bottom, and cap was 0.45, 0.50, and 0.50 mm, respectively. Accordingly the volume of MUT required for the case was about 70 microliters. The specimen which MUT was encapsulated was inserted to the coaxial sample holder and complex scattering (*S*) parameters from 1-10 GHz were taken using a vector network analyzer (Hewlett-Packard, HP 8720D). *S*-parameters whose reference planes were both upper and lower surface of the specimen were obtained by shifting reference planes of the measured *S*-parameters. After that we obtained *S*-parameters of MUT in numerical calculations mentioned below in order to take away unwanted plastic case portions. The specimen can be divided into three coaxial portions: Inner cylindrical wall, outer cylindrical wall, and middle core including MUT between their walls. From the viewpoint of electric circuit it corresponds to a series connection of the three two-port networks. Impedance (*Z*) parameters of the middle core were obtained using the relationship: *Z*-matrix of the specimen equals to the sum of their three *Z*-matrices. *Z*-matrix of the specimen was obtained by converting *S*-matrix of it by a reference impedance. *Z*-matrix of outer and inner wall was obtained from ε and μ measured in advance using solid specimens of the plastic material and outer and inner diameters of their cylindrical walls. *Z*-matrix of the middle core was converted *S*-matrix again. The middle slender core can be divided into three coaxial portions: a part of cap, a part of bottom, and MUT. The core corresponds to a cascaded connection of the three two-port networks. Transfer (*T*) parameters of MUT were obtained using the relationship: *T*-matrix of the core equals to the product of their three *T*-matrices. *T*-matrix of the core was obtained by converting *S*-matrix of it. *T*-matrix of a part of bottom and cap was obtained from ε and μ of the plastic material used and bottom and cap thickness. Finally ε and μ of MUT were calculated from *S*-parameters of it using Nicolson-Ross-Wier algorithm [1, 2]. In this study, the air at the volume was measured as MUT in order to confirm a validity of the proposed method. The dependences of real and imaginary part of relative permittivity of air obtained by this method on frequency were shown in Fig. 2(a) and Fig. 2(b). Although the both values had a margin of error of plus or minus 10% a constant and nearly ideal relative permittivity of air was confirmed in the band measured from these figures. This result indicates that the proposed method is effective for measuring non-solid materials.

AQ-14. Comparative Analysis of Core Loss Calculation Methods for Magnetic Materials Under Nonsinusoidal Excitations.

Y. Li[1], S. Yue[1] and Q. Yang[2]

1. Hebei University of Technology, Tianjin, China; 2. Electrical Engineering, Tianjin Polytechnic University, Tianjin, China

I. Introduction Magnetic components in power electronic devices usually suffer from nonsinusoidal excitations. In this paper, a brief description about the existing core loss calculation methods for nonsinusoidal excitations is given. Then calculation formulas of aforementioned methods for two typical excitation waveforms, that is square and rectangular with variable duty cycle, are derived and analyzed. Core loss of nanocrystalline FT-3KS, under both sinusoidal excitations and above two nonsinusoidal excitations, are measured on an established test setup. The experimental results are then compared with the calculated values from derived formulas. It is found that the waveform coefficient Steinmetz equation (WcSE) is more applicable for the case of relatively small harmonic content of *H*, while the improved generalized Steinmetz equation (IGSE) has relatively good precision when the harmonic content is large. The results can provide reference for core loss prediction. II. Core Loss Calculation A. Brief Review of Existing Methods Traditionally, core loss for sinusoidal excitations can be divided into hysteresis model method, core loss separation method and Steinmetz equation (SE) method. In recent years, many other core loss calculation approaches based on SE have been developed for non-sinusoidal excitations, including the modified Steinmetz equation (MSE)[2], the generalized Steinmetz equation (GSE)[3], the improved generalized Steinmetz equation (IGSE)[4] and waveform coefficient Steinmetz equation (WcSE)[5]. In this paper, we only discuss SE, MSE, IGSE and WcSE for IGSE is considered as an improved version of GSE. B. Calculation Formulas for Typical Waveforms In this part, the calculation formulas are derived by applying MSE, GSE, IGSE and WcSE to square and rectangular waveform excitations, which will be presented in the full paper. It can be seen from these formulas how the core loss is affected by the waveform duty cycle *D*. III. Experimental Verification and Discussions A. Core Loss Measurement Both sinusoidal excitations and two nonsinusoidal excitations with variable *D* [0.05-0.95] are built to conduct the experiments, as shown in Fig. 1. The *B-H* loop measurement method is selected to calculate core loss for the copper loss is excluded. Fig. 2 (a) and Fig. 2 (b) illustrate the exciting voltage and current waveforms of square excitations and rectangular excitations at 10kHz when *D* is 0.3 (up), 0.5(middle), 0.7(bottom), respectively. B. Results Comparision and Discussion Fig. 2 (c) and Fig 2 (e) present the comparision results of loss prediction through SE, MSE, IGSE, WcSE and the corresponding percentage errors under square excitations with variable *D*, at 10 kHz and 0.8T. For square excitations, it is clear that the WcSE exhibits better accuracy (>92%) in predicting core loss than SE, MSE and IGSE for a duty cycle range of about[0.4-0.6]. However, the accuracy decreases rapidly with the duty cycle out of this range, where the IGSE shows relatively good prediction instead. Similarly, Fig. 2 (d) and Fig 2 (f) indicate the comparision results of loss prediction and the corresponding percentage errors under rectangular excitations with variable *D*, at 10 kHz and 0.8T. In this case, the IGSE demonstrates satisfactory precision (>90%) over the whole range of duty cycle, although the WcSE is more accurate in the range of [0.6-0.95]. Actually, the above phenomena can be summarized as: the WcSE is more suitable for the case of relatively small harmonic content of exciting current (namely *H*), while the IGSE, due to the consideration of major and minor hysteresis loops resulting from harmonics, can maintains a relatively good accuracy where the harmonic content counts. For square excitations, the harmonic currents are gradually increasing with *D* approaching 1 or 0 from 0.5. For rectangular excitations, it has the same effect as the previous one when *D* approaches 0 from 1. More details about the discussion will be presented in the full paper. IV. Conclusions In this paper, the calculation formulas for square and rectangular excitations are derived based on the existing methods. Core loss of nanocrystalline FT-3KS, under both sinusoidal excitations and above two nonsinusoidal excitations, are measured on an established test setup. The experimental results are then compared with the calculated values from derived formulas. It is found that the waveform coefficient Steinmetz equation (WcSE) is more applicable for the case of relatively small harmonic content of *H*, while the improved generalized Steinmetz equation (IGSE) has higher precision when the harmonic content is relatively large. The results can provide reference for core loss prediction.

AQ-15. Design and Analysis of a Novel High Frequency 2-D Magnetization Structure with Ultra-Thin Silicon Steel Sheet.

Y. Li[1], Y. Dou[1], C. Zhang[1], A. Li[1] and J. Zhu[2]
1. Hebei University of Technology, Tianjin, China; 2. Electrical engineering, University of Technology, Sydney, Sydney, NSW, Australia

I. Introduction The measurement of high frequency magnetic properties is very important, not only in the application of emerging power electronics and special motors, but also in traditional motors and transformers, because the existence of higher harmonics will cause large additional losses. Whereas, the Epstein frame can only measure the 1-D magnetic properties, and the high frequency magnetic properties are measured with ring sample method. In addition to these, numerous engineering-oriented testing electromagnetic analysis methods and devices have been proposed in [2]- [4]. In order to solve these problems, the high frequency magnetic properties of silicon steel sheets should be measured, or the ultra-thin silicon steel and nanocrystalline that can generate high-frequency magnetic field are used as cores to measure the2-D high-frequency magnetic properties. To magnetize the sample to saturation, ultra-thin silicon steel is chosen as the material of magnetization circuit instead of nanocrystalline, because the saturated magnetic density of the device can be higher if the sample is saturated. Ultra-thin silicon steel is gradually applied to electromagnetic equipment for its excellent magnetic characteristics, which is of great significance in accurate magnetic properties measurement in high frequency. By using this material, a novel high frequency 2-D magnetization structure with multi-layer excitation winding and composite sensing box is proposed. In order to measure vector *B* and *H* of the nanocrystalline or ultra-thin silicon steel sheet samples in high frequency, a feedback control method based on LabVIEW is applied, which can effectively diminish the adverse effects of harmonics and obtain more uniform magnetic fields. II. novel 2-d magnetization structure A. Modeling of the 2-D Magnetization Structure The novel 2-D magnetization structure consists of four "C-type" cores, magnetic material specimen and four multi-layer exciting windings, which are wound around the orthogonal core poles, as shown in Fig. 1(a). In order to magnetize the specimen to saturation in high frequency, a high-grain-oriented ultra-thin (0.05mm) silicon steel is applied in the excitation core, which can increase the excitation field and reduce the core loss, comparing with the common silicon steels. The testing specimen is placed in the center of the 2-D tester and jointed by four core poles. As illustrated in Fig. 1(b), the four "C-type" cores are almost the same shape except for the core pole part. They can be classified into two types according to the different core pole shapes. The multi-layer excitation winding is composed of three layers with different turns, which can be connected in series or parallel to satisfy variable exciting frequency range, flexibly. B. B-H Composite Sensing Structure The *B-H* composite sensing structure combines one piece of testing specimen, two fixing frames, two guarding pieces, two sets of *B-H* composite sensor, as shown in Fig. 2(a). The *B-H* composite sensor is fixed in the fixing frame as shown in Fig.2 (b), which consists of two crossed *H*-sensing coils and *B* needle probes, that is B_x, B_y, H_x, H_y. *H* sensing coils are wrapped around the epoxy resin board with 80 turns to test the magnetic field strength in both directions. According to the theory that the strength of magnetic field along the tangential direction is continuous at the boundary of the different media, the *H*-sensing coils can detect the magnetic field strength *H* on the specimen surface. Therefore, the air gap between the *H*-sensing coils and the testing specimen should be as smaller as possible. The magnetic flux density *B* can be detected by four needle probes placed on the four corners of the epoxy resin board. The magnetic material specimen needs to be magnetized by a strong and homogenous field. To acquire a uniform field, two guarding pieces, which are the same material and with the same grain oriented direction as the specimen, are attached on every surface of the specimen. Fig.2 (c) exhibits the distinctive comparison of the magnetic flux density distribution with and without guarding pieces. By comparing the simulation results in the diagram, it can be concluded that the adoption of guarding pieces obviously improves the uniformity of the field on the specimen surface, improving the measurement precision significantly. III. 2-d Magnetic Properties Measurement Systerm The existing 2-D magnetic properties measurement system mainly consists of 2-D magnetic properties tester, *B-H* composite sensing structure, NI PXIe-6368, differential amplifier circuit and two power amplifiers, which are used to amplify the excitation signal. In order to get an ideal magnetization loci within the specimen, the feedback control method based on LabVIEW is used, which greatly diminishes the adverse effects of harmonics and increase the accuracy of the measurement. Excitation of different frequencies are given to the tester, thus a series of well controlled circular *B* loci and corresponding experimental *H* loci are obtained at 50 Hz, 500Hz, and 1kHz for ultra-thin silicon steel sheet. The detailed measurement and analysis will be presented in the full paper.

Nowadays, as the rapid development of electronic and communication technology, the various devices are developing towards miniaturization and lightweight, especially the devices with small size and high performance are ever increasingly demanded. A challenge in this process is that the reduced size of device often produces performance degradation due to the fact that the performance of many devices is dependent on their size. In recent years, magneto-dielectric ferrite materials have received considerable attention and show unique advantage for miniaturized and high-performance radio frequency (RF) and microwave devices since ferrites have concomitant medium to high permeability and permittivity. Such as in antenna applications, by employing a ferrite substrate, antenna's dimensions can be largely reduced while larger impedance bandwidth is also expected to be achieved. In this paper, a serious of NiZnCo ferrites with the simultaneous additions of CaO and SiO_2 are synthesized, and the magnetic and dielectric properties of the samples are investigated over a wide frequency range of 10 MHz-1 GHz. The crystal phase, densification and microstructure of the NiZnCo samples were analyzed in detail to correlate with the variations of the magnetic and dielectric properties. NiZnCo spinel ferrites with nominal composition $Ni_{0.5}Zn_{0.3}Co_{0.2}Fe_2O_4 + x$ (CaO, SiO_2) (where x = 0, 0.3, and 0.6 wt% and the molar ratio between CaO and SiO_2 is 1:1) were prepared by solid-state reaction method. For the present experiment, the second time ball-milling was prolonged to 24 h and the samples were sintered at 1100 °C for 3 h in an air atmosphere. The phase compositions of the sintering samples were determined by X-ray diffraction (XRD) using Cu Kα radiation at room temperature. The XRD results indicate that all the samples show the formation of cubic spinel structure. The microstructures of the samples were examined by scanning electron microscope (SEM) and an energy-dispersive spectrum analyzer (EDS). The effects of CaO-SiO_2 additions on the magnetic and dielectric properties of NiZnCo ferrite were systematically investigated. The complex permeability and permittivity spectra, as well as magnetic and dielectric losses of the samples were measured in 10 MHz-1 GHz (here using E4991 impedance analyzer). Fig. 1(a) shows the measured real permeability μ' with CaO-SiO_2 content from 0 to 0.6 wt%. It is observed that the permeability increases gradually with CaO-SiO_2 addition. With x varying from 0 to 0.6 wt%, μ' increases from ~7.0 to ~7.3 at 10MHz. The permeability ε', however, exhibits obvious decrease with x, as illustrated in Fig. 1(b). For the undoped NiZnCo ferrite, ε' is around 10.5 over the studied frequency range. With 0.3 wt% CaO-SiO_2 addition, ε' decreases to ~10.0, and when x is up to 0.6 wt%, ε' decreases to ~9.5. These variations in magnetic and dielectric properties were proved to be closely related to the changed microstructure and densification. Additionally, the losses of the samples are found to be closely dependent on CaO-SiO_2 addition content. Fig. 2 presents the variations of dielectric loss tan δ_ε with CaO-SiO_2 content at 100 MHz and 300 MHz, respectively, and there are similar variations at the two frequencies. At 300 MHz, tan δ_ε is about 1.9×10^{-3} for the samples with x=0 and 0.3 wt%, and for the sample with x= 0.6 wt%, tan δ_ε is reduced to 1.5×10^{-3}. For the doped NiZnCo ferrites, the decreased dielectric loss is attributed to the combined effect of the high-resistance CaO and SiO_2. The above observations indicate that a certain amount of codoping of CaO and SiO_2 can modify both the magnetic and dielectric properties of NiZnCo ferrite, with opposite effects on the permeability and permittivity. This point could be helpful to balance the impedance matching of ferrite materials to free space environment ($Z = Z_0 (\mu'/\varepsilon')^{1/2}$, where Z_0 is impedance of free space) for realizing miniaturized and high-performance RF and microwave devices.

Magnetic RAM (MRAM) is experimentally proved intrinsically immune to radiation effects including heavy-ion irradiation and total ion does [1-3] as the data is represented by the spin instead of charges. It is considered as a promising candidate for aerospace and avionic electronics. However, its CMOS peripheral read/write circuits are much more vulnerable to radiation-induced single event upset (SEU) and multi-bit upset (MBU), also called soft errors [4]. Therefore radiation hardening techniques are required to correct soft errors induced by irradiation. Currently, existing radiation hardening techniques are focused on sensing amplifiers of spin transfer torque (STT)-MRAM rather than write circuits since the write pulse is longer than the radiation-induced current pulse. However, for spin orbit torque (SOT)-MRAM, the magnetization switching time (<1ns) is comparable to the width of radiation-induced pulse. Therefore write circuits for SOT-MRAM is seriously required to harden since it may be disturbed by irradiation to switch the storage state of magnetic torque junction (MTJ), which called non-volatile SEU (NVSEU) [5]. Although radiation hardening techniques of sensing amplifiers have been proposed, such as C-element and XOR logic gate [6], they cannot correct MBU induced by charge sharing especially with the decreasing process dimension. In this work, we first proposed a novel hardening peripheral CMOS read/write circuitry for SOT-MRAM shown in Fig. 1. By using a physics-based SOT-MTJ compact model and a 65nm CMOS design kit, hybrid simulations are performed to validate the radiation tolerance of the novel peripheral read/write circuitry. For write circuits, sensitive nodes are A and B shown in Fig. 1(a). Unprotected write circuits may be disturbed by NVSEU to induce incorrect magnetization switching. For hardening write circuits, wherever radiation-induced particles strike, the struck node can be recovered within hundreds of picoseconds through added redundant nodes and feedback connections. Meanwhile the incorrect magnetization state is corrected, as verified by the simulation results of Fig. 2(a). For hardening read circuits shown in Fig. 1(b) [7], sensitive nodes may be Q, Qb, S0 and S1 depending on the stored data. For example, during the clock rising edge of reading "0", sensitive nodes are node Q, S0 and S1. Meanwhile Qb is a stable high voltage node since it is connected to PMOS transistors (when PMOS is struck, a positive transient pulse is generated [8]). Every sensitive node is immune to SEU as the following reasons: i) When node Q is turned "1" by a struck particle, S0 and S1 as cross-coupled connections retain initial states. Q is discharged through PM16 to recover. ii) When node S0 is turned "0" by a struck particle, S1 stays floating state with "0" and Qb stays throughout high voltage as the driving ability of PM12 is stronger than PM15. iii) Similarly, S1 is corrected through the similar path to S0 since the hardening read circuits are symmetrical. In addition, if nodes S0 and S1 are simultaneously struck to induce MBU, the proposed hardening read circuits also can be recovered, as shown in Fig. 2(b). Although the proposed read circuits are vulnerable to MBU for the rest multi-sensitive nodes (i.e. S0-Q and S1-Q), the solution is that using physically apart approach [9] to expand the space between sensitive nodes (the layout is omitted). More importantly, the proposed hardening read circuits effectively reduce the hardware area compared to those of the previous works [5-6]. The circuitry reliability is also validated by a Monte-Carlo statistical analysis tool taking into account process variations. This spintronic/CMOS circuitry can be reliably integrated into aerospace and avionics electronics in hostile environments.

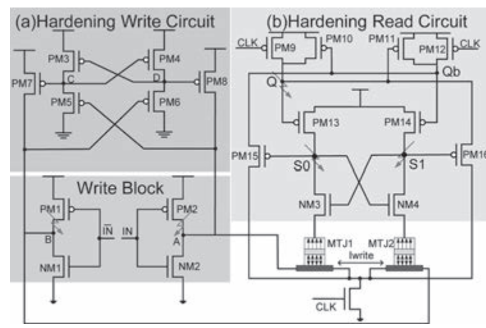

Fig. 1. Schematic of the proposed radiation hardening peripheral circuitry for SOT-MRAM cell whose storage element is a pair of MTJs to maintain opposite magnetization direction (parallel and antiparallel). (a) Hardening write circuits, which include six PMOS transistors (PM3-PM8) and feedback connections to perform the hardening construction. (b) Hardening read circuits, which utilize a pair of cross-coupled connections (i.e. NM3-NM4). Nodes Q and Qb are driven by two PMOS transistors. Nodes S0 and S1 are driven by a NMOS and a PMOS transistor. Meanwhile, their gates are connected to two different nodes. For reading "0", outputs Q and Qb are "0" and "1" (i.e. MTJ1 and MTJ2 are in low and high resistance states, respectively).

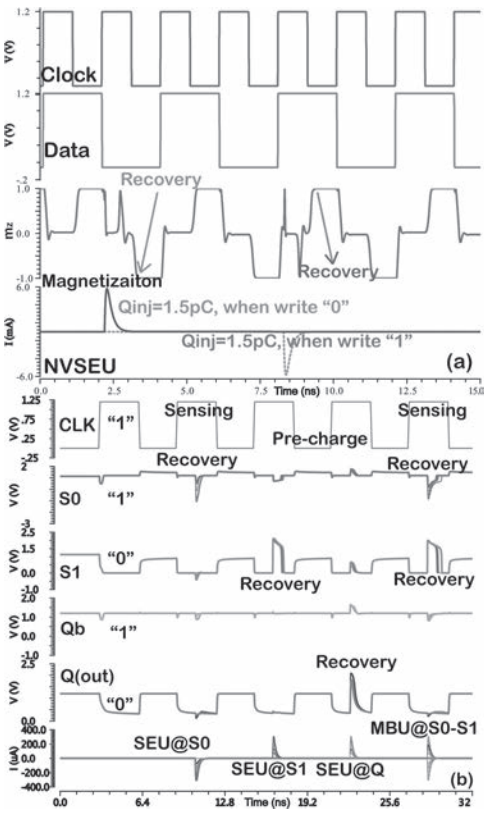

Fig. 2. (a) Transient simulation waveforms of the hardening write unit when Q_{inj} is 1.5 pC. The magnetization state can be recovered in several hundred picoseconds no matter write "1" or write "0". (b) Transient simulation waveforms when Q_{inj} varies from 20 fC to 100 fC. Struck nodes are S0, S1, Q and S0-S1 respectively, and output Q can be correctly accessed without soft errors.

AR-02. Magnetization uniformity and threshold current of out-of-plane precession in spin-torque oscillator with synthetic ferrimagnet free layer under perpendicular magnetic field: Micromagnetic simulation study.

T. Kanao[1], T. Nagasawa[1], H. Suto[1] and K. Mizushima[1]

A spin-torque oscillator (STO) is a microwave oscillator based on a magnetoresistive (MR) element [1,2], and has been investigated for applications such as information storages, communications, and computing units. For these applications, large output signal and stable oscillation are necessary. So far, it has been reported that the large output signal can be obtained by out-of-plane precession (OPP) of free layer in an STO based on a magnetic tunnel junction (MTJ) and having an in-plane pinned layer [3-6]. This is because in OPP change of angle between the magnetizations of free and pinned layers is large and the relative angle change is converted into the output signal through the large MR effect of the MTJ. To further improve the output power and the stability of the OPP, we have recently fabricated an STO based on an in-plane MTJ with a synthetic ferrimagnet (SyF) free layer (SyF-STO). We have chosen the SyF free layer because improvement of the output power and the stability has been reported for in-plane oscillation [7-9]. We have investigated whether the OPP is possible in the SyF-STO. As a result, by the OPP of the free layer we have obtained large output power of the order of 1 μW in perpendicular field [10]. (In Ref. [10] we reported the maximum output power of 3.7 μW. This value includes an error in estimation, and the correct value is 0.93 μW.) In this study, to clarify the reason for the large output power obtained in the SyF-STO, we compare the SyF-STO with an STO with a single free layer (SFL-STO) by micromagnetic simulation. Figure 1 shows schematics of these STOs. The SyF-STO has two free layers which are antiferromagnetically coupled (AFC) by the interlayer coupling. The pinned layers are also AFC. An external field H_z and a current I are applied in the perpendicular direction. The spin-transfer torque acts on the free layer 2 and the pinned layer 1. To the bottom pinned layer, a -x-direction magnetic field is applied, modeling an exchange bias field. In the simulation, we use the parameters corresponding to the sample in the experiment. The parameters for the SFL-STO are the same as the SyF-STO except that the SFL-STO has a single free layer. Figure 2(a) shows oscillation powers of each STO as a function of H_z for I=8.5 mA, which are obtained from the y-components of the spatially-averaged magnetizations. The oscillation power is estimated by time average of square of the y-component of normalized magnetization. For H_z≥5 kOe, both STOs exhibit the large oscillation powers due to the OPP. In the SyF-STO, the magnetizations of the two free layers are synchronized and their in-plane components are in opposite directions. The oscillation power is larger for the SyF-STO. In the parameter range of the OPP, the oscillation frequencies of both STOs show essentially the same dependence on H_z, that is, the oscillation frequencies increase, showing a step. By investigating the waveforms of the magnetizations, we find that this step originates from coupled magnetization oscillation of the free and pinned layers due to magnetic dipolar field and the spin-transfer torque. This dependence of the oscillation freqeuncy on H_z well reproduces that observed in the experiment [10]. Such steps of oscillation frequency have been reported for SFL-STOs with OPP [1-3,7,11]. To clarify the reason of the difference of the oscillation power, we compare amplitudes of the spatially-averaged magnetizations of the free layers. Figure 2(b) shows time averages of the amplitudes. Since the magnetization is normalized, the amplitude is closer to 1 when the magnetization is spatially uniform. It is found that the amplitude for the SyF-STO is kept near 0.9 for the OPP, while that for the SFL-STO decreases to about 0.75 at around H_z=5 kOe. This difference means that the free layer magnetization of the SyF-STO is uniform compared with the SFL-STO. Inset in Fig. 2(b) shows magnetization configurations of the free layers of the SyF- and SFL- STOs for H_z=5 kOe. The y-component is shown by the color scale at a moment when the in-plane components of the spatially-averaged magnetizations are in the x-direction. In the SyF-STO, although local fluctuations can be seen, their magnitudes are relatively small. On the other hand, in the SFL-STO, the free layer is divided into two regions in which the in-plane components of the magnetizations are almost in opposite directions. This non-uniform magnetization pattern reduces stray field outside the free layer, and stabilizes magnetic field distribution. From this result we think that the almost uniform magnetization precession in the SyF-STO is because the SyF free layer reduces the stray field and thus the magnetic field distribution can be stabilized even by the uniform magnetizations. The uniform OPP of free layer magnetizations leads to the larger output power, which is a possible explanation for the large output power observed in the experiment [10]. Finally, in Fig. 2(c) we compare threshold current for the OPP, and find that the threshold current is smaller for the SyF free layer. It can be thought that this lower threshold current enables the OPP by a bias voltage lower than a voltage at which the dielectric breakdown of the MTJ occurs.

AR-03. Fabrication of $L1_0$-MnAl thin films with high perpendicular magnetic anisotropy for STT-MRAM.

M. Parvin[1], M. Kubota[1], M. Oogane[1], M. Tsunoda[2] and Y. Ando[1]
1. Applied Physics, Graduate School of Engineering, Tohoku University, Sendai-shi, Japan; 2. Electronic Engineering, Tohoku University, Sendai, Japan

Magnetic tunnel junctions with perpendicularly magnetized ferromagnetic materials (*p*-MTJs) have great potential to realize the ultra-high-density STT–MRAM. The switching current density (J_{co}) in STT-MRAM is directly related to saturation magnetization (M_s) and Gilbert damping constant (α) of the ferromagnetic free layer of MTJs [1]. In order to achieve high thermal stability and low switching current density in *p*-MTJs, ferromagnetic materials with large perpendicular magnetic anisotropy energy (K_u), small M_s and low α are required. Here, we focus on a $L1_0$-MnAl alloy, which exhibits small M_s and high K_u[2,3]. In our previous works, we obtained large K_u in $L1_0$-MnAl films prepared at high substrate temperature [4]. However, high-substrate-temperature can cause increasing roughness of the films and atomic diffusion between the MnAl films and their buffer layers. In this work, we systematically investigated substrate and annealing temperature dependences of structural and magnetic properties in the MnAl thin films. The film stacking structure was MgO(001)-sub./CrRu(40)/MnAl(50)/Ta(5) (in nm). All the films were prepared by a magnetron sputtering system. The Mn-Al alloy target composition was $Mn_{46}Al_{54}$.The substrate temperature (T_s) during deposition was varied from 200^{0}C to 400^{0}C and the post-annealing temperature (T_a) was varied from 200^{0}C to 500^{0}C. The crystal structure of MnAl(50nm) films was investigated by an X-ray diffraction (XRD). The magnetic properties and surface morphology of the films were measured by superconductive quantum interference device (SQUID), vibrating sample magnetometer (VSM), and atomic force microscope (AFM). We confirmed that CrRu buffer layers had good structural property and very smooth surface morphology after annealing at 650^{o}C. Fig. 1showsXRD patterns of the films at T_s =250^{o}C with different annealing temperature. In the XRD patterns,(001) and (002) peaks of $L1_0$-MnAl were observed. This result indicates that both $L1_0$-ordered and (001)-oriented MnAl films were successfully fabricated. The peak intensity of $L1_0$-MnAl was improved with increasing both substrate and annealing temperature. However, surface roughness drastically increased above T_s = 300^{o}C. The annealing temperature dependence of magnetic properties was systematically investigated in MnAl films with T_s = 250^{o}C. A very high K_u was obtained at T_a = 350^{o}C as shown in *M-H* curve in Fig. 2.We finally obtained a $L1_0$-ordered MnAl film with high K_u of 13.0 Merg/cc, relatively low M_s of 497 emu/cc and small roughness (R_a)of 0.3 nm in the condition of T_s = 250^{o}C and T_a =350^{o}C. The optimized MnAl film will be greatly useful to realize the high-density STT-MRAM. This work was part of a research and development project for ICT key technology to realize future societies.

Introduction Spin transfer torque (STT) switching is considered as a promising writing scheme to realize a Gbit-class magnetic random access memory (MRAM). To create a high density MRAM with more than 10 Gbit capacity, further improvements of the memory cells with high thermal stability Δ and low switching current density J_{sw} are required. We have designed bi-multilayers (MLs) stack with high Curie temperature (T_C) Co/Pd and low T_C CoPd/Pd MLs for the memory layer to achieve efficient spin transfer torque (STT) switching [1, 2]. Previously, we have reported that the switching of only the high T_C Co/Pd MLs at 170°C promoted the full switching of bi-MLs hybrid stack due to the exchange coupling between high and low T_C MLs [1]. In this work, we fabricated a tri-MLs hybrid stack with Co/Pd, CoPd/Pd, and Co/Pt MLs, since the tri-MLs stack is calculated to be more efficient than bi-MLs stack, and we report temperature dependence of the hysteresis of the tri-MLs and STT switching of the memory layer with low T_C CoPd/Pd. Experimental method The tri-MLs hybrid stacks were fabricated by magnetron sputtering on thermally oxidized silicon substrates. The stack is substrate / Ta (10 nm) / Pt (5nm) / [Pt (1.2 nm) / Co (0.4 nm)]$_6$ ML / [Pd (1.2 nm) / $Co_{48}Pd_{52}$ (0.3 nm)]$_3$ ML / [Pd (1.2 nm) / Co (0.4 nm)]$_3$ ML / SiN (5 nm). The intermediate Pd/CoPd ML exhibits low T_C of ~ 130°C, and we also fabricated the sample replacing the low T_C Pd/CoPd by Pd (4.5 nm) as a control sample. We refer to the former stack as stack A and the latter stack B. Hysteresis loops were checked by magneto-optical Kerr spectrum measurement system at various sample temperatures. Experimental result Figure 1 (a) shows hysteresis loop of stack A at room temperature. The loop exhibits square shape indicating that the magnetizations of tri-MLs switch simultaneously due to the exchange coupling through intermediate CoPd/Pd MLs. On the other hand, at 172°C, the loop exhibited two-step feature suggesting the Co/Pd and Co/Pt MLs switch independently as shown in Fig. 1 (b). The H_c of Co/Pd and Co/Pt MLs were estimated to be 0.42 kOe and 1.8 kOe, respectively. The H_c of the two MLs were similar to those of sample B with intermediate Pt 4.5 nm layer (not shown in the figure). Figure 2 shows temperature dependence of Kerr rotation and coercivities of the two MLs in the stack A estimated from the hysteresis shown in Fig. 1 (a) and (b). The Kerr rotation gradually decreased with increasing the temperature. The single step hysteresis, indicating the two MLs switch simultaneously, was observed up to 120°C, and then the two-step feature with different H_c of Co/Pd and Co/Pt MLs was obvious above 130°C, which is consistent with T_C of the intermediate CoPd/Pd ML. The H_c of Co/Pd (Co/Pt) ML decreased (increased) with increasing the temperature, which may indicate the gradual decrease of the exchange coupling through the CoPd/Pd ML by elevating the temperature. In the presentation, STT switching of the bi-MLs stack with CoPd/Pd and Co/Pd MLs is also discussed.

AR-05. Magnetic Properties of Mn-based Heusler alloy films with Ru doping.

L. Ren[1], Y. Zheng[1], Y. Liu[1] and K. Teo[1]
1. Department of Electrical & Computer Engineering, National University of Singapore, Singapore

Recently Mn-based Heusler alloys have attracted considerable attention for the potential spintronic applications due to their high spin polarization, low damping constant, high magnetic anisotropy, and low magnetization [1-3]. Especially the tetragonal Mn-based Heusler alloys like Mn_3Ga, Mn_3Ge, Mn_2RhSn have been found to be possible candidates for spin transfer-torque applications [4, 5]. It is noted that most of the previous investigations are focused on Mn-based heusler alloys composed of 3*d* transition metal elements like Cu, Co, Fe, and Ni. But there are few reports about Mn-based Heusler alloys composed of 4*d* and 5*d* elements [6]. Here we report a series of Mn-based Heusler alloy films with Ru doping grown on MgO substrate with Cr buffer layer using co-sputtering method from Ru and a series of Mn_xGe (x = 2, 2.2, 2.4, 2.5) targets. All the films were deposited at room temperature and then *in-situ* annealed at 700 *K* for 1h. Finally, a 2 nm Ta cap layer was deposited at room temperature in order to prevent oxidation. X-ray diffraction measurements were carried out using *Singapore Synchrotron Light Source* (*SSLS*). The results indicate that all the films with the thickness of 35 nm exhibit ordered $L2_1$ structure and that the epitaxial relationship is $Mn_{3-x}Ru_xGe$ [110]//Cr [110]//MgO [100]. The magnetizations of the films were measured at room temperature using VSM in a magnetic field of up to ±2 T along [100], [110], and [001] directions of the film. The measurement results of the 35 nm $Mn_{2.2}Ru_{0.8}Ge$ film are shown in Fig. 1, which indicates that the direction perpendicular to the film is a magnetic hard axis. Moreover, the magnetization shows very sharp switching at 25 Oe with applied filed along [110] direction of the film, and the residual magnetization almost equals the saturation magnetization value 135 emu/cc. Besides, the magnetization along [100] direction is a hard magnetic axis compared to the [110] direction one. For further comparison, we selected the easy axis *M-H* loop measurements of all the films with different Ru concentration as shown in Fig.2. The results indicate that both residual magnetization (M_r) and saturation magnetization (M_S) increase with Ru concentration increasing, while the coercivity (H_C) becomes smaller. Considering of the different valence electrons number (N_v) between Ru (N_v=8) and Mn (N_v=7), the fact that the Ru substitution of Mn can alternate the total magnetic moment and ferrimagnetic magnetic structures of the $Mn_{3-x}Ru_xGe$ Heusler alloys. Our attempts provide alternative candidates for the Heusler alloys-based spintronic applications.

Reducing the switching current keeping the thermal stability in nanomagnets with perpendicular anisotropy are key factors in the development of STT-MRAM, which is expected to be a next generation nonvolatile memory[1][2]. In this paper, we investigated the effect of the Dzyaroshinskii-Moriya interaction (DMI) on the switching current and the thermal stability in nanomagnets[3][4]. It is expected that the magnetization structure and the swiching mechanism of nanomagnets will be changed by DMI, therefore not only the swiching current but also the thermal stability will be changed. We investigated the conditions to reduce the switching current keeping the thermal stability by DMI using micromagnetic simulations. In the simulation, a circular disk with 30 nm of the diameter and 2 nm of the thickness was used as the recording layer of STT-MRAM. The disk was discretized by 1.875×1.875 ×2 nm^3 of the calculation cells. The material parameters used in the simulation were a saturation magnetization M_s = 600 emu/cm^3, a gyromagnetic ratio γ = 17.6 Mrad/s/Oe, an exchange stiffness constant A = 1.0 μerg/cm, the Gilbert damping constant α = 0.1~0.001, and the DMI constant D = 0.0~1.0 erg/cm^2 [5]. The thermal stability factor (Δ) changes by the perpendicular anisotropy constant (K_u) and the DMI. We investigated the condition to keep the thermal stability factor of Δ = 60 [6] by simulations (Fig. 1). The pulse width (t_p) of the spin current was varied for 0.1~10 ns. Figures 2 (a) - (c) show the effect of the Gilbert damping constant, pulse width, and DMI on the switching current density. The switching current decreased with increasing DMI for t_p =0.1,1,10 ns and α=0.001 (Fig.2(a)), t_p =0.1,1 ns and α=0.01 (Fig.2(b)), and t_p = 0.1 ns and α = 0.1 (Fig. 2 (c)). The switching current was decreased 60% in maximum. In the short pulse case (t_p = 0.1 ns), the reduction rate of the switching current does not change by the Gilbert damping constant. However in a long pulse, the switching current increasese as the Gilbert damping constant is increased (Figs. 2 (b), (c)). The results are explained as follows. In the previous study, an empirical equation of the switching current was derived (Eq. 1) [6]; $I_{sw} = 2eM_sV / \mu_B gP\ (\alpha\gamma 2K_u / M_s + C_1 / t_p)$ (1) where, $C_1 = [\ln\{(1-\cos\theta_{crit}) / (1+\cos\theta_{crit})\} - \ln\{(1-\cos\theta_{init}) / (1+\cos\theta_{init})\}]/2$, θ_{init} is the initial magnetization angle with respect to the easy magnetization axis, and θ_{crit} is the critical angle ($\theta_{crit} = \pi - \theta_{init}$). Therefore, C_1 changes by θ_{init}. The right side of Eq. 1 has two terms. In order to keep the thermal stability as described above, it is necessary to increase K_u, therefore the first term increases as D is increased. However, the initial magnetization angle (θ_{init}) increases with increasing D, and then C_1 is decreased, therefore, the second term decreases. The first term is small when α = 0.001, the switching current is determined mainly by the second term, therefore, the switching current decreases as DMI is increased (Fig. 2(a)). On the other hand, when α is large and t_p is long, the second term decreases, therefore, the switching current increases as DMI is increased (Figs. 2 (b), (c)).

Magnetization dynamics are strongly influenced by damping process, which describes energy dissipation of magnetization. For spin-transfer torque magnetic random-access memory (STT-MRAM), it is very crucial to know an exact value of the damping constant because the critical current density of STT-MRAM is proportional to the damping constant. In the determination of the damping constant, a ferromagnetic resonance (FMR) spectroscopy which provides information on the magnetic damping through study of the linewidth of the microwave absorption peak (full-width half-maximum, FWHM) is widely used [1,2]. However, FMR technique requires un-patterned ferromagnetic thin films, so that FMR technique is hard to apply to the nano-sized patterned MTJ cell, which is practically important. In this paper, we report the effect of the damping constant on the FWHM of switching time distribution in case of nano-size patterned MTJ by solving Fokker-Planck equation (FPE). Proposed method relies on the recent experiments of the time evolution of the device conductance change in sub-ns STT switching event in perpendicular MTJ [3]. One derived a FPE for the probability distribution of the angle as a function of time in case of MTJ [4]. With a limit of the large energy barrier where the thermal stability factor is larger than 60, the approximated analytic expression of FWHM of switching distribution, δ, in reduced time scale (reduced by $\alpha\gamma H_k/(1+a^2)$) can be obtained as below $\delta=\{W(0,-1/2e)-W(-1,-1/2e)\}/2v$, ... (eq. 1) where W(k,x) is the kth branch of the Lambert W-function and $v = H_{app}/H_k -1$, and H_{app} is the applied field and H_k is effective anisotropy field. Figure shows the difference between the exact solution and approximated solution assuming a larger energy barrier (eq.(1)). The difference between exact and approximated solution is quite large (~5% with low current v=0.5) in case of small thermal stability factor. However, in case of a high thermal stability factor larger than 60, the difference becomes smaller than 1% at v=0.5. It shows that the approximated equation is valid when assuming a high thermal stability factor (Δ>60 is easily achieved in STT-MRAM). To conclude, we find that δ is a function of damping constant and derive its approximated solution in the limit of high energy barrier. This analytic solution shows a good agreement with full numerical results. Practically, the thermal stability factor required for MRAM cell is higher than 60 so that the reliable value of damping constant can be extracted by measuring δ and analyzing it with the proposed approximated solution. We believe our work is helpful to estimate the damping constant in the device level.

Power consumption of logic operations has become the key bottleneck hindering the miniaturization of ICs. All Spin Logic Device (ASLD) using pure spin current, instead of charge current, is considered as a promising candidate for building future ultra-low power computing systems [1]. A typical ASLD based on ferromagnetic (FM) material is illustrated in figure 1a. Applying a voltage to the FM injector, a spin accumulation can be generated in non-magnetic (NM) channel. This spin accumulation can propagate spin angular momentum by spin diffusion, and switch the FM detector via Spin Transfer Torque (STT) effect [1,2]. Exclusive of lower power consumption, higher computing speed is another significant requirement for future logic device [1,3]. Recently, researchers have observed ultra-fast magnetic dynamics in ferrimagnetic (FI) alloys composed by rare-earth (RE) metal and transition metal (TM) [4-6]. Different from FM materials, the magnetic properties of RE-TM alloys in figure 1b are controlled conjointly by RE and TM sublattices [4]. Considering the different magnetizations and gyromagnetic ratios, the value of total angular momentum for RE-TM alloy can be calculated as the difference between angular momenta of RE element and TM element. In fact, this angular momentum can be controlled by adjusting the concentration of RE metal [4] or the temperature[5-6]. When the total angular momentum tends to vanish, FI alloys will arrive at an angular momentum compensated point (AMCP), where antiferromagnetic-like properties appear [4]. It has been demonstrated that laser or Spin Orbit Torque (SOT) effect assisted by external magnetic field can activate this mechanism [4-5,7]. However, neither of these activating methods suits ASLD, since laser and external magnetic field will largely increase the power consumption and harm the integrability. We hence propose an alternative ASLD structure based on RE-TM FI material to realize ultra-fast speed. $Co_{1-x}Tb_x$ FI alloy is used to replace the FM layer in the proposed ASLD (figure 1b). Moreover, spin torque induced by SOT effect is applied to FI layer, driving the magnetization of $Co_{1-x}Tb_x$ to precess at an extremely high frequency [5]. Here we apply a reasonable condition x = 0.165, which is close to the value for experimentally proved AMCP, to implement the following analyses. As shown in figure 2a, the lowest energy state for precession under the sole impact of SOT is a circle in x-z plane, indicating that the precession caused by SOT effect doesn't have a certain destination. In this occasion, magnetization switching in FI alloys is inaccessible. To break the precession balance, we introduce a spin current propagated from the injector which can exert STT effect on FI detector. Under the co-effect of these two external forces, the distribution of energy states changes, and the magnetization of FI detector can stabilize at the unique lowest energy state point shown in figure 2b. In order to describe the magnetic dynamics of FI layer, we use the typical Landau-Lifshitz-Gilbert (LLG) equation which contains effective magnetic field term, damping term, SOT term and STT term [8-9]. Figure 2c shows the switching process of $Co_{0.835}Tb_{0.165}$ layer. SOT current drives the initial magnetization to precess, while STT current prefers to stabilize the magnetization at the lowest energy state. Also, magnetizations for Co and Tb sublattices stay opposite during the switching. This process takes 2.4 ps, about 2 orders lower than the FM detector (0.2ns shown in figure 2d), which means a much quicker computing speed. Our work contributes to improve the performance of ASLD, and it is also a further step to explore the application of ferrimagnetic material in future potential spintronics devices.

AR-09. Evaluation of ultrahigh-speed magnetic memories using field-free spin orbit torque.

Z. Wang[1], L. Chang[1], X. Lin[1], J. Yang[1], Y. Zhang[1] and W. Zhao[1]
1. Beihang University, Beijing, China

Spin orbit torque (SOT) is a promising technology of magnetization switching thanks to the high-speed, low power and separate read/write paths [1-2]. In particular, sub-nanosecond switching delay qualifies the SOT device as a candidate for the non-volatile cache memory. Generally, such an ultrafast switching is achieved by enhancing the initial spin torque in specific device geometries (e.g. a perpendicular magnetization with an in-plane-polarized spin current). However, in most cases an additional magnetic field is required to achieve the deterministic switching by breaking the structure symmetry. The use of magnetic field hinders the application of the SOT in non-volatile memories. Therefore recently field-free SOT mechanisms have been proposed based on various technologies such as the wedge-shaped asymmetric structure [3], tilted anisotropy [4], spin-Hall-assisted spin transfer torque (SHA-STT) [5-6], and antiferromagnet/ferromagnet exchange bias [7-8]. Nevertheless, some of them employ the special fabrication processes or device structures, which are difficult to be applied to the design and evaluation of the non-volatile memories or circuits. In this work, we focus on two emerging mechanisms of field-free SOT switching, which use the general device structure and thus show good compatibility with the existing non-volatile designs [9-10]. The first mechanism is shown in Fig. 1(a)-(b), where an in-plane magnetic tunnel junction (MTJ) is deposited above a heavy-metal with a cant angle between the easy-axis and charge current. The breaking of structure symmetry enables bipolar deterministic switching. The second one occurs in the conventional three-terminal SOT-MTJ with a perpendicular easy-axis, where it is demonstrated that an appropriate field-like torque can induce the deterministic switching. But this switching is non-bipolar and thus a read operation is needed before the data writing. Here, we evaluate the performance of above two switching schemes in the field of magnetic memories to show their application potential. First, we program two Verilog-A models of the three-terminal SOT-MTJs switched by the above-mentioned schemes. Combined with a CMOS 28 nm design kit, a magnetic random access memory based on two-transistor-one-MTJ bit-cell is designed (see Fig. 1(a)). Transient simulation is performed to validate the feasibility of our models (see Fig. 1(c) for the simulation results of the first switching mechanism). Then, the results of access transistor size and the write energy under a switching time of 500 ps are shown in Fig. 2, where the thermal stability barrier is fixed by adjusting the anisotropy constant at various MTJ sizes. For the first switching mechanism, the performance is strongly dependent on the cant angle of the easy-axis. Clearly an optimal cant angle is found around 45°. In the case of smaller cant angle, the performance degradation is attributed to the competition among SOT, anisotropy field and damping torque. For a cant angle larger than 45°, the easy-axis is close to the polarization direction of the spin injection and thus the incubation delay becomes dominant. Until the cant angle is up to 90°, the spin torque reduces to the conventional STT so that a huge access transistor is needed to provide the adequate current for the ultrafast switching. Finally, the results of the second switching mechanism show insignificant variation and more excellent performance than the first switching mechanism, partly due to the high efficiency of field-like torque-induced magnetization precession. Another reason is that, as the switching is non-bipolar, a unidirectional current can achieve the switching and thus the source degeneration of the access transistor is avoided. Nevertheless, the non-bipolar switching requires a read-before-write operation and leads to a circuit overhead. Therefore a trade-off needs to be taken into account for the performance comparison of these two switching mechanisms.

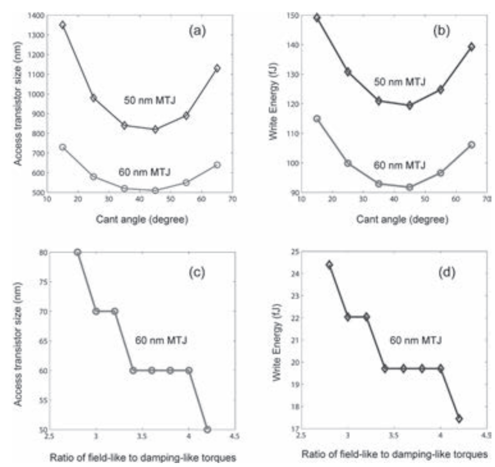

Fig. 2. Performance results of the first (a)-(b) and second (c)-(d) switching mechanisms. In (a) and (b), the width of the heavy-metal is equal to the length of the MTJ long-axis to ensure the sufficient range of the cant angle. The same aspect ratio is used for both the heavy-metal and MTJ.

AR-10. Observation of local spin signals at room temperature in germanium lateral devices.

M. Tsukahara[1], M. Yamada[1], T. Naito[1], Y. Fujita[1], S. Yamada[1,2], K. Sawano[3] and K. Hamaya[1,2]
1. Graduate School of Engineering Science, Osaka University, Toyonaka, Japan; 2. Center for Spintronics Research Network, Osaka University, Toyonaka, Japan; 3. Advanced Research Laboratories, Tokyo City University, Todoroki, Japan

For realizing CMOS-compatible spintronic devices, electrical spin injection and detection in Si[1] and Ge[2] have been explored. In particular, Ge is expected to be a next-generation channel material for CMOS transistors because the electron and hole mobility are twice and four times as large as those in Si. As evidence for spin transport in semiconductors, four-terminal nonlocal magnetoresistance measurements with Hanle-effect curves have been utilized [3-5]. Recently, we reported evident room-temperature spin transport in *n*-type Ge (*n*-Ge) by using four-terminal nonlocal magnetoresistance measurements [6], meaning the demonstration of pure spin current transport. For Ge-based device structures with nonvolatile memory effect [7], the observation of two-terminal local magnetoresistance effect is also important. However, there is no report on the local spin signals at room temperature in *n*-Ge. In this study, we show evident two-terminal local spin signals at room temperature in lateral spin valves (LSVs) with *n*-Ge spin transport channel. Using LSVs with low resistance-area product (*RA*) ferromagnetic Heusler-alloy/Ge Schottky-tunnel contacts, we can detect hysteretic resistance changes depending on the magnetization states between the spin injector and detector. The condition for observing the local spin signals in our LSVs is within a framework of the theory by A. Fert and H. Jaffrès [8]. We fabricated LSVs [Fig. 1(a)] with the *n*-Ge spin transport channel (~ 10^{19} cm^{-3}) and the ferromagnetic Heusler-alloy contacts, Co_2FeAl (CFA). The detailed fabrication processes of LSVs and the growth procedure of the spin transport channels and CFA/*n*-Ge contacts are shown elsewhere [6,9]. To adjust the *RA* values to 100 - 300 Ωμm^2 in the spin-injector and spin-detector contacts, we tuned the concentration of the δ-doped P atoms [10] near the CFA/*n*-Ge interface. The sizes of the spin injector and detector were 0.4 × 5.0 μm^2 and 1.0 × 5.0 μm^2, respectively, and the edge-to-edge distance (*d*) between the contacts was ~0.35 μm, as shown in Fig. 1(a). To confirm reliable spin transport in *n*-Ge, we firstly measured four-terminal nonlocal magnetoresistance, ΔR_{NL} (= ΔV_{NL} / *I*), and its Hanle-effect curves at 150 K, as shown in Figs. 1(b) and 1(c), respectively. These nonlocal signals represent the generation, manipulation, and detection of pure spin currents in *n*-Ge. Using the same device, we recorded a two-terminal local spin signal at 150 K, as displayed in Fig. 2(a). Evident positive ΔR_L (= ΔV_L / *I*) changes ($|\Delta R_L|$) at 150 K with hysteretic nature can also be observed. The value of $|\Delta R_L|$ is nearly twice as large as that of $|\Delta R_{NL}|$ at 150 K, consistent with the one-dimensional spin diffusion model [11,12]. These features are largely different from the previous works on Si-based LSVs with MgO tunnel-barrier contacts [13,14]. Figure 2(b) shows a local spin signal measured at room temperature, together with a minor-loop data, in the same LSV. Even at room temperature, a clear hysteretic magnetoresistance curve and a clear minor-loop meaning that the anti-parallel magnetization state between two ferromagnetic contacts is stable can be seen. By comparing $|\Delta R_{NL}|$ with $|\Delta R_L|$ at room temperature, we can also confirm $|\Delta R_L|/|\Delta R_{NL}|$ ~ 2 [11,12]. This is the first experimental demonstration of the two-terminal local magnetoresistance at room temperature in *n*-Ge based devices. However, the ratio of the magnetoresistance (*MR*) is still small (~0.001 %). According to a standard theory based on the one-dimensional spin drift-diffusion model by A. Fert and H. Jaffrès [8], r_b^* ~r_N is an ideal condition for observing a larger *MR* ratio in ferromagnet/semiconductor/ferromagnet structures with tunnel barriers, where r_b^* indicates *RA* in this study and r_N is the spin resistance of the *n*-Ge layer (~8.4 Ωμm^2). Although it is generally difficult for MgO tunnel barriers to reduce the *RA* value down to less than ~ 1000 Ωμm^2 [13,14], we now obtain the *RA* value of ~100 Ωμm^2 by using δ-doping techniques, leading to r_b^*/ r_N ~10. This condition is within a framework of the theory by A. Fert and H. Jaffrès [8]. To further enhance the *MR* ratio, we should reduce the value of *RA* down to ~10 Ωμm^2 in CFA/*n*-Ge contacts. This study will open a way for developing Ge spintronic applications with low power consumption. Spin field effect transistor (spin-FET) is one of the fundamental spin-based devices which promises to replace the conventional CMOS device thanks to the advantage of ultra-low power consumption. The interesting scheme of spin-FET proposed by Datta and Das is using a gate voltage to control the spin modulation which can realize the switching and logical output [1]. Plenty of efforts on realizing the spin-FET have been done by a number of groups both theoretically and experimentally [2]-[5]. The basic mechanism of spin-FET is using two ferromagnetic (FM) electrodes for spin injection and detection, a gate voltage control for modulating the spin current flowing through the two-dimensional electron gas (2DEG) formed in the semiconductor channel. The injected spin current can be controlled by a Rashba effect-induced effective magnetic field. An applied gate voltage can generate an electric field to modulate the Rashba effect and therefore the spin current. Spin detection is realized by measuring the relative orientation between the spin polarization of the arriving electrons and the magnetization of the FM electrode at the drain. In this work, we proposed a new structure called multi-gate spin-FET, which uses two gates to control the spin current in one 2DEG channel. The structure is shown in Fig. 1 (a). Two gates are set serially on the channel in order that the injected spin current can be modulated by the two gates successively. The spin injection and detection can be modeled based on Datta-Das theory [1]. The dependence of the spin precession angle on the gate voltage is calculated as $\Delta\theta=2m^*\alpha(V_g)L/h^2$, where $\Delta\theta$ is the spin precession angle, m* is the effective mass, α (Vg) is the Rashba effect coefficient which is a function of the gate voltage Vg, L is the channel length and h is the reduced Planck constant. More details about the electrical models can be found in our previous work [6]. The expression of α (Vg) is strongly dependent on the material of the semiconductor channel. For a two-gate spin-FET, the spin precession angle can be calculated as $\Delta\theta=\Delta\theta_1+\Delta\theta_2=2m^*[\alpha(V_{g1})L_1+\alpha(V_{g2})L_2]/h^2$. Thus the final spin precession angle is decided by both gate voltage modulation and the channel length. Unlike the conventional CMOS transistors cascading, the multi-gate spin-FET can generate different outputs using the same input (gate voltage) but with different channel lengths. We set the gate voltage to 0 V as logic input “0” and 1.4 V as logic input “1”. Fig. 1 (b) shows the different outputs with different kinds of channel length settings. For a single channel, if we set the length to 86 nm, the output will be “0” (“1”) when the input is “1” (“0”) as shown in Figure 1 (b). Under this setting, the function of the spin-FET is the same as a P-type CMOS transistor. For the 82 nm channel, the output is “0” (“1”) when the input is “0” (“1”) which acts as an N-type CMOS transistor. Also, we can get a fixed output “1” regardless of the logic inputs. Fig. 1 (c) shows the output with the various combinations of inputs and channel lengths, here we fix the length of the first channel to 82 nm. The results of output voltage indicate that the multi-gate spin-FET can form a NAND logic gate when the second channel length is 82 nm. Also, an XNOR logic gate can be obtained if the second channel length is set to 78 nm. Furthermore, other different kinds of logic gates can be implemented with only one multi-gate spin-FET device by varying channel lengths. In these simulations, we fix the injection current to 1 mA and assume that the resistance between the drain and the source is 1.4 KΩ. The BiTeX (X=I, Br, and Cl) material is used for the semiconductor channel which experimentally shows a very large Rashba effect coefficient (α~3.8eÅ) [7]. Thus the period phase shift can be definitely obtained in a short channel. Following the above results, a plenty of logic circuits can be designed with the multi-gate spin FETs. In Figure 2 (a), a compact 2-bit full adder is designed using both multi-gate spin-FETs and single-gate spin-FETs. Two multi-gate spin-FETs are configured to XNOR logic gates and three multi-gate spin-FETs function as NAND logic gates. The single-gate spin-FETs are set to P-type CMOS function. The transient simulation results shown in Fig. 2 (b) validates the function of the 2-bit full adder. Only 7 semiconductor channels are used, which is much more compact than the conventional CMOS full adder. Thus the multi-gate spin-FETs provides an approach to achieving the area-efficient and low power logic computing.

The application potential of spin-orbit-torques in magnetic random access memory attract great attention and research interest in spin-orbit coupling in heavy metals like Platinum. Thus the spin relaxation time, as a crucial parameter to investigate spin relaxation mechanism in the heavy metals, requires accurate and effective estimation. However, the traditional ways such as electron spin resonance (ESR) or time-resolved optical technique developed by Elezzabi *et al*. fail for thin films of heavy metals with short. So the spin injection and detection as a well-developed electrical transport method, is important candidate to estimate the. Although working reliably in Au or Cu, four-terminal non-local spin valves is not able to be adopted in the systems with ultrashort spin diffusion length. A traditional three-terminal method is also widely utilized to estimating of semiconductors and light metals. Its reliability, however, has recently been challenged by some experiments in which tunneling anisotropic magnetoresistance (MR) or spin blockage MR rather than the MR induced by spin injection and subsequent Hanle effect is more appropriate to explain the data. traditional dc three-terminal method seems not reliable in ferromagnetic metal/tunnel barrier/nonmagnetic metal systems in which the tunnel barrier resistances are at least several orders of magnitude larger than the spin-injection-induced additional resistance. In our work, the spin-injection-induced magnetoresistance of which the magnitude is comparable with other MR phenomena originating from the tunnel barrier is observable at room temperature as well as low temperatures in the second harmonic signals (Figure 1 and 2). Three-terminal and second harmonic method are combined in our measurement in Pt and Ta systems. Furthermore, we could estimate of heavy metals through fitting the signal with Lorentz function. The of Pt about 3.8 ps at room temperature. This experimental approach make it possible to directly acquire of heavy metals with electrical method.

AR-13. Spin Dice Based on Orthogonal Spin Transfer Devices.

X. Li[1] and L. You[1]
1. School of Optical and Electronics Information, Huazhong University of Science and Technology, WuHan, China

With the advent of the era of big data, data information to bring convenience to lives at the same time, the problem of information security has become increasingly prominent. True random number generator (TRNG) based on physical entropy sources such as thermal fluctuations acts a crucial role in cryptography and information security applications. [1-4] Multi-junctional magnetic tunneling junction (MTJ) Spin dice based on orthogonal spin transfer devices, a new type of random number generator (RNG) is proposed. Orthogonal spin-transfer devices use a spin-polarizing layer magnetized perpendicularly to a free layer, to push free layer with perpendicular anisotropy in metastable (high energy) state, when current or power is on. Thermal noise is the key source to bias the magnet off its metastable state. Once the power is off, the anisotropy field and demagnetization field relax the free layer magnetization from metastable state to one of the two stable states, produces a true random bit whose value is determined solely by thermal noise in magnetization switching. There are two tunneling layers put among three ferro-magnetic layers, as depicted in Fig. 1(a). In-plane anisotropy is owned by layer_1 and layer_2, out-of-plane anisotropy is owned by layer_3. Here layer_3 is considered as spin polarizing layer, while layer_2 and layer_1 is assumed as free layer and reference layer, respectively. A reference magnetic layer is used to read out the magnetic state of free layer. In the initial state, all of the three layers' magnetization are stay in its anisotropy direction. In 1st stage, writing current, mainly carried the polarize direction same as magnetization of layer_3, keeps the magnetization of aimed layer_2 in metastable state, therefore the magnetization of layer_2 lies perpendicular to the plane upwards or downwards according to the current direction. In 2nd stage, writing current is turned off, uniaxial magnetic anisotropy energy relaxes the magnetization to one of the stable states, that is to say, thermal noise tilts the magnetization to be parallel to the plane, in +x direction or -x direction, a true random bit is determined. And in 3rd stage, reading current, which is not large enough to switch the magnetization of layer_2, is applied on the proposed spin dice to read the random bit generated in 2nd stage. The macro-spin simulations are performed to evaluate our spin dice device performance. The saturation magnetization (Ms), exchange constant (A), magnetic anisotropy constant (Ku) and Gilbert damping factor (α), for aimed layer_2 are 1.34 MA/m, 30×10^{-12} J/m, 670 KJ/m^3 and 0.014, respectively, spin polarization (p) for layer_1 and layer_3 are 0.3 and 0.7, respectively. Environment temperature (T) is 300 K. Writing current density is 1.85×10^7 J/cm^2, and reading current density is 2×10^6 J/cm^2. In writing process and reading process, spin polarized current both from layer_1 and layer_3 give a spin torque to layer_2 in the magnetization procession. With properly spin polarization set, the polarization value could hardly have any influence on the generating process of RNs. Limited by time and sever, only 10000 RNs were generated and evaluated. Among these 10000 RNs, 4990 processions have a final state of +x direction saturation magnetization in aimed layer_2. We also evaluated the quality of the RNs by using the statistical test suite NIST SP-80018 [5], the RN sequence only failed a few tests due to the small data size, the high passing test numbers promising the proposed spin dice a high quality TRNG. The multi-junctional spin-dice promises low energy-consumption, non-volatility,high scalability, easy operation, stable writing process and reading process. With the simulation results provided, we argue that the proposed spin dice can overcome the earlier described problems [2] such as scalability and high-quality randomness. We argue that the proposed multi-junctional spin dice is a true random number generator and a promising candidate for a scalable truly random number generator suitable for encrypting.

AR-14. Magnetization behaviors of magnetic tunnel junctions driven by the spin-orbit torque.

T. Wu[1]
1. Graduate School of Materials Science, National Yunlin University of Science and Technology, Douliu, Taiwan

Recently perpendicular magnetic tunnel junctions (pMTJs) attract much interest because of higher thermal stability and smaller writing currents for applications in magnetoresistive random access memory (MRAM). In order to have high magnetoresistance (MR) ratio, the thickness of barrier layer in pMTJ is usually less than 2 nm, which restricts the maximum writing current. To overcome this issue, the spin-Hall effect (SHE) has been shown to be a promising solution to replace the conventional spin-transfer torque (STT) writing scheme. The in-plane polarized spin current produced by SHE can reverse the free-layer magnetization through STT; however, for pMTJs, additional mechanisms such as applied field or exchange-bias coupling are required to switch out-of-plane magnetization. Until now, most of studies focus on the reversal behaviors of single perpendicular-anisotropy layer and only few reports are about full pMTJ stacks. In this study we report the experimental results of magnetization reversal of pMTJ by SHE. The pMTJ stacks consisting of Ta(5)/$Co_{40}Fe_{40}B_{20}$(1.2)/MgO(2)/$Co_{20}Fe_{60}B_{20}$(2.3)/Ta(5)/Ru(5) were deposited on SiOx substrate. The numbers in parentheses are layer thicknesses in nm units The $Co_{40}Fe_{40}B_{20}$ layer serves as the free layer, while $Co_{20}Fe_{60}B_{20}$ is used as the fixed layer. The film was annealed at 200 and 300 ^{o}C for one hour, respectively, and then patterned into devices of various sizes for resistance measurements. The R-H and R-I measurement results are depicted in Fig.1. The lateral dimension of the device is 900x1200 nm2. From Fig. 1(a) one can see that both the free and fixed layer magnetizations switched in a single step at clearly seperated switching fields, and the MR ratio is 31%. Oppositely, at current below 0.1 mA under 30 Oe applied field, a fast falling of the resistance can be observed as shown in Fig. 1(b) with MR ratio 180%. The nonlinear R-I curves indicate that the magnetization of the fixed layer rotated even at very small current.

AR-15. Recognizing and memorizing patterns with delayed feed-back spin-torque nano-oscillators.

For many recognition and classification tasks, the brain processes information with much less power than any computer. Therefore, developing neuromorphic chips opens the path to reducing dramatically the energy consumption of data processing. Biological neurons can be seen as interconnected non-linear oscillators which generate a collective chain-reaction response to an excitation. Memory in biological neural network is part due to the intrinsic behavior of each neuron and part due to the recurrences that occur in the network. Recently we have shown experimentally that a nanoscale spin torque oscillator can be used to achieve spoken-digit recognition thanks to its non-linearity and reliability[1]. Among the different strategies for brain-inspired computing with spin torque oscillators[1, 2], we leveraged the transient dynamics of a single oscillator to mimic the chain-reaction response of a whole neural network. The oscillator plays one by one the role of each neuron: the temporal chain reaction replaces the spatial chain reaction of a biological neural network. This reservoir computing with a single node[3] did only use the oscillator intrinsic memory which is insufficient when longer term memory is needed. Optical delayed feedback systems have shown their efficiency at dealing with memory tasks such as chaotic series prediction[3], but they suffer from a scalability limitation. Here we show experimentally that a delayed feedback loop added to a spintronic oscillator can create memory and improve recognition in cases where memory is critical. The spin torque oscillators that we use are magnetic tunnel junctions with a vortex magnetization configuration in the FeB free layer. Due to a high TMR ratio (130%), the emitted power of such oscillators is of the order of the microwatt. These oscillators also have a very low linewidth[4]. The preprocessed input is created by an arbitrary waveform generator (figure 1) and is injected to the oscillator as a varying voltage. A delay feedback loop made of an electronic delay line of 4300ns and an amplifier is added so that the oscillator is fed by the input signal and its own past response. It creates a longer term memory than the ~200ns intrinsic memory of the oscillator induced by its relaxation. The operating point is tuned by changing the dc current and the magnetic field. The response of the oscillator is sent through a diode that extracts its amplitude and recorded with an oscilloscope. The classification is achieved by reconstructing an output signal which is a linear combination of points from the recorded response. To investigate the effect of delayed feedback on pattern recognition performances, we perform the piecewise classification of sine and square[3] waveforms. 160 preprocessed periods of sine and square are sent in random order to the system (figure 2a). A clear effect of the feedback loop is observed in the oscillator response which varies even when the input voltage is zero because of its own past emission (figure 2b). The feedback allows improving the classification for many different operating points (figure 2c and 2d). Error reduction is up to a factor of 11. In this talk we will highlight that some patterns cannot be classified without remembering the previous input patterns and that all the errors without feedback are concentrated on these cases. We demonstrate that feedback brings memory of previous states without deteriorating the signal and achieves a nearly perfect separation of the inputs. Thanks to the memory it brought, clear benefic effects of a delay feedback loop on classification are shown. This work opens the path to identifying patterns in complex data sequences such as chaotic series. *This work was supported by ERC grant bioSPINspired 682955*

AS-01. Domain structure and magnetic properties of magnetostatically coupled epitaxial Co nanostripe arrays with induced anisotropy.

A. Kozlov[1], A. Kolesnickov[1], E. Pustovalov[1], A.S. Samardak[1] and L. Chebotkevich[1]
1. School of Natural Sciences, Far Eastern Federal University, Vladivostok, Russian Federation

Magnetostatic interaction in the arrays of magnetic nanostripes plays an important role in the switching processes and significantly affects the critical fields, spin dynamics, magnetotransport properties and orientation of effective magnetic anisotropy [1]. Shape anisotropy in such arrays leads to the closure of the magnetic flux at the poles of adjacent nanostrips. If in the system of magnetic coupled nanostrips to induce the magnetic anisotropy oriented across the nanostrip long axis, this will change the micromagnetic configuration of each nanostrip in the array due to the appearance of the laminar domain structure formed by domains with an antiparallel orientation of the magnetization [2]. In this work we investigate the switching processes in 800-2000-nm wide Co nanostrip arrays with mutually perpendicular anisotropies (shape anisotropy and steps-induced anisotropy). We study the field-dependent behavior of spin vortices in Neel domain walls of the laminar domain structure of the magnetostatically coupled epitaxial nanostrip arrays. The dependence of the critical fields on the width and number of nanostripes in the array is established and the mechanisms of the magnetization reversal processes were investigated. The nanostripe arrays were produced by focused ion beam etching of the 15 nm Co films deposited by molecular beam epitaxy on the vicinal Si(111) surface. Magnetic properties were investigated by magneto-optical Kerr effect, magnetic force and Kerr microscopies. Micromagnetic simulations were performed with OOMMF software. Experimental MFM-image and micromagnetic simulation (fig.1.) of domain structure of four 800-nm wide nanostripes with 80 nm distance, is showed that magnetostatic interaction between nanostripes favors the magnetization orientation leading to a closure of the magnetic flux. The magnetization process starts from the shift of vortices along the domain walls. The direction of the movement depends on the vortex chirality. The displacement of the Neel domain walls starts only after the vortices achieve the nanostrip edges in magnetic field value is more then 50 Oe. Moreover in this work we established the dependence of the magnetization switching field on the number of nanostrips in an array and on their width was clearly observed when the H_c value had the same order as the dipolar interaction field between nanostrips. We revealed rather complex mechanisms of magnetization reversal depending on direction of the applied magnetic field. If the field applied along the long side of nanostrips, then domains with vortex walls nucleated. With the increasing field, vortices moved along the domain walls and finally transformed them into 90° Neel walls. Only after this, domains started to grow and completely reversed the magnetization at the higher fields. If the magnetic field was aligned along the easy axis of magnetization, then magnetization reversal mode was represented by the vortex domain nucleation and propagation without movement of vortices in domain walls. We found that magnetization reversal mechanisms are driven by the effective magnetic anisotropy and dipolar coupling between nanostrips, but they are independent on the width of nanostrips. AS-02. Exchange bias in Co/CoO core-shell nanowires: roles of antiferromagnetic grain size distribution and interfacial spin glass.

X. Wen[1], K. Gandha[3], P. Liu[2] and *J. Yang*[1]

1. Physics, Peking University, Beijing, China; 2. Physics, University of Texas at Arlington, Arlington, TX, United States; 3. Ames Laboratory, US Department of Energy, Ames, IA, United States

ABSTRACT Exchange bias effect in aligned Co/CoO core-shell nanowires with high aspect ratio was studied. Large exchange bias fields of about 2.2 kOe and 1.0 kOe in easy axis and hard axis, respectively, were obtained after field cooling. We demonstrate that both antiferromagnetic grains and the interfacial spin glass make strong contribution to the observed exchange bias, which is demonstrated with both the cooling field dependence of the exchange bias field and the training effect at different temperatures. The difference in the thermal activation temperature for these two magnetic states leads to a bimodal distribution of the blocking temperature which, in combination with the interplay between the fluctuating spin ordered antiferromagnetic grains and the demagnetizing field of Co core, is likely to explain the anomalous drop of coercivity at the temperature in range from 200 to 110 K. INTRODUCTION The Co/CoO composites have been fairly intensively studied, which is motivated by the exchange bias effect (EB). This effect has a significant impact on the technological applications of data storage products, spintronic devices, permanent magnets, and many other devices. After the discovery of this effect in Co/CoO particles, EB effect has been found in a large number of heterogeneous structures such as layer structures, core-shell structured nanoparticles, and FM nanoparticles embedded in an AFM matrix compounds. Nevertheless, to date, both experimental and theoretical investigations of the EB effects have been mainly focused on the layered structures and core-shell structured nanoparticles with well-defined FM/AFM interfaces. Meanwhile, core-shell nanowire with high aspect ratio has also attracted a lot of research activities due to its unique features. In this paper, we have investigated the temperature dependence of EB effect and the training effect in quasi one-dimensional Co/CoO core-shell nanowires. This study underlines the importance of the AFM grain size distribution and spin glass fluctuation in the exchange-bias mechanism. METHODOLOGY Cobalt nanowires with high aspect ratio (diameter to length d/l = 1:10) have been synthesized via a solvothermal chemical process, which has been described in ref. Then the Co nanowires are naturally oxidized in air forming a core-shell structure. After few weeks the system reaches a stable magnetic state via a passivation mechanism. The nanowires were dispersed in epoxy and oriented by using an external magnetic field of 15 kOe before the epoxy completely curing. The solidified epoxy was shaped as a rod along the orientation of magnetic field. All the magnetic hysteresis loops were measured by superconducting quantum interference device (SQUID) magnetometer. RESULTS AND DISCUSSION Fig. 1 is the HRTEM images of Co/CoO nanowires and the cross section of orientated Co/CoO nanowires dispersed in epoxy. It can be seen from Fig. 1(a) that the nanowire is about 200 nm long with a 9 nm thick Co core surrounded by a CoO shell of 4nm thick. Fig.1(b) is the high-resolution transmission electron microscope (HRTEM) image of the cross section of the orientated nanowires, where the Co core and CoO shell are identified with two circles. Fig. 2 (a)-(b) indicate a strong disordered spin state at the interface with competitive FM and AFM exchange interactions. To get a further exploration the interfacial spin glass, the relationship between H_E and cooling field was studied. The sample was firstly to various temperatures of 5 K, 60 K and 100 K under various cooling fields H_{FC}. Then, a hysteresis loop was measured after each FC. As shown in FIG. 2 (f), the H_{FC} dependence of H_E varies with temperature.

Recently, one-dimensional magnetic nanostructures have been intensively investigated for its widely use in high density magnetic recording media, drug delivery, transistor as well as spintronic devices. Meanwhile, the combination of two different materials in one hybrid nanowires (NWs) and nanotubes (NTs) may provide a novel way to control electric polarization by magnetic field or use an electric field to regulate magnetization state. Besides, by adjusting the proportion of two materials, this new entity may exhibit superior properties and conquer the short comings of its individual component. It is known that the template assisted electro-deposition method is simple and economical in synthesizing magnetic NWs and NTs, and most importantly it is easily combined with other technologies. In this work we first fabricated $CoCr_2O_4$ nanotube by dipping the AAO template in a sol–gel solution. Subsequently, filling Ni nanowires inside $CoCr_2O_4$ nanotube using electro-deposition to form core-shell $CoCr_2O_4$/Ni hybrid nanowires. The morphology and magnetic properties of $CoCr_2O_4$ nanotubes and hybrid $CoCr_2O_4$/Ni nanowires at different temperature were investigated. An enhanced coercivity and saturation field were observed for $CoCr_2O_4$/Ni core-shell NWs compared to single-phase Ni NWs. Then, we also conducted micromagnetic simulation to explore the magnetization reversal process of the hybrid nanowires. Results showed that there exsits a strong coupling between the shell and core layers during the magnetization reversal process. We believed that this new structure may have potential use in future high density magnetic recording medium and varies multifunctional devices.

The FeRh alloy with B2-order shows a first-order phase transition from an antiferromagnetic (AFM) to a ferromagnetic (FM) phase with rising temperature at around 370 K.[1] The AFM to FM transition temperature is suppressed under the application of external magnetic field because of the reduction of the free energy of the FM phase.[2] This transition temperature suppression by an external field enables the derivation of some thermodynamic parameters from magnetization measurements,[3] which gives consistent results with thermal measurements.[4, 5] From these reports, it is known that both a bulk specimen and a thin film of FeRh exhibit similar transition temperatures and entropy changes. Recently, a discontinuous and asymmetric resistance change around the AFM – FM phase transition was reported in submicron wires of FeRh.[6] This anomalous behavior was said to be due to a suppression of the nucleation process of antiferromagnetic domains during the cooling process, which is also expected to make a significant difference to the thermal properties. However, it is difficult to conduct thermal or magnetization measurements on such small volume samples. Here, we report resistivity measurements of submicron wires of FeRh as a function of temperature and external magnetic field. As the resistance change in a submicron specimen reflects local magnetic states, entropy change and energy loss due to temperature hysteresis were estimated from electrical transport measurements. Epitaxial films of B2-ordered Pd-doped FeRh alloys were prepared by DC magnetron sputtering from an $Fe_{47}Rh_{50}Pd_3$ alloy target with a thickness of 60 nm on top of MgO (001) substrates. According to the elemental substitution effect by a Pd doping,[7] the phase transition temperature of FeRhPd films was decreased to 290 K. Submicron wires were fabricated by electron beam lithography and Ar ion milling. Cu electrodes were deposited on top of the wires for 4-terminal resistance measurements. An external in-plane magnetic field was applied parallel to the current. The resistance of a 270-nm-wide wire as a function of both temperature and in-plane magnetic field are shown in Fig. 1, with an inset of a SEM image of the wire. Asymmetric temperature and magnetic field hysteresis loops are observed, being consistent with the previously reported behavior.[6] We derived an entropy change in AFM and FM phases, ΔS, from these transport measurements. The largest resistance change during the transition from FM to AFM phase occurred at 0 T and 256.6 K in a temperature-driven measurement, and at 240.0 K and 1.50 T in a field-driven measurement. A latent heat exported during the transition from high-temperature to low-temperature phase is $T\Delta S$. The sum of the latent heat and Zeeman energy term $H\Delta M$ represents a total exported energy during temperature- or field-driven phase transition. ΔM is a change in magnetization between FM and AFM phases, here we use a value of 1.6 T from magnetometry on an unpatterned film sample shown in Fig. 2. We obtained an entropy change ΔS = 115 mJ cm^{-3} K^{-1}, which is comparable to reported values for a bulk specimen[4] (138 mJ cm^{-3} K^{-1}) and a thin film[3] (140 mJ cm^{-3} K^{-1}). We also compared the energy loss during the temperature loop in a submicron wire with that in a thin film. The energy loss Q' is a sum of latent heat around a temperature hysteresis loop. As we have derived ΔS for this specimen, Q' can be determined from M-T plot: $Q' = \oint S(T)\, dT = (\Delta S/\Delta M) \oint M(T)\, dT$. The temperature hysteresis loop of the magnetization of the film before patterning is shown in Fig. 2 with red symbols. From the calculation of the M-T hysteresis area, we obtained 2.56 J cm^{-3} of energy loss in the unpatterned film. Though it is difficult to measure the magnetization of a sample with a tiny volume, estimation of FM volume ratio in a submicron wire is possible from electrical transport measurements as shown in Fig. 2 with black symbols. Q' in our submicron wire was 3.28 J cm^{-3}, which was 28% larger than that in a film. Because both were calculated on the identical film before and after patterning, this increase was surely due to size effect of the specimen. In conclusion, we performed electrical transport measurements on submicron wires of Pd-doped FeRh alloys. As the resistance on a submicron specimen reflects local magnetic states, entropy change ΔS and hysteresis energy loss Q' were estimated from electrical measurements. We also found a change in Q' before and after shaping into wires, which exhibited an increase by 28% on a submicron structure. This discrepancy is mainly contributed by an abrupt change during the transition from FM to AFM phase probably due to a suppression of AFM domain nucleation. We achieved a quantitative evaluation of an influence of domain nucleation process in submicron wires by simple electrical measurements.

AS-05. Atomic pair ordering and strain relaxation in thermally and vacuum Annealed NiCu nanowires prepared in Al_2O_3 nanoporous templates.

N. Ahmad[1] and q. abbas[1]
1. Physics, International Islamic University, Islamabd, Pakistan

The magnetic nanowires have been widely investigated to understand their physical and magnetic properties and their applications in magnetic nanodevices [1] nanosensors [2], recording media [3], and microwave circulator [4]. The NiCu nanowires are used in spintronics and microwave absorption devices. Transition metals and their alloys have been fabricated by electrochemical deposition into anodic alumina oxide (AAO) template nanopores which is very low cost and versatile technique to synthesize magnetic nanowires and nanotubes having tunable length and diameter with high aspect ratio [5, 6]. A low cost and direct method to synthesize Ni nanowires such as AC electrochemical deposition in AAO (anodized aluminium oxide) templates are used. AAO templates are preferred over the polycarbonate membrane due to regular pore structure, high density and wide area [7]. Recently nickel cobalt (Ni-Co) nanowires have been fabricated in square shape by electrochemical method and the planar Hall Effect is observed in detail. Also the anisotropic magneto resistance (AMR) is measured. Cobalt nanowires with uniform and regular arranged patterned have been prepared by electro deposition method having diameter 80nm and the length 40nm at different pH values [8]. Nickel (Ni)-Copper (Cu) alloy nanowires with diameter about 65 nm and aspect ratio about 180 were synthesized in highly porous Al_2O_3 templates via AC electrodeposition method. The as-deposited nanowires were simple annealed and vacuum annealed at 300, 400, and 500. Annealing of alloy caused homogenization in alloy nanowires which give degenerate the magnetic properties. The elemental composition of nanowires was checked through energy dispersive X-ray spectroscopy and found 75:25 ratio between Ni and Cu respectively. Structural and magnetic properties of as-deposited, simple and vacuum annealed nanowires were studied by X-ray diffraction and vibrating sample magnetometer. Result revealed that nanowires have stable face center cubic phase with polycrystalline nature and it was not affected after annealing but only improved the structure parameters. Magnetic properties were studied along two different axis of nanowires and results shows that nanowires have easy magnetization axis along to long-axis wire due to higher aspect ratio. Furthermore, Coercivity and remanence ratio of $Ni_{75}Cu_{25}$ nanowires were improved after annealing but effects were more prominent in vacuum annealing due to atomic pair ordering and strain relaxations.

AS-06. Controlled growth of Fe_3O_4 nanopillars and their magnetic properties.

M. Guan[1], G. Dong[1], Z. Zhou[1] and M. Liu[1]
1. Xi'an Jiaotong University, Xi'an, China

Single-crystal Fe_3O_4 nanopillars were deposited on $SrTiO_3$ substrate using pulsed laser deposition. The nanopillars were shaped by using an AAO template as the mask. The dimension of the nanopillars can be modified by choosing the different AAO template. The XRD results shown an single crystal behavior of the nanopillars. The magnetic properties of the nanopillars was recorded using Vabriating Sample Magneticmeter(VSM) and electric paramagnetic resonance(ESR), both shown ferromagnetic behavior of the nanopillar. Our result provide an new choice to deposit Fe_3O_4 nanopillars.

AS-07. Effect of size on multiferroic $SmMn_2O_5$ nanorods.

T. Hsu[1], C. Yang[1], C. Yang[1], Y. Tung[1], C. Kao[1], W. Wu[1] and K. Lin[2]
1. Physics, Chung Yuan Christian University, Taoyuan City, Taiwan;
2. Department of Chemical Engineering and Material Science, Yuan Ze University, Zhongli, Taiwan

Three sizes $SmMn_2O_5$ multiferroic nanorods are fabricated by the hydrothermal method. The HRTEM images show the diameters ($<L_C>$) × axial of three samples are 58(17) nm×25(6) nm, 92(21) nm×32(8) nm, and 126(25) nm×52(13) nm. Figure 1(a) displayed an antiferromagnetic (AFM) peak at around 6K, which was correlative with Sm magnetic ordering and independent of $<L_C>$. A small AFM peak appeared at 26 K, 28 K, and 30 K in $<L_C>$ = 58 nm, 92 nm, and 126 nm sample, respectively. It is correlated with the Mn magnetic ordering and shifts to higher temperature with the $<L_C>$. All samples show a hysteresis loop at 2 K. The coercivity decreased as the size increasing to $<L_C>$ = 126 nm. The temperature profile of Raman spectra exhibited a red-shift of A_g+B_{1g} mode (680 cm^{-1}) only appears in the $<L_C>$ = 126 nm sample. This observation implied the interaction between the Mn ions via Mn-O bond is more sensitive to temperature in large SmMn2O5 nanorods. These results reveal the structure and magnetic properties are influenced by the size. The critical dimension is between the $<L_C>$ = 92 nm and 126 nm.

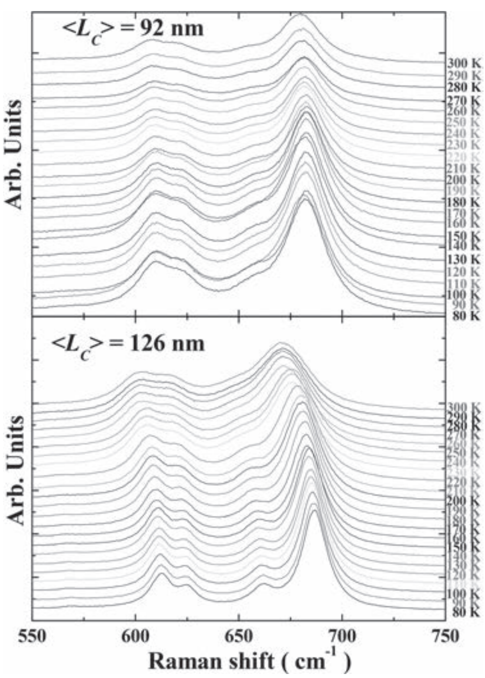

Fig. 2. Raman spectra of $<L_C>$ = (a) 92 nm and (b) 126 nm samples at various temperatures.

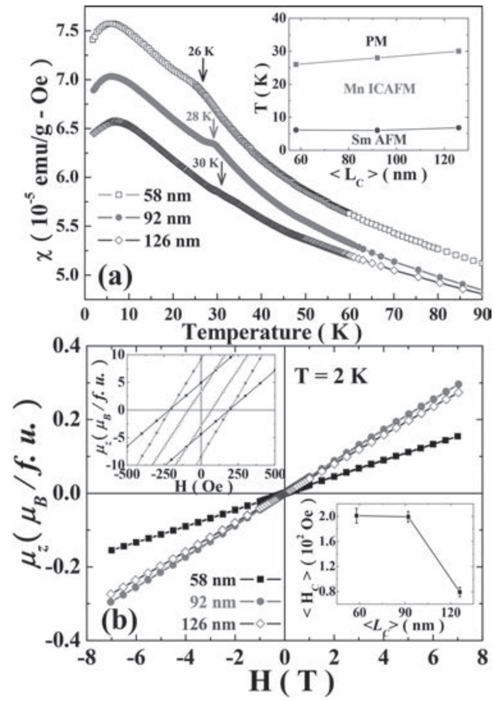

Fig. 1. (a) Zero-field cooling curves of magnetic susceptibility of nanorods with $<L_C>$ = 58 nm, 92 nm, and 126 nm (b) Hysteresis loop of nanorods with $<L_C>$ = 58 nm, 92 nm, and 126 nm.

AS-08. Fabrication of high-density metal alloy nanodots by a facile block copolymer inclusion method.

T. Maity[1], T. Ghoshal[2] and S. Roy[1]
1. Tyndall National Institute, Cork, Ireland; 2. University College Cork, Cork, Ireland

We report the fabrication of ultra-high density ordered arrays of magnetic metal alloy nanodots by a simple and cost-effective facile block copolymer inclusion method. Spectroscopic, microscopic and structural characterisations show that the nanodots have uniform size, shape and their placement mimics in the large area i.e. wafer scale. The size of the nanodots varies between 10 nm to 35 nm and can be controlled by the fabrication process. The magnetic nanodots show good thermal stability and strong adherence to the substrate surface, making them useful for high density memory and other nanomagnetic device applications. [1,2] To fabricate such precise patterned magnetic nanostructures for device applications, lithographic approaches by electron beam, optical interference, X-rays or nanoimprint are being employed but are limited by cost and speed. Self-assembly techniques such as di-block copolymer (DBCPs) microphase separation can be used as an alternative and cost-effective technique. [3, 4, 5] Ordered patterns of magnetic nanodots have been fabricated by using DBCP micellar films and selective chemical co-ordination of metal precursors to one polymer blocks. Using the techniques reported here, we are able to generate different magnetic nanodots array of both alloy and oxides with controllable size and separation over wafer-scale areas. At first step hexagonal array of the oxide nanodots (A_XO_Y) are fabricated. After that, the oxide nanodots are reduced to metal nanodots where the oxygen is removed. The size of the nanodots can be varied by process modification. In Figure 1 the scanning electron microscopy (SEM) image and atomic force microscopic (AFM) image of Ni nanodots have been shown. Detail characterisations have been done to investigate the magnetic properties of such nanodots of different sizes (10 – 35nm) and composition (Ni, Fe, NiFe, etc). The magnetic properties of such nanodots depend on the size of the nanodots. The nanodots diameter size above ~20 nm shows ferromagnetic behaviour throughout the temperature range (2 – 300 K) whereas nanodots with diameter size below ~20 nm show superparamagnetic behaviour at room temperature with a blocking temperature (T_B) below room temperature. In figure 2.a the zero-field-cooled, field cooled and remanence (ZFC, FC and REM) magnetization (M) versus temperature (T) measurements of 25 nm Ni nanodots array are plotted which shows the ferromagnetic behaviour of the nanodots array throughout the temperature range. The inset figure shows M vs T measurement for superparamagnetic Ni nanodots with size ~20 nm and blocking temperature (T_B) at ~150 K. In Figure 2.b the hysteresis loops measured at 300K and 2K are shown. The dipole-dipole interaction between the well-ordered hexagonal arrays influence the overall magnetic properties of the nanodots which can lead to increase of blocking temperature (T_B). By the reported cost effective block copolymer inclusion method it's possible to deposit ultra-high density nanodots array of different metals/metal-alloys which can be used for next-generation nano-scale magnetic devices like high-density memory.

AS-09. One–Pot Synthesis and Surface Modification of Lauric-Acid-Capped CoFe2O4 Nanoparticles.

Y. Teng[1] and P. Pong[1]
1. Electrical and Electronical Engneering, The University of Hong Kong, Hong Kong, Hong Kong

Ferromagnetic cobalt ferrite (CoFe2O4) nanoparticles (NPs) have attracted enormous attention because they has large coercivity values due to the high intrinsic magnetocrystalline anisotropy and can translate into a higher heat dissipation than other ferrite nanoparticle with similar size [1], and thus they can be used to induce magnetic hyperthermia for various application [2-3]. Several synthesis methods of cobalt ferrite nanoparticles have been reported previously. However, the reported methods involved multiple-step syntheses which is more sophisticated and time-consuming to obtain the desired resulting nanoparticles. Therefore producing nanoparticles with an efficient and facile route is still challenging. In this work, a facile one-pot method was developed for the synthesis of lauric-acid-capped CoFe2O4 nanoparticles (cobalt ferrite nanoparticles) with promising stability and uniformity, and the nanoparticles were further transferred into aqueous phase through surface modification using surfactants including CTAB and SDS. These water-soluble cobalt ferrite nanoparticles can be directly functionalized with target biomolecules to be applied in aqueous environment for biosensing, protein separation and drug delivery [4-5]. Experimental The monodisperse lauric-acid-capped CoFe2O4 nanoparticles were synthesized via one-pot reaction of Fe(acac)3 and Co(acac)2, and 1,2-tetradecanediol in benzyl ether mixed with lauric acid and a small amount of oleic acid [6]. The as-synthesized nanoparticles were transferred to water using CTAB and SDS following the protocol previously developed in [7]. Furthermore, the performance of water-soluble lauric-acid-capped CoFe2O4 nanoparticles for drug loading was conducted. The morphology and structure of CoFe2O4 nanoparticles were analyzed by transmission electron microscopy (TEM) and selected area electron diffraction (SAED). The elemental analyses of the as-synthesized nanoparticle powders were performed using energy dispersity X-ray spectroscopy (EDX) while X-ray powder diffraction patterns of the particle assemblies were collected by X-ray diffractometer (XRD). The CoFe2O4 nanoparticles were characterized by the presence of various functional groups by Fourier transform infrared spectrometer (FTIR). The ultraviolet visible spectroscopy (UV-Vis) characterized the optical property of CoFe2O4 nanoparticles. The magnetic properties of CoFe2O4 nanoparticles were investigated using vibrating sample magnetometer (VSM). Results and discussion The resulting CoFe2O4 nanoparticles were nearly spherical with particle size of 15.3 ± 1.7 nm as shown in Figure 1(a), and they can be slightly dissolved in water due to the use of lauric acid as the surfactant (solubility in water = 55 mg/L at 20 °C). The CTAB and SDS modified CoFe2O4 nanoparticles are presented in Figure 1(c) and 1(d). The SDS modified CoFe2O4 nanoparticles exhibit better uniformity and stability without coalesce and agglomeration,indicating that surface modification using SDS is a more effective strategy for phase transfer of CoFe2O4 nanoparticles. FTIR shows characteristic bands (in the range of 900–1600 cm-1) for the SDS surfactant, and the absorption band nearly 1600 cm-1 confirmed that the surfactant were successfully modified on CoFe2O4 nanoparticles. Magnetic hysteresis loops of both pure and SDS modified CoFe2O4 nanoparticles at room temperature are shown in Figure 2(b). The coercivity of the CoFe2O4 is around 185 Oe, which is much larger than that of Fe2O3 nanoparticles. This indicates that the incorporation of the Co cation in the Fe-O matrix greatly increases the magnetic anisotropy of the CoFe2O4 materials. The magnetic properties of the SDS modified CoFe2O4 nanoparticles also present superparamagnetic properties. The saturation magnetization (Ms) of the SDS modified CoFe2O4 nanoparticles is 33.6 emu/g, which is smaller than that of the pure CoFe2O4 nanoparticles (72 emu/g). The dispersion behavior of the lauric-acid-capped CoFe2O4 nanoparticles was investigated by observing the stability of nanoparticles suspension in aqueous medium as shown in Figure 2(c). The sample was dispersed in water and the stability of the suspension sustained even after 48h. The stable suspension of the CoFe2O4 nanoparticles indicates the existence of the hydrogen bond between the aqueous solution and lauric acid layer. The aqueous solubility of the lauric-acid-capped CoFe2O4 nanoparticles makes it an ideal candidate for various in-vivo biomedical applications like cancer treatment [8]. Conclusion In summary, the study reported a facile one-pot heat-up method to synthesize the monodisperse ferrite spinel lauric-acid-capped CoFe2O4 nanoparticles. The lauric-acid-capped CoFe2O4 nanoparticles with particle size of 15.3 ± 1.7 nm were successfully obtained. The phase transfer of lauric-acid-capped CoFe2O4 nanoparticles through further surface modification in water with CTAB and SDS were achieved. The water soluble lauric-acid-capped CoFe2O4 nanoparticles can be utilized as promising candidate in cell sorting and labeling applications and as MRI contrast agent in aqueous solution.

AS-10. Enhanced photocatalytic degradation of tri-chlorophenol by Fe_3O_4@TiO_2@Au photocatalyst under visible-light.

K. Song[1], k. Choi[2], B. Park[3] and J. Jung[1]

1. Chemistry, Gangneung-Wonju National University, Gangneung city, The Republic of Korea; 2. 1Institute of Biomaterials, Kwangwoon University, Seoul, The Republic of Korea; 3. Department of Electrical & Biological Physics, Kwangwoon University, Seoul, The Republic of Korea

Over the last century, rapid modernization and quick industrialization have cause to increased discharge of noxious pollutants into rivers and the sea. Also, the population growth has led to increased use of chemical fertilizers and pesticides for surplus production. Among them, chlorophenols are widely used as biocides and pesticides. Specifically, 4-chlorophenol has been used as a disinfectant at home, in hospital and farms [1], as well as an antiseptic in root canal treatment [2]. Most of the chlorophenols released into the environment go into water, and can cause severe effects on the liver and the immune system of human body. Furthermore, chlorophenols (such as 2, 4, 6-trichlorophenol) are possibly carcinogenic. Therefore, it is of utmost importance to mineralize the chlorophenols in water to harmless products. Therefore, an efficient and ecofriendly treatment for removal of phenolic compounds from water system has become an urgent demand. Removal technologies of phenolic contaminants in the fluid streams were classified in two types as separation (such as distillation extraction, adsorption, membranes-related processes) and destructive ones (such as supercritical, wet air, thermal and catalytic oxidations) [3, 4]. Advanced oxidation processes (AOPs) [5], such as heterogeneous photocatalysis [6] and Fenton-like oxidation [7], were categorized to the destructive type and reported that can effectively remove CPs [8]. Titanium dioxide (TiO_2) is the most popular photocatalyst due to its highly stable chemical structure, relatively low cost, lack of toxicity, and photo-generation of highly oxidizing holes [9]. In this study, a facile and efficient approach for the fabrication of Fe_3O_4@TiO_2@Au particles with a good core–shell structure has been demonstrated. The synthetic protocol involves the coating of successive layers of TiO_2 nanoparticles on to a magnetic core using a sol-gel method at low temperature. To further improve the visible light responsiveness and the dispersibility of the catalysts, noble Au nanoparticles were deposited on the surface of the Fe_3O_4@TiO_2 particles through a chemical anchoring route. The Fe_3O_4@TiO_2@Au photocatalyst exhibited high photocatalytic activity in the degradation of 2, 4, 6-trichlorophenol under UV-VIS light. Also, the Fe_3O_4@TiO_2@Au photocatalyst showed an effective photocatalytic activity under only visible light.

AS-11. Solvothermal Synthesis of Uniform Water-Soluble Fe_3O_4 Nanoparticles.

S. Lee[1], Y. Chen[1] and A. Sun[1]
1. Chemical Engineering and Materials Science, Yuan Ze University, Taoyuan, Taiwan

Biomaterials are becoming increasingly important in biomedical practice, particularly as the population ages. Iron oxides magnetic nanoparticles such as magnetite (Fe_3O_4) and maghemite (γ-Fe_2O_3) have attracted much attention due to the superparamagnetic properties, biocompatibility and low toxicity which are promising candidates in application in biomaterials to the synthetic scaffolds, drug carriers, sensing media, etc. In addition, the size, dispersity and magnetic property of the magnetic nanoparticles are significance in biomedical applications [1]. Different methods of synthesizing magnetite nanoparticles were developed to address the above conditions [2, 3]. However, the hydrophobic or polydisperse are still found in products and really require cumbersome post-synthesis size selection procedures, which are not suitable for biomedical applications. In order to obtain uniform particle size, hydrophilic surface and aqueous dispersibility, the solvothermal method was proposed in this study. The anionic polyelectrolyte poly(4-styrenesulfonic acid-co-maleic acid) sodium salt (PSSMA) was used as a stabilizer to synthesis of electrostatic stabilization magnetite nanoparticles since it can strongly coordinate to iron cation to form linear polymeric molecules further restrain grain growth and the containing carboxyl groups can modify particle surface to be hydrophilic [4]. Typically, anhydrous ferric chloride, anhydrous sodium acetate, PSSMA, L-Ascorbic acid and appropriate amount of deionized water was thoroughly dissolved in ethylene glycol into a Erlenmeyer flask. After addition of sodium hydroxide which was placed in an oven and heated to 190°C for 10 h. The products were separated by magnetic separation and then washed with deionized water and ethanol for several times. Finally, the obtained products were dried in a vacuum oven. Results pointed out that the magnetic nanoparticles with excellent water dispersity and uniform size by modified solvothermal method. The amount of coated polymer, PSSMA, can strongly influence the particles size and size distribution. X-ray Diffraction (XRD) data showed diffraction peaks at $2\theta = 30.2°$, 35.5°, 43.2°, 53.6°, 57.2° and 62.7°, which can be indexed to (220), (311), (400), (422), (511) and (440) planes of Fe_3O_4 in a cubic phase, respectively. Vibration Sample Magnetometer results showed the nanoparticles are superparamagnetic magnetite. Dynamic Light Scattering results showed tunable particle size with narrow size distribution. Furthermore, the uniform size distributions with diameter about 120 nm were obtained in Transmission Electron Microscope (TEM) images. High Resolution-TEM confirmed the good crystallinity and clear lattice images with *d*-spacing about 2.54 Å, which can be indexed to (311) plane of cubic magnetite. The detail mechanism to affect particle size and dispersion will be discussed in full manuscript.

I. INTRODUCTION As one of the most interesting magneto-responsive smart materials, magnetorheological (MR) fluids, micron or sub-micron sized soft-magnetic particles suspended in a nonmagnetic liquid of hydrocarbon or silicone oil, have drawn a huge attentions recently, due to their rapid, continuous and reversible phase change from a liquid-like to solid-like state within milliseconds [1]. This phenomenon occurs by forming chain structures following the magnetic field direction, induced by attractive magnetic dipole interactions among the adjacent magnetic particles, while showing a Newtonian fluid-like behavior of random dispersion of the particles under zero magnetic field. This chain-like structure formation intensifies rheological properties of the MR fluids such as yield stress, shear viscosity, shear stress, and dynamic modulus [2]. Based on these advantages of controlling their rheological and mechanical characteristics, MR fluids have been widely investigated in their industrial applications such as engine mount, vehicle shock absorber and polishing devices, with some commercialization. As for typical materials to form MR fluids, carbonyl ion (CI) particles have been widely accepted with their suitable particle size and high saturation magnetization [3]. In spite of these advantages, CI particles often show dispersion stability problem because of their high density, limiting their engineering applications [4]. Thus, numerous methods were introduced to overcome these problems [5]. Instead of progressing complicated methods of modifying CI characteristics, iron oxide (Fe_3O_4) particles with enough magnetic properties as well as low density, have been also adopted, along with their improved anti-corrosion characteristics owing to the oxidation state. In this study, triangular Fe_3O_4 based MR fluid is expected to provide stronger chain structure than spherical Fe_3O_4 particles because the contact angle of triangular Fe_3O_4 is larger than that of spherical Fe_3O_4 [6], being stacked well due to the prism structure. II. EXPERIMENT Following the synthetic process reported [7], iron chloride hexahydrate ($FeCl_36H_20$) (1g) was liquefied in ethylene glycol (25ml), being stirred for 30 min with a magnetic bar to form a clear solution, and then both 1,3-propanedimaine (10ml) and CH_3COONa (3g) were added. The solution was mixed for 30 min and put into a stainless-steel autoclave. It was then heated at 200 degC and maintained for 12h. The black Fe_3O_4 particles were washed with ethanol and water for several times, following their drying process in an oven at 55 degC for 10h. The synthesized Fe_3O_4 particles were dispersed in silicone oil with 7 vol% particle concentration. The morphology of the synthesized particles was checked by using transmission electron microscopy (TEM) (CM200, Philips, U.S.A), and the rheological behavior of Fe_3O_4 based MR fluid was measured using a rotational rheometer (Physic MCR 300, Anton Paar, Germany) which possesses an external magneto-cell (MRD 180, Anton Paar, Germany). III. RESULT AND DISCUSSION Figure 1 shows TEM image of size and surface morphology of the triangular shaped Fe_3O_4 nanoparticles fabricated, in which most of the Fe_3O_4 particles has triangular and flat morphology with some particle size distribution. As for their MR performance, Fig. 2 represents flow curves of shear stress of triangular Fe_3O_4-based MR fluid as a function of shear rate ranging from 0.01 to 30 (1/s) for various magnetic field strengths. From the controlled shear rate test, the measurement points were set from initial values of 10s to final values of 2s in a log-log scale. Under the zero magnetic field, the shear stress linearly increases with increasing the shear rate, following a Newtonian fluid-like behavior of a typical dilute suspension. However, under applied magnetic fields, the MR fluid shows a sharp increase of its shear stress with applying magnetic field strengths and the shear stresses represent a plateau area over the entire shear rate range, also showing distinctive solid-like behaviors with a yield stress. This phenomenon occurred owing to the formation of a fibril-like structure of magnetized triangular Fe_3O_4 nanoparticles. Because the MR fluid showed characteristics of non-Newtonian fluid possessing yield stress, the Cho-Choi-Jhon equation with six-parameters was adopted in order to fit the flow curves given in Fig. 2, as can be seen from the solid lines. Furthermore, along with their typical MR characteristics, triangular Fe_3O_4 based MR fluid demonstrated higher MR performance compared to spherical Fe_3O_4 [6] for potential engineering application, because of high stacking ability and surface contact angle of the triangular Fe_3O_4 nanoparticles. Furthermore, the dynamic yield stress obtained from Fig. 2 was further analysed as a function of applied magnetic field strength with a power-law correlation along with various dynamic moduli results which will be beneficial to its engineering application [8].

AS-13. Structure and magnetic properties of MnBi nanoparticles prepared by laser ablation and arc discharge method.

X. Wang[1], H. Qian[2], *P. Si*[1], Y. Yang[2], C. Choi[2], J. Park[2], X. Wang[1], H. Ge[1], K. Shinde[2] and K. Chung[2]
1. China Jiliang University, Hangzhou, China; 2. Korea Institute of Materials Science, Changwon, The Republic of Korea

MnBi has attracted renewed research interests as hard magnetic materials due to its large magnetocrystalline anisotropy and unusual positive temperature coefficient of coercivity. To produce coercivity in MnBi, it is crucial to reduce the dimensions of the MnBi powders, which are usually prepared by ball milling and the size of the powders is in micrometers [1, 2]. MnBi nanoparticles with reduced size in the range 100-300 nm were fabricated from a mixture of Bi_2O_3 and Mn in the presence of Ca as reducing element by a mechanochemical process [3]. MnBi ribbons/powders with further reduced grain size of 20-30 nanometers were prepared by melt spinning method [4] The arc discharge method and the laser ablation method have been widely used for the synthesis of nanoparticles. However, no reports of these methods on the synthesis of MnBi powders could be found. In this work, the MnBi spherical nanoparticles with size around 100 nm or less were prepared by arc discharge method, as shown in Figure 1. The MnBi powders prepared by laser ablation method show a wide size distribution in the range of several tens of nanometers to several micrometers. The composition of the MnBi powders is different from that of the original alloys due to varied evaporation rate of Mn and Bi at high temperatures during arc discharge and laser heating. The samples were annealed at varied temperatures for varied time intervals, after which the structure and magnetic properties of the samples were studied systematically. Fig. 2 shows the magnetic hysteresis loops of the MnBi nanoparticles prepared by laser ablation and heated at different temperature for varied time intervals. The coercivity of the MnBi powders reached up to 0.8 T after annealing at 423 K for half hour and was reduced to 0.3 T when the annealed at 538 K. With increasing annealing time, the coercivity of the powders was further reduced. We ascribed the reduced coercivity of MnBi to the grain growth with annealing temperature and time. However, the saturation magnetization increases with increasing annealing temperature and time due to the formation of MnBi phase. This work was supported by NSFC (Nos. 51671177, 11074227) and the Future Materials Discovery Program through the NRF funded by the Ministry of Science, ICT and Future Planning (2016M3D1A1027835).

AS-14. Organization and magnetic properties of FePt nanoparticles deposited on graphene/Ir moiré pattern.

F. Tournus[1], P. Capiod[1], L. Bardotti[1], A. Tamion[1], O. Boisron[1], C. Albin[1], V. Dupuis[1], G. Renaud[2] and P. Ohresser[3]

1. Institut Lumière Matière, Université Lyon 1 & CNRS, Villeurbanne, France; 2. CEA-INAC, Grenoble, France; 3. Synchrotron SOLEIL, Gif sur Yvette, France

The FePt alloy, when chemically ordered in the $L1_0$ phase, is among the magnetic materials displaying the highest magnetic anisotropy constant (K around 7 MJ/m^3). Therefore it is a perfect candidate for ultra-high density magnetic storage applications, provided nanoparticles can be prepared in such a high anisotropy phase [1]. Another requirement for applications, as well as for fundamental studies, is to organize the magnetic nanoparticles in a 2D array. In parallel to investigations on chemically synthesized systems, a great effort is devoted to the bottom-up elaboration of nanomagnet arrays following a physical route. In this context, one widely used path consists in using template surfaces with specific sites regularly distributed. Such a 2D lattice can be obtained with the moiré phenomenon, which appears when two crystalline structures of slightly different cell parameters are stacked. Thus, a graphene layer epitaxially grown on a Ir(111) surface displays a 2D spatial modulation corresponding to a hexagonal lattice of 2.5 nm cell parameter [2]. For the first time, we have characterized the organization and the magnetic properties of FePt nanoparticles on such a moiré pattern. We will first describe the formation of size-selected (typically from 2 nm to 4 nm) FePt nanoparticles by Low Energy Cluster Beam Deposition (LECBD) and the preparation of FePt/graphene/Ir(111) samples. We will discuss the organization of such particles on specific sites of the moiré lattice, as determined by grazing incidence x-ray scattering measurements (GISAXS technique) (figure 1) and x-ray diffraction performed at the European Synchrotron Radiation Facility (ESRF) [3]. The deposited nanoparticles are sensitive to the moiré pattern and we find that the resulting organization can be preserved up to temperatures around 700°C. Finally, we will report a clear evolution of the magnetic properties of the FePt nanoparticles induced by annealing (phase modification, anisotropy modification, interface effects between FePt and the graphene...), while the particles keep their individuality (no layer formation is observed). This is put into evidence by X-ray Magnetic Circular Dichroism (XMCD) measurements on the DEIMOS beamline at SOLEIL Synchrotron (figure 2). The magnetic properties will also be compared to those of FePt diluted in an amorphous carbon matrix [4].

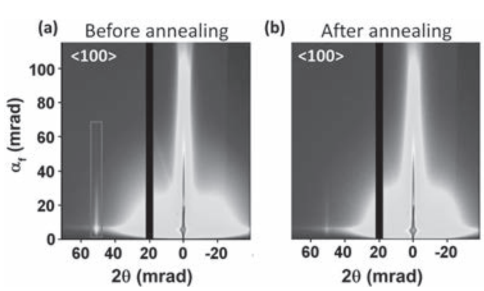

Fig. 1. GISAXS intensities, along the <100> direction of the moiré lattice, before (a) and after (b) annealing at 700°C. The presence of the correlation peak (red frame on left) in those directions reflects the hexagonal organization of the FePt nanoparticles on the graphene/Ir moiré lattice.

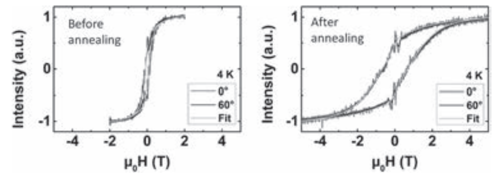

Fig. 2. Low temperature (4 K) hysteresis loop, deduced from XMCD measurements (at Fe L_3 edge) at different indicence angles (normal incidence, i.e. 0°, and 60°) for FePt nanoparticles before (left) and after (right) annealing. The hysteresis loops display an isotropic behavior and can be fitted to infer the magnetic anisotropy value in each case: a huge increase is observe (reflected by the coercivity increase) upon annealing, which is the signature of $L1_0$ chemical ordering of the particles.

AS-15. Research on Eddy Current Testing of Functional Polymer Composite Material.

Z. Cai[2] and *C. Liu*[1]

1. Province-Ministry Joint Key Laboratory of Electromagnetic Field and Electrical Apparatus Reliability, Hebei University of Technology, Tianjin, China; 2. East China Jiaotong University, Nanchang, China

1. Introduction Eddy current testing method can be used to realize the noncontact measurements for mechanical quantities, material testing and flaw detection which made of conductive material (e.g., metallic material, carbon fiber reinforced polymer material and so on)[1-2]. Therefore, electromagnetic nondestructive method have rarely used in functional applications, such as electro-magnetic interference shielding and absorbing material. Nowadays, the coating of shielding and absorbing material is widely used by specific conductive material which made of polymer composite material mixed with conductive particles. The insulating matrix of polymer composite material is separated by nanoscale conductive filler particles. Recently, the experimental results on the lift-off effect show that the induced voltage of the coil with alternating current changes regularly with the variations in the distance between the coil and the composite object. This phenomenon indicates that there exists an eddy current composed of the tunnelling current and the conduction current in the composite object. The results indicate that eddy current testing method has the potential to apply specific conductive polymer composite non-destructive testing. 2. Mechanism analysis To realize the damage of specific conductive polymer composite based on eddy current effect, we fabricate a composite specimen. Nanoscale Fe/FeSiB is used as conductive phase, Nylon is used as insulating matrix. After several hours of mixing, the polymer material composed of Fe/FeSiB and Nylon is fabricated. Nylon is separated by nanoscale conductive filler particles. As the conductivity of nanoscale conductive filler particles is far more than that of nylon, the adjacent Fe/FeSiB can be considered as electrodes. According to the classic conclusions on the conductivity of the composite [3], if the distance between the adjacent conductive filler particles is small enough, the tunneling effect occurs. Fig. 1 shows the schematic of the process that the electrons pass through the potential barrier. Based on the previous research on the tunneling effect of the polymer composite material, the tunneling current density J can be given by the function of the distance between the adjacent particles D and the height of potential barrier λ. 3. Results Fig. 2 shows the relation between the excitation frequency and the impedance of the composite spiral element when the lift-off is zero. The induced voltage amplitude of 1MHz excitation decreases observably with the lift-off increased, while under the other frequencies excitation (low-frequency stage), the induced voltage amplitude almost consistent no matter whether the lift-off is zero or infinite. The behavior "eddy current phenomenon" is caused by the specific electromagnetic effect of "insulating" polymer composite material. 4. Conclusions The experiment results indicate that high frequency eddy current effect is existed if polymer composite material mixed with conductive particles approaches the spiral eddy sensor carried with alternating current. The impedance amplitude and angle of the composite element decrease with the increasing of the testing frequency. Therefore, the impedance of the eddy sensor can be used to find the superficial defect of the composite material. The finite element analysis results show that the concentration and the size of conductive particles which have the monotonous influence of equivalent capacitance. Therefore, the eddy sensor has the potential for the nondestructive testing of stealth structure with high frequency. The future works can be summarized as follows. To extend the application scope, the superficial defect characteristics of the composite material should be studied quantitatively. To make the higher sensitivity of the eddy testing, the key technologies (i.e. the optimization of eddy sensor, etc.) should be developed to improve the impedance change effects, such as environment dependent degradation of the composite material.

I. Introduction In the case of BLDC (Brushless Direct Current) motors, cogging torque is produced with motors containing permanent magnets. A shape design for reducing the cogging torque, which is a cause of vibration noise, is essential [1][2]. Many methods have been suggested to reduce the cogging torque. The most prevalent is the use of the ease of application and the use of relatively inexpensive changes in the rotor and stator shape during construction [3]. The application of a notch is also one of the methods using the shape changes of the rotor and stator, and a method for applying the notch position and size as variables has been reported [4][5]. In this study, two different notches were applied to the stator tooth to reduce the cogging torque. The two sloping notches were used a diagonal line of different angles at different asymmetric locations. The optimal experiment planning, LHS, was used to locate the optimal location and radius and sloping angles, and the creegging model and optimization technique, as well as genetic algorithms, were used to approximate the model. The objective function was the cogging torque, and the constraints were set to make the torque and efficiency higher than a certain value. The validity of this paper was verified by comparing characteristics through finite element analysis. The accuracy of the 3D method was verified by comparing the results of the cogging torque experiment and 3D analysis of the conventional model with the conventional asymmetric notch, and then with the characteristics of the sloping notch model using the existing model, the sloping notch model. II. Single-Phase BLDC motor A single-phase BLDC motor is generally arranged in a region where the torque is zero because a rotor position may fail to perform an initial start-up operation, thereby solving the problem by configuring the shape of the stator asymmetrically. On the other hand, an asymmetric stator shape affects the cogging torque. Moreover, because the cogging torque causes vibration noise, the shape design for reducing the cogging torque is essential [4][5]. Cogging torque means a non-uniform torque of a stator inevitably generated in an electric motor using a permanent magnet, and a torque in the radial direction, in which the magnetic energy of the electric motor is minimum, i.e., a state in which the electric motor moves to an equilibrium state. These cogging torques are the cause of noise and vibration. Therefore, it is essential to consider the cogging torque for a motor that requires precision. The cogging torque is determined by B_{nNL} and G_{nNL}, and the application of the appropriate notch changes the effective slot number, so that the value of changes and the cogging torque can be reduced. On the other hand, when the asymmetric air-gap is applied, the relative permeance function of the air-gap is not constant but asymmetric. In this paper, the position, radius and sloping angle of notch (a) and notch (b) were designed asymmetrically, as shown in Fig. 1. The notch was designed by applying the optimization technique to determine the optimal position, radius, and sloping degree. III. Stator Shape Optimal Design for Cogging Torque Reduction To minimize the cogging torque reduction, an optimized design analysis was used to apply a sloping notch to the stator teeth. The position angle, radius, and sloping angle of each notch (a) and notch (b) were set as variables. The torque and efficiency are important characteristics affecting the performance. So these seted Constraints condition. LHS was used to extract the samples. The creegging model and genetic algorithm were applied to model the approximation and optimal design method. ● Objective function - Reduce the cogging torque ● Constraints - Efficiency ≥75[%] (5), Torque ≥295[Nm] ● Design variables - 0 ≤ X1 (Notch (a) deg) ≤ 20[°], 0 ≤ X2 (Notch (a) Size) ≤ 3[mm], -20[°] ≤ X3 (Notch (a) Sloping deg) ≤ 20[°] - 0 ≤ X4 (Notch (b) deg) ≤ 20[°], 0 ≤ X5 (Notch (b) Size) ≤ 3[mm], -12[°] ≤ X6 (Notch (b) Sloping deg) ≤ 12[°] IV. Stator design optimization result Fig. 2 compares the cogging torque of the initial and proposed models through finite element analysis. In the case of the basic model, the cogging torque was reduced by 39.2 [%] from the basic model while maintaining the efficiency and torque of the initial model at 65.5 [mNm]. Compared to the finite element analysis results, the error rate was less than 1.3 [%], which is consistent with the finite element analysis results. V. Conclusion This study examined the stator shape of a single phase BLDC motor with the aim of reducing the cogging torque. An asymmetric sloping notch was applied to reduce the cogging torque in a single phase BLDC motor with an asymmetric air gap. To minimize the cogging torque within the limited conditions, the position, radius, and sloping angle of the notch were determined by an optimization method using a genetic algorithm. The cogging torque of the proposed model using the sloping notch was found to be 40.3 [mNm], which was 38.5% lower than that of the basic model (65.6 [mNm]).

INTRODUCTION A linear oscillating actuator (LOA) is a machine that performs linear reciprocating motion within specific strokes at a specific frequency. With advantages such as high transmission efficiency, simple structure, and low noise, LOA is more suitable for electro-medical machines, electric hammers, linear pumps, refrigeration compressors, and other similar fields, than the traditional way by using rotatory motor and crankshaft [1]. The LOA can be classified as longitudinal flux LOA (LFLOA) and transverse flux LOA (TFLOA) according to the flux path. In the LFLOA, the direction of the current flow and the direction of the moving part are vertical, while the direction of the current flow in the TFLOA is parallel to the direction of the moving part. It is generally known that the transverse flux structure used in a machine can simultaneously increase power density and efficiency [2]. However, there is no research on the output power and efficiency in relation to the flux path in the two types of LOA of the same volume yet. Therefore, this study compares the electromagnetic characteristics of the LFLOA and TFLOA. For comparison, the axis and radius lengths of the two types of LOA are set equal. Next, both moving parts of LFLOA and TFLOA consist of permanent magnets. The moving-magnet-type LOA can lighten the moving part, produce a desired stroke through the length of the permanent magnet, and has a higher power density than the moving-iron-core type. Finally, the volume of the moving magnet is set the same. Under the above conditions, the optimal design of LFLOA and TFLOA is carried out. Finally, electromagnetic characteristics, such as magnetic flux density, force, and efficiency at a specific frequency, are compared. Fig.1. (a) shows two-dimensional (2D) and three-dimensional (3D) analysis models of the LFLOA. The LFLOA consists of an inner core, outer core, coil, and permanent magnet. Because the outer core consists of two shoes, one or three-pole permanent magnets are used to construct a magnetic circuit [3]. In this LFLOA model, the three-pole magnets are used to increase the magnetic flux density. As can be seen from the 3D analysis model, the magnetic flux in the LFLOA flows in the axial direction, and this type of LOA is radially laminated to reduce core loss. Fig.1. (b) also shows the 2D and 3D analysis model of the TFLOA. The TFLOA consists of the inner core, outer core, coil, permanent magnet, and a non-ferromagnetic material. To create the magnetic circuit in the TFLOA, the non-ferromagnetic material is inserted between the outer cores and the moving permanent magnets of the four poles are connected in reverse. In this type of LOA, the magnetic flux flows radially, and the outer core is stacked axially to reduce core loss. Fig.2. (a) shows the magnetic flux density distribution and flux flow in LFLOA and TFLOA. In the TFLOA, it can be seen that the flow of magnetic flux in the upper core is opposite to that in the bottom core. Fig.2. (b) shows the magnetic flux density at the air gap in the LFLOA and TFLOA. Fig.2. (c) shows the force characteristics of LFLOA and TFLOA in terms of the current. Under the same condition, the LFLOA is more dominant in the force characteristics. More detailed discussions and analysis results will be presented in the final paper. AT-03. Analysis of Flux Reversal Permanent Magnet Machines with Different Consequent-Pole PM Topologies.

H. Li[1] and *Z. Zhu*[1]
1. Electronic and Electrical Engineering, University of Sheffield, Sheffield, United Kingdom

Abstract—This paper comprehensively studies electromagnetic performance of flux reversal permanent magnet (FRPM) machines with different consequent-pole PM (CPM) topologies. Several possible CPM topologies are firstly introduced and classified by different numbers of PM pieces and PM locations on stator teeth. Then, the magnetic flux distribution and torque performance of each CPM topology are analyzed and compared by both analytical and finite element (FE) analyses, from which the CPM topology with the highest torque density is identified. 1. Introduction FRPM machines [1, 2] have advantages of robust rotor structure and easy heat management of PMs, making them promising in low-speed and high-torque applications. However, the large equivalent air-gap length resulted from surface-mounted PM (SPM) topology limits the field modulation effect of rotor teeth, thus impairing the torque performance. In [3], one kind of CPM topology is proposed to replace the SPM topology, which is beneficial to improve the armature field and the resulted torque, as well as to reduce the PM volume, as shown in Fig. 1(a). For each stator tooth, one PM piece together with the adjacent ferromagnetic piece make the magnitude and direction of flux through the coil vary with the relative rotor position. Moreover, the magnetization directions of PMs are identical for all the stator teeth, but the PM locations are different for two adjacent stator teeth. Therefore, the CPM topology can be designated as N/Fe-Fe/N. In this paper, three new CPM topologies are proposed, as shown in Fig. 1(b)-(d), which are designated as N/Fe-N/Fe, N/Fe/N/Fe-Fe/N/Fe/N, and N/Fe/N/Fe-N/Fe/N/Fe, respectively. Similar to N/Fe-Fe/N, each stator tooth of N/Fe-N/Fe has one PM piece and one ferromagnetic piece. However, the PM locations of all the stator teeth are identical. Both N/Fe/N/Fe-Fe/N/Fe/N and N/Fe/N/Fe-N/Fe/N/Fe have two PM pieces and two ferromagnetic pieces on each stator tooth, and the PM locations of two adjacent stator teeth are different for the former, while they are exactly the same for the latter. Considering the fact that different CPM topologies largely influence the PM field in air-gap and associated winding connections, the torque performance of different CPM topologies is quite different. Therefore, the comparison of various CPM topologies will be the main focus of this paper as it is of great significance for the design of FRPM machines aiming at high torque density. 2. Torque Comparison of Various CPM-FRPM Machines Four 14-pole-rotor FRPM machines with different CPM topologies are globally optimized under the same stator outer diameter (90mm), stack length (25mm) and copper loss (20W), and their torque results are compared in Fig. 2. It should be noted that for Type1 and Type2, the stator slot number N_s=12; for Type3 and Type4, N_s=6. As can be seen, the average torques of the CPM-FRPM machines are largely affected by CPM topologies, which can be illustrated from the following two aspects: 1) The CPM topologies with identical PM locations on two adjacent stator teeth are more likely to produce higher torque than those with different PM locations, e.g. Type2 has 13% higher torque than Type1, Type4 has 34% higher torque than Type3; 2) The CPM topologies with two PM pieces on each stator tooth produce higher torque than those with one PM piece, e.g. Type3 has 34% higher torque than Type1, Type4 has 60% higher torque than Type2. The influence of PM location and number of PM pieces can be attributed to the different working harmonics of air-gap field in different CPM topologies. In terms of PM location, it influences the order (pole-pair number $p_{m,k}$) of the PM field harmonics, for Type1 and Type3, $p_{m,k}=|mN_s/2+kN_r|$; for Type2 and Type4, $p_{m,k}=|mN_s+kN_r|$, where m is the order of Fourier series of PM magnetomotive force (MMF) and m=1,2,3…, k=0,±1,±2…, is the order of the permeance harmonics produced by salient rotor teeth, and N_r is the rotor pole number. As for the number of PM pieces on each stator tooth, although it has no influence on the order of the field harmonics, it largely influences the magnitude of each harmonic. Taking Type2 and Type4 for example, for Type2, the N_sth harmonic is of the largest magnitude whereas the $2N_s$th harmonic has the largest magnitude in Type4. The detailed analysis and comparison of working harmonics in different CPM topologies will be given in full paper, and the optimal number of PM pieces will also be discussed. 3. Conclusion In this paper, various FRPM machines with different CPM topologies are analyzed and compared. It is found that the torque performance of the CPM machine is largely related to the CPM topology. In full paper, for each CPM topology, the detailed analysis of working harmonics, key design parameters and performance comparison against the SPM counterpart will be given. In addition, two prototypes with different CPM topologies are being manufactured, of which the test results will be provided.

AT-04. Influence of Aluminum Die-Cast Rotor Porosity on the Efficiency of Induction Machines.

J. Yun[2,1] and S. Lee[1]
1. Korea University, Seoul, The Republic of Korea; 2. Hyundai Electric Co., LTD, Yongin, The Republic of Korea

I. Introduction With the increasing demand for energy efficiency, the international legislative actions are enforcing motor manufacturers to produce motors that meet the mandated efficiency ratings [1]-[2]. This makes it crucial to predict the motor efficiency with high accuracy in the design stage. Porosity in aluminum die cast rotors is inevitably introduced during the die casting process and causes the rotor fill factor (FF) to vary from motor to motor for a given design. This causes non-negligible variance in motor performance considering that rotor losses account for up to 20% of induction machine losses. However, the influence of porosity distribution in rotor bars and end rings is not properly considered in existing publications [3]-[5]. This makes it difficult for motor designers to predict the performance of motors accurately to guarantee that they meet the specified efficiency. In this paper, a method based on a combined 2 and 3 dimensional finite element analysis (2D/3D FEA) that takes the porosity level and distribution into account is proposed for accurate prediction of motor performance. The proposed method is verified through FEA and experimental testing. II. Proposed method It is important for the motor designer to use suitable analysis tools to meet mandatory motor efficiency regulations. The equivalent circuit model most commonly used for optimizing the design does not provide sufficient accuracy because the influence of non-ideal factors are not taken into account. Although FEA is well suited for precise prediction of motor performance, 2D FEA is not capable of accounting for the effect of the rotor end region, and the limitation of 3D FEA is the excessive computation time. The main concept of the proposed method is to perform a half single slot pitch 3D FEA shown in Fig. 1(a) for precise calculation of rotor end ring resistance and leakage reactance, R_{ring} and X_{ring}, and then perform a 2D FEA of the slot portion with the end ring parameters obtained. The FF and porosity distribution in die-cast rotors were accounted for in the 2D and 3D FE models based on the X-ray scans shown in [6]. It was assumed that porosity is concentrated in the center of the bars in the slot portion, and distributed in the radial center of the end rings close to the rotor core, as shown in Figs. 1(b),(d). The proposed method was compared to the conventional method that assumes uniform distribution of porosity. FEA and experimental testing were performed on a 440 V, 8 P, 15 kW induction motor to analyze and verify the proposed method. The temperature of the stator winding and rotor end ring were obtained using a thermocouple installed on the end winding surface and a thermal tape in end ring. The no-load and load tests were performed according to IEC 60034-2-1 [7] for calculating the full-load efficiency. The influence of FF and porosity distribution on motor performance was investigated by performing FEA and experimental testing on rotors with 67% and 93% FF. The end ring parameters for the proposed method were calculated using the half axial length, single slot pitch rotor 3D FE model shown in Fig. 1(b). The transient solution is obtained with the pre-determined values of R_{ring} and X_{ring}, and the 2D FE 1/8 model shown in Figs. 1(c),(d). For the rotor with 93% FF, the rotor conductor losses obtained assuming uniform porosity distribution in the bar and end ring is lower (by 2.5%, 1.9%) than that of the test results and proposed method. As a result, the error in the efficiency estimate with proposed method is noticeably lower by -0.01%, when compared to conventional method (+0.30%). This indicates that the proposed method can predict the performance with improved accuracy. For the rotor with 67% FF, the error in the efficiency were +0.78%, and -0.08% for conventional and proposed methods, respectively. This shows that the values with conventional method have a tendency to overestimate the values of motor efficiency significantly. This can be attributed to the influence of porosity distribution on the rotor loss not being taken into account, which leads to lower rotor loss estimates. Test results show that the rotor loss for the 67% FF rotor is 75% larger than that of the 93% FF rotor. The increased ohmic loss in the rotor cage has a significant impact on the temperature rise of rotor bars from 87°C to 117°C, and also causes the temperature in the stator winding to increase from 84°C to 97°C. The full-load efficiency obtained with experimental testing is 91.81% and 90.15% for rotors with 93% and 67% rotor FF, respectively. This shows that porosity has significant impact on efficiency of die-cast rotors to a degree where it can fail to meet efficiency classes. The relationship between FF and motor performance was investigated by performing the calculations with the proposed method for varying FF levels between 67% and 100% as shown in Fig. 2. There is a 2.04% decrease in motor efficiency as the rotor FF is decreased from 100% to 67%. The following can be concluded from the FE and test results: - Rotor FF and porosity distribution have a significant influence on motor efficiency - The proposed method can provide reliable prediction of motor efficiency

AT-05. Influence of Cooling Air Flow Velocity on Temperature Rise and Output Power for Permanent Magnet Servo Motor.

G. Zhao[1], X. Gao[1], Y. Wang[1] and B. Bai[1]
1. Shenyang University of Technology, Shenyang, China

I.INTRODUCTION Power density is a very important index for permanent magnet servo motor. The motor is asked to output more power and more torque in a finite volume, as a result the problem of the higher motor temperature rise is becoming more and more prominent with the increase of power density. So more researchers pay more attention in the heat dissipation of the motor, more heat dissipation methods are adopted to reduce the temperature rise and the influence of the internal flow field of the motor on the temperature rise is studied [1][2]. The flow field and temperature field of the motor are analyzed by the flow-heat coupling in [3][4], but the quantitative relation between the velocity of the cooling air and the temperature of the motor is not involved. Because the air flow velocity can influence the heat dissipation coefficient and the heat dissipation capability, in this pater the Finite Element Method (FEM) is used to analyze the flow-heat of the permanent magnet servo motor and the flow field and temperature field in the motor are analyzed. Then the influence of the flow velocity of the cooling air on the temperature of the motor is studied and the best flow range is found. Finally the experiment is carried out to verify the validity of the simulation and summarize the influence of cooling air velocity on motor temperature. II. GEOMETRY MODEL In this paper, a three-dimensional calculation model is established and the corresponding boundary condition is applied to the finite element analysis based on an 8-pole 36-slot surface mounted permanent magnet servo motor. For calculation convenience the motor model is simplified properly, as shown in Fig.1. III. ANALYSIS AND EXPERIMENT Applying the rated rotational speed to the rotor and simulating the internal air flow field, temperature distribution of the motor is figured out, as shown in Fig. 2. Fig 2(a) shows the distribution of fluid velocity inside the motor and Fig. 2(b) shows the steady-state temperature distribution cloud picture. According to Fig.2 the winding end temperature is the highest, the reason is that the convection heat dissipation coefficient of the winding end is less than the heat conduction for this kind of fully-closed motor. The convection heat dissipation coefficient of the motor is proportional to the velocity of the fluid velocity. So the velocity of the cooling air can affect the motor temperature rise. The relationship between the motor temperature and the cooling air velocity is obtained through calculating the steady motor temperature in different cooling air velocity by FEM, as shown in Fig.3. According to Fig.3 the motor temperature gets lower for higher cooling air velocity. But the changing trend is not linear, the motor temperature decreases rapidly even if a relative slow velocity of the cooling air exerts to the motor, the tendency of the motor temperature reduction get gently when the cooling air velocity boosts. The cooling effect does not improve much when the cooling air velocity goes beyond 3m/s. In order to verify the validity of the method, a series of experiments are done on the permanent magnet servo motor, as shown in Fig.4. The experimental data at different cooling air velocities are shown in table 1. By comparing the experimental data, It can be seen that the motor winding end temperature decreases remarkably by 40 degree centigrade when the cooling air velocity is 3m/s and the FEM analysis agree with the experimental data well. Now that the motor temperature can be reduced remarkably because of the exertion of the cooling air, the motor output capacity must be enhanced and the power density can be boosted. So another experiment and analysis have been done. The output power is increased from 630W to 780W at the same air flow velocity 3m/s, the tested and calculation results are shown in table 2. When the motor works in the overload torque 5Nm, its temperature is also within the reasonable temperature rise requirements, and the motor output power increases by about 24%, but the temperature increases by about 14% merely. Therefore, the motor capacity is improved by improving the velocity of cooling air. IV.CONCLUSIONS This paper investigates the effect of cooling air flow velocity on the temperature and output capacity of permanent magnet servo motor. The fluid field and the temperature distribution are analyzed by FEM in different cooling air velocity and the experiments are carried out to verify the validity of the FEM analysis. Increasing the velocity of the cooling air can decrease the motor temperature and enhance the motor power density. More details will be given in full paper.

AT-06. The Method for Reducing Intrinsic Shaft Voltage by Suitable Selection of Pole-arc Coefficient in Fractional Slot Permanent Magnet Synchronous Machines.

B. Peng[1], X. Wang[1] and W. Zhao[1]
1. Shandong University, Jinan, China

1. Introduction Fractional slot Permanent magnet synchronous machines (FSPMSMs) are widely used in electric vehicles, industrial automation, wind power, and other fields[1]. However, the bearing damage and premature failure occur frequently due to the shaft voltage. Actually, with certain pole and slot number combinations will generate a net dissymmetry flux to induce intrinsic shaft voltage, even without rotor eccentricity, inter-turn short circuit or other faults. When the shaft voltage exceeds a threshold, the bearing oil film breakdown will induce a large bearing current and corrode bearing. In order to reduce the maintenance cost, plenty of researches have been concentrated on the shaft voltage and bearing current mitigation technologies[2]. In [3], ceramic bearings were used to avoid the electric corrosion of shaft voltage, but it has the disadvantage of low mechanical strength. In [4], a conductive ring microfibers was proposed to provide a low impedance path to ground for bearing currents, yet it needs to be replaced frequently due to wear. In order to solve these disadvantages and suppress the intrinsic shaft voltage in FSPMSMs without additional devices, this paper proposes a novel mitigation method based on suitable selection of pole-arc coefficient by analytical analysis. Then, the optimal pole-arc coefficient is verified and corrected by finite element analysis(FEA). 2. Principle of intrinsic shaft voltage in FSPMSMs In general, the flux under per pole is divided into two equal fluxes as clockwise flux Φ_L and anti-clockwise flux Φ_Y in stator yoke after across the air gap. However, when the motor magnetic circuit is imbalance, the Φ_L is not equal to the Φ_Y, a net dissymmetry flux as (Φ_Y-Φ_L) will be yielded as shown in Fig. 1. And the superposition of the net dissymmetry flux under each pole pairs can be equivalent to a shaft encircling flux which can link with shaft and induce shaft voltage. 3. Determination of the optimal pole-arc coefficient by analytical analysis In the following analytical analysis, the permeability of the rotor yoke and stator core are assumed as infinite. On the based of orthogonality of trigonometric functions, when the slot number N_s and pole number p satisfies the relationship as $p(2n\text{-}1)=kN_s$ (like 8-pole/9-slot, 6-pole/9-slot), there would exist a net dissymmetry flux which can be expressed as: $B_{nk}=\sum\lambda_k F_{2n\text{-}1}\cos[(2n\text{-}1)\omega_e t]$(1) where ω_e is the electrical angular velocity. λ_k is the kth order harmonic of the stator slotting effect coefficient; $F_{2n\text{-}1}$ is the $(2n\text{-}1)$th order harmonic of magnetic-motive-force (MMF) of permanent magnet (PM) (n, k=1,2,3…). $F_{2n\text{-}1}$ can be expressed as: $F_{2n\text{-}1}=4/[(2n\text{-}1)\pi]h_m\sin[(2n\text{-}1)\alpha_p\pi/2]$(2) where h_m and α_p are the thickness and pole-arc coefficient of PM respectively. The intrinsic shaft voltage which is induced by B_{nk} can be defined as: $V_s=\sum V_{s\_2n\text{-}1}=\sum(1\text{-}2n)\omega_e\lambda_k F_{2n\text{-}1}S_L\sin[(2n\text{-}1)\omega_e t]$(3) Meanwhile, the of $V_{s\_2n\text{-}1}$ is $(2n\text{-}1)=kN_s/p$ times to stator current frequency f. Based of (3), suppressing $F_{2n\text{-}1}$ can reduce the value of V_s. And for costs saving, it prefers adjusting pole-arc coefficient to changing the magnet shape for reducing $F_{2n\text{-}1}$. Hence, if the pole-arc coefficient meets the values as: $\alpha_{py}=2m/(2n\text{-}1)$ (4) where m=1,2,3…$(n\text{-}1)$, the amplitude of $F_{2n\text{-}1}$ and $V_{s\_2n\text{-}1}$ will reduce to 0 due to $\sin[(2n\text{-}1)\alpha_p\pi/2]=0$. For 6-pole/9-slot FSPMSMs, V_{s_3} is the fundamental component of shaft voltage whose amplitude is much larger than subharmonic V_{s_3}. From (3) and (4), it owns a maximum value as V_{s_3m} when α_p=1, and reaches the minimum as 0 when α_p=0.67 or 0.33. Considering the influence of pole-arc coefficient on other performances in motor[5], 0.67 is deemed to the optimal pole-arc coefficients in this machine which achieves maximum suppression of shaft voltage. 4. Correct of the Optimal Pole-arc Coefficient by FEA By FEA, the shaft voltage in 6-pole 9-slot FSPMSMs with different pole-arc coefficients are calculated under open circuit and 1000 r/min rated speed, hence the fundamental frequency of shaft voltage is 150Hz from (3). The region is set as (0.6, 1) to find the optimal pole-arc coefficient by the method of bisection. As a result, the amplitudes of fundamental shaft voltage in 6-pole/9-slot FSPMSMs with different α_p are shown in Fig.2. It is obvious that 0.63 is the more optimal α_p since its amplitude of V_{s_3} can be approximated at 0. Although it does not reach the minimum value, the amplitude of V_{s_3} in the machine with α_p=0.67 is much lower than the one with α_p=1, whilst the error between the optimal values calculated by analytical analysis and FEM is little. 8-pole/12-slot and 8-pole/9-slot FSPMSMs are also analyzed to increase the persuasiveness in the full paper. 5. Conclusion The method of suitable selected pole-arc coefficient has been proved to suppress the intrinsic shaft voltage effectively. In addition, to ensure precision and save time, a superposition method should be adopted to determine the optimal pole-arc coefficient, where the optimal value was firstly calculated by analytical analysis, then was corrected constantly by FEA to reach an exact value.

AT-07. Comparison of Rotor Eddy Current Losses in Fractional-Slot Concentrated-Winding IPM machines with Different Rotor Topology.

L. Cong[1,2], X. Li[1] and *L. Wu*[2]

1. College of Electrical Engineering, Guangxi University, Nanning, China; 2. School of Automation and Electrical Engineering, Linyi University, Linyi, China

I. Introduction Interior permanent magnet (IPM) machines have been widely used in many applications, such as electric vehicle, servo drive, and so on, due to its high torque density [1]. By using fractional-slot concentrated-winding (FSCW),the IPM machines have short end windings and less copper loss, and can further improve torque density under same cooling capacity. However, the IPM machines with FSCW have rich harmonics of magnetomotive force (MMF) and the higher rotor eddy current losses [2]. This paper will compare the rotor eddy current losses in FSCW IPM machines with different rotor topology and discuss rotor topology's influence on the harmonics of the armature field. II. Topology and Specification of FEA Models Figs. 1 & 2 show 12-slot 10-pole and 9-slot 10-pole IPM machine's FEA models with different rotor topology. The specification of IPM machine's FEA models is listed in Table I. To compare rotor eddy current losses reasonably, the stator outer/inner diameter, stator yoke, air gap, stack length, size of each magnet, slot opening width and electric loading of all IPM machines are set same value, respectively. III. FEA Results of Torque and Eddy Current Losses In this section, the MMF harmonics and rotor eddy current losses of IPM machines are detailed analyzed by the theoretical and FEA method. The main harmonics of the MMF in 12-slot/10-pole and 9-slot/10-pole IPM machines are listed in Table II & III, respectively. In the Table, the slip [%] is defined as the slip of the rotor speed relative to the rotation speed of MMF's harmonics and the MMF [%] is defined as percentage of the harmonics magnitude to working harmonics [3]. Fig. 3 shows the FEA results of the electromagnetic torque and rotor eddy current losses in 12-slot/10-pole IPM machines under the maximum of torque/current control. It can be seen the torque of the IPM machine with I type, V type and spoke rotor type are 8.61 Nm, 8.75 Nm and 9.44 Nm, respectively. The IPM machine with spoke rotor type has the highest torque due to its parallel connection magnetic circuit type and small magnetic resistance per pole. The rotor eddy current losses of I type, V type and spoke rotor type IPM machines are 12 W, 7.6 W and 8.6 W respectively. The rotor eddy current losses in the 12-slot/10-pole IPM machines are mainly caused by the 1st and 7th order harmonics of MMF. The pole-shoes in I type IPM machine is very small, the armature field by 1st and 7th order MMF harmonics can easily penetrate each magnet and produced the higher eddy current losses. The V type and spoke type IPM machines have larger pole-shoes, the armature field by 7th order MMF harmonics partly penetrate pole-shoes only and don't produced PM eddy current losses, so, the rotor eddy current losses in V type and spoke type IPM machines are less than I type machine. According to the Table II, the 7th order harmonics of MMF is a dominant component, the each pole armature field of which will penetrate 2 piece magnets in V type IPM machine and the 1 piece in spoke type IPM machine, therefore the armature field by 7th order harmonics of MMF in V type IPM machine is less than that in spoke type machine. Due to the 7th order harmonics of MMF be dominant component, the rotor eddy current losses in V type IPM machine is less than that in spoke type IPM machine in spite of the 1st MMF harmonic be significant reduced by its specific rotor topology. Fig. 4 shows the FEA results of the electromagnetic torque and rotor eddy current losses in 9-slot/10-pole IPM machines under the maximum of torque/current control. It can be seen the torque of the IPM machine with I type, V type and spoke rotor type are 8.81 Nm, 9.03 Nm and 9.74 Nm, respectively. The reason of the highest torque in IPM machine with spoke rotor type is analyzed above. The rotor eddy current losses of I type, V type and spoke rotor type IPM machines are 35.2 W, 25.2 W and 37 W respectively. According to the Table III, the 4th order harmonics of MMF is a dominant component, and which will produce the longer wave-length armature field of each pole. The each pole armature field by 4th order harmonics of MMF can penetrate 2 piece magnets in I type IPM machine, 2 to 4 piece magnets in V type IPM and 1 to 2 piece magnet in spoke type IPM machine, therefore the armature field by 4th order MMF harmonic is least in V type IPM machine and is largest in spoke type machine. As a result, the eddy current loss in V type IPM machine is least. Compared to I type IPM machine, the spoke type IPM machine has the highest eddy current losses due to its largest dominant armature field, although which has less 1st order harmonic armature field and other higher armature fields are mainly penetrate pole-shoes only. IV. Conclusion This paper is detailed analysis the armature field by MMF and eddy current losses in FSCW IPM machines with different rotor topology. Under the same electric loading, the FEA results reveal that the V type IPM machine has the least eddy current losses both in 12-slot/10-pole and 9-slot/10-pole combination machines. The spoke type IPM machine has less eddy current loss than I type IPM machine in 12-slot/10-pole combination and has larger eddy current loss than I type IPM machine in 9-slot/10-slot combination.

AT-08. Design and Analysis of A Mechanical Flux-varying PM Machine with Auto-rotary PMs.

X. Liu[1], Z. Zhang[1], H. Xu[1], J. Xiao[1] and Z. Liu[1]
1. School of Electrical Engineering and Automation, Jiangxi University of Science and Technology, Ganzhou, China

I. Introduction Due to the constant magnetic field of the permanent magnet(PM) machine, its terminal voltage cannot be maintained constant as a generator[1], and the constant power area is narrow and the adjustable speed range is also limit as a motor[2]. In order to overcome these shortcomings, a new type of mechanical flux-varying PM machine with auto-rotary PMs (MFVPMM) is proposed in this paper. The operation principles of this machine presented are analyzed, and its flux weakening ability is studied by FEA. II. Text A. Machine topology Fig.1 shows the topology structure of MFVPMM which includes stator winding, stator core, PM, rotor core. The armature winding adopts single layer distributed short pitch winding. The material of PM adopts N36Z_20, which magnetic induction coercive force is -920000 A/m. The material of rotor core and stator core adopts M19_29G. There is a slot on the cylindrical PM, which can connect with mechanical flux-adjusting device. Fig.2 shows the mechanical device, which clearly shows its parts and their mechanical relations. Disc have sliding chutes and connecting rod slots, which can make sliding block rectilinear moving and gear auto-rotating respectively. The sliding block connects with the disc by the spring. The surface of disc and sliding block is set to the ideal state, which means ignoring the friction between them. The sliding block is the driven source of mechanical flux-adjusting device and makes full use of centrifugal force to drive the gear. There exists some distance between initial sliding block and gear, which ensures no flux weaken under basic speed. *B. Operation principle* Fig.3 shows the operation principle of ARPMMFVPMM, the PM flux linkage of machine, Ψ_f, is supplied by the PMs in one pole, which is the result of vector synthesis. When the PMs rotates an angle, such as 30°, the composite PM flux linkage is √3/2 than basic, which achieves the effect of *d*-axis demagnetization. Fig.4 shows the principle of mechanical flux weakening. When the machine operates under basic speed, the magnetizing direction of PMs is radial. The PMs will rotates with an angle automatically when the motor operates above basic speed, and its magnetizing direction is varied. As a result, the air-gap flux density can be changed correspondingly. C. FEA model And Results Fig. 5 (a) shows the FEA structure, the structure of machine is axisymmetric and centrosymmetric, and its pole is 8. Fig.5 (b) gives its FEA mesh model with 141127 nodes and 101494 elements. Fig.6 shows the flux density distribution in the MFVPMM. By comparing the same color map and color of flux density contour, the flux is weakened evidently by the proposed mechanical device. Fig.7 and Fig.8 shows the flux linkage and the induced EMF when the machine operates at different speed(the basic speed is 750rpm), which shows that the flux and EMF of MFVPMM can be reduced with the proposed Mechanical device. The analysis results shows that an excellent field control ability has obtained for the proposed MFVPMM with the simple structure. III. Conclusions A new type of auto-rotary PMs mechanical flux-varying PM machine is proposed in this paper. The magnetic flux distribution, winding flux linkage and EMF, flux weakening ability are analyzed by 2D FEM. The results show that a good field control ability without any additional loss is obtained for the ARPMMFVPMM. Therefore, the ARPMMFVPMM can be widely applied in the fields of constant power driven and constant voltage generation.

AT-09. Development of Variable Stress Applying System for Shrink Fitting of Stator Housing in IPM Motor.

J. Kitao[1], J. Aizawa[1], M. Nakano[1], M. Yamada[1] and A. Daikoku[1]
1. Mitsubishi Electric Corp., Hyogo, Japan

High efficiency electrical machines such as rotating machines and transformers are expected to be realized for solving the environmental problem. It is well known that the iron loss of stator core for rotating machines increases by a mechanical stress caused by the shrink fitting of the stator housing. In order to clarify the influence of the mechanical stress to the characteristics of rotating machines, several papers [1]–[6] describe the simulation technic such as the combined analysis of a mecahnical stress and an electromagnetic field. In this paper, we develops the variable applying stress system with the hydraulic unit to clarify the influence of the shrink fitting to the motor characteristics. Fig. 1 shows the schematic of the variable applying stress system. We designed these system following three requirement. (a) The circumferential compressive stress of the stator core caused by these system is more than 100 MPa. (b) These system can adjusts the circumferential compressive stress of the stator core at an interval of 1 MPa. (c) These system uniformly applies the circumferential compressive stress of the stator core in the axial and circumferential direction. In order to realize the concept of these three points, these system is adopted the hydraulic mechanism. When the hydraulic unit applies the oil pressure to the oil room, the pressure bulk head is deformed by the oil pressure and consequently the circumferential compressive stress is generated in the stator core. These system can adjusts the circumferential compressive stress of the stator core by the oil pressure of the hydraulic unit. The circumferential compressive stress, which is measured by eight biaxial strain gages installed on the surface of the back-iron for the stator core, is changed linearly with respect to the applied oil pressure by the hydraulic unit, and the maximum circumferential compressive stress is generated more than 100 MPa under the oil pressure 15 MPa. Fig. 2 shows the measurement results of the iron loss in no-load with respect to the applied oil pressure by the hydraulic unit. The load motor rotates the test motor, which is adopted the interior permanent magnet motor with concentrated winding, at a constant rotating speed. Then, the loss of the test motor with the unmagnetized and magnetized permanent magnet rotor in no-load is measured by the torque detector. The iron loss of the test motor is calculated by a difference between the loss of the test motor with the magnetized permanent magnet rotor ant it with the unmagnetized permanent magnet rotor, which is included only the mechanical loss without the iron loss. As the applied oil pressure increases, the iron loss is gradually increased and the iron loss under the circumferential compressive stress of 100 MPa (applied oil pressure 15 MPa) in the stator core is increased by 2 times compared with the non-stress. As explained above, the proposed system can measures the iron loss of the actual motor under mechanical stress with various operating point. The more measurement results will be included in the full paper. ACKNOWLEDGMENTS This paper is based on results obtained from the Future Pioneering Program "Development of magnetic material technology for high-efficiency motors" commissioned by the New Energy and Industrial Technology Development Organization (NEDO).

AT-10. Study on structure aimed at low vibration of 16-pole 18-slot IPM motor for Mild-HEV.

Y. Hirai[1]
1. Motor Drive Laboratory, Tokyo City University, Tokyo, Japan

I. INTRODUCTION The efficient construction method of mild hybrid is to minimize the mechanical loss by directly connecting the engine and the assist motor. The shape of the motor to be directly connected to the engine output shaft has a flat structure with a diameter of 250 to 300 mm and an axial length of 60 to 90 mm, and various multipolar PM motors have been proposed in order to obtain high output and high power generation. As a slot pole combination, it is known that a combination of 8-9 is good, but it was said to be impractical due to the problem of magnetic imbalance due to eccentricity. For large diameter motors, it is possible to combine 16-18 times, which is considered an effective combination. In this paper, we propose an IPM motor with 16 - 18 - combination for mild hybrid considering performance and low vibration during startup and power generation. The usefulness of 16 poles and 18 slots combination and the cogging torque torque ripple reduction structure were clarified by finite element analysis. II. SLOT COMBINATION STUDY OF MOTOR The principle of the cogging torque generation, the slot combination is a significant impact. Therefore it is possible to reduce by changing the combination of the number of poles and the number of slots. Therefore, we focused on the 8-pole 9 slot. This combination is the exciting side is a magnetic unbalance the pole. Therefore vibration during rotation is increased when the shaft is displaced. However, by the doubling of the ratio of the pole and the slot (16-pole 18-slot), it is possible to reduce the influence of these problems. In addition, it is possible to further reduce the cogging torque and torque ripple. Using SPMSM model were cogging torque analysis of 4 patterns of "16-pole 18-slot" and "8-pole 12-slot", "12-pole 18-slot", "20-pole 24-slot". The results are shown in Fig. 1 (a). Fig. 1 (a), 16 poles 18 slots, it is possible to most cogging torque is reduced has been confirmed. Thus, creating the IPM motor model at 16 poles and 18 slots. Fig. 1 (b) shows the created IPMSM model. In addition, it indicates the motor specifications in Table I. III. IMPROVEMENT OF THE COGGING TORQUE AND TORQUE RIPPLE As a method of optimizing the torque waveform, a method of providing a cutout or the like in the rotor / stator opposing part is known, but this method generates an order component due to the notch shape in addition to the basic order, This may cause noise and vibration. In this magnetic circuit, the gaps between the rotor-stator as shown in Fig. 2 (a), employing a rotor shape gradually expanding toward the switching portion of the stator core. Thus, to mitigate the steep magnetic flux change in the air gap and reduce the cogging torque and torque ripple without placing a new order components. Fig. 2 (b) shows the model after applying the shape. Fig. 2 (c), (d) shows the cogging torque before and after application of the shape and the torque ripple improvement effect at 200 Arms energization, Table II shows the average torque and torque ripple rate values. By changing the curvature, the cogging torque 1/7 times reduced, the average torque 5Nm improved, torque ripple it was confirmed that the reduced about 6%. IV. CONCLUSION Characteristics of 16 pole 18 slot IPM motor directly connected to the engine output shaft were analyzed and compared with other multipolar motors. It was confirmed that the reduction of cogging torque and torque ripple without increasing order components by changing the curvature of the stator and the rotor. The proposed motor is currently prototyping and the results will be presented on the conference.

AT-11. Torque Improvement in Partitioned Stator Wound Field Switched Flux Machine By Using Assisted Ferrites.

Z. Wu[1] and Z. Zhu[1]
1. Electronic and Electrical Engineering, The University of Sheffield, Sheffield, United Kingdom

Wound field (WF) synchronous machines without rare-earth permanent magnet (PM) have been attractive recently due to lower cost than PM machines [1]. The wound-rotor synchronous machines suffer from brushes and slip rings which are essential for DC field excitation [2]. However, they can be eliminated in the wound-stator synchronous machines in which both DC winding and AC windings are placed in the stator, e.g. the WF switched flux (WFSF) machine [3], [4]. Due to the magnetic gearing effect in the stator-excitation machines [5], [6], the partitioned stator WFSF (PS-WFSF) machine having separated DC and AC windings in two stators and hence a higher total slot area and >19% larger torque is proposed and analyzed in [7], e.g. the 12/10-stator/rotor-pole PS-WFSF machine shown in Fig. 1(a). In this paper, to further improve the torque density of the 12/10-stator/rotor-pole PS-WFSF machine shown in Fig. 1(a), short-circuited ferrites are introduced to reduce the inner stator tooth saturation and improve the air-gap field density. The developed 12/10-stator/rotor-pole PS-WFSF machine with assisted ferrites can be obtained as shown in Fig. 1(b). They have similar machine topologies, i.e. two stators wound by AC windings and DC winding, respectively, and a sandwiched rotor consists of several modulation iron pieces. The only difference is that the short-circuited ferrites are introduced in the proposed topology. As shown in Fig. 1(c), flux density B_1 can be produced in both the inner stator tooth and the inner air-gap due to the WF magnetomotive force (MMF). However, an opposite flux density B_2 can be generated in the short-circuited magnetic circuit for the ferrite MMF, as shown in Fig. 1(d), whilst the corresponding inner air-gap flux density is B_3. Due to the opposite directions of B_1 and B_2, as shown in Fig. 1(e), the inner stator saturation and hence the iron loss will be decreased with a reduced flux density B_1'-B_2', where $B_1' > B_1$ and $B_2' > B_1$. Moreover, as shown in Fig. 1(e), the inner air-gap flux density can be improved from B_1 in the machine without ferrite to $B_1' + B_3'$ in the machine with ferrite, where $B_3' < B_3$. Therefore, both the open-circuit phase flux-linkage and the average electromagnetic torque can be improved in the proposed PS-WFSF machine with assisted ferrites. This can be evidenced by the 2D FE predicted results shown in Fig. 1(f) and Fig. 1(g). As shown in Fig. 1(f), the fundamental phase flux-linkage when the AC coil number of turn is N_{ac}=1 can be improved by 2.33%, from 0.272mWb to 0.278mWb. However, since the on-load inner stator tooth saturation in the PS-WFSF machine without ferrite is stronger than the open-circuit one due to armature reaction, the average electromagnetic torque can be more effectively improved by 3.76%, from 1.47Nm to 1.53Nm, when both the DC winding copper loss p_{cuf} and the AC windings copper loss p_{cua} are 30W and the machines operate at BLAC mode under zero d-axis current control, i.e. i_d=0, due to negligible reluctance torque [7]. Moreover, as shown Fig. 1(h), a higher total copper loss and hence a stronger saturation in the machine without ferrite will result in more effective torque improvement in the its counterpart with ferrites. Both the proposed 12/10-pole PS-WFSF machine with assisted ferrites and its counterpart without ferrite are built and tested to validate the FE predicted results. The machine components are shown from Fig. 2(a) to Fig. 2(d), i.e. Fig. 2(a) for the shared outer stator, Fig. 2(b) for the shared cup rotor, Fig. 2(c) for the inner stator with ferrites and Fig. 2(d) for the inner stator without ferrite. The comparison between the measured and 2D FE predicted phase-back-EMFs is given in Fig. 2(e) and Fig. 2(f), respectively. It can be observed that the 2D FE predicted results agree well with the measured results in both machines. The comprehensive comparison including loss and efficiency between the proposed topology with ferrites and its counterpart without ferrite will be given in the full paper, together with the investigation of the average torque separation by DC winding and ferrites by using frozen permeability.

I. INTRODUCTION Wound field synchronous machines (WFSMs) utilize rotor windings to generate flux without magnet. However, the current in field winding causes much copper loss, thereby the efficiency is decreased and temperature rise is increased. With the development of the permanent magnets (PMs), the permanent magnet synchronous machines (PMSMs) have been widely used in many industry applications instead of the WRSMs. But its development is restricted by the high cost of PMs and the limited supply of the rare earth magnets [1]. And another problem is that once the magnet is magnetized, it is difficult to achieve flux weakening control [2]. Furthermore, the danger of the demagnetization should be considered when PMSMs design. To overcome these problems, many kinds of hybrid excited machines have been developed. Inserting PMs into rotor's slot opening, there are two kinds of assist effects: one is the reduction of the magnetic saturation, and the other is the direct flux linkage increase of the armature windings from the permanent magnets. And the total assisted effects are ensured for wide load condition [3]. The demagnetization analysis of the assisted-PM is evaluated due to sudden three-phase short circuits in [4]. Meanwhile, it can be benefit for the motor's reluctance torque and affect the operation range. In paper [5], the optimized single flux barrier is introduced in the WRSMs. It is an effective and simple method to improve the motor's reluctance torque and widen the operating region. In this paper, PM was introduced in a WRSM with a single flux barrier configuration for high quality wide load condition and wide operating range, then the rotor shape of PM-Assisted Wound Field Synchronous Machine (PMa-WFSM-B) was optimized for improving torque characteristic and decreasing torque ripple under constant permanent magnet (PM) volume and motor size. The optimization method mainly includes Kriging method and genetic algorithm (GA). Then, JMAG-Designer is used as the tool of 2-D finite-element analysis to confirm the validity. II. MODELING, OPTIMIZATION AND DISCUSSION Fig.1 shows the rotor topologies of the investigated models, which stator has six slots with three-phase concentrated windings. The normal single flux barrier in the basic model was chosen to stop the magnetic field line in q-axis and increase the reluctance torque. NdFeB is assisted in the slot opening as the proposed model to decrease pole magnetic saturation and increase the direct flux linkage of the armature winding. And it is considered that the torque performance can be improved by optimizing the rotor shape. There are five design variables selected as shown in Fig.2: *h* is the width of the assisted-PM, whereas the length of the assisted-PM *w* is automatically changed in order to keep the volume of assisted-PM as a constant, *m* and *l* are the main parameters to define the rotor slot area and the magnetic flux path of the Assisted-PM. *d* is the width of single flux barrier that can keep the new motor with a wider operating range. *x* is the offset distance between the rotor pole center and flux barrier center which can adjust the magnetic unbalance of the two pieces in each rotor pole. Because the assisted-PM changes the across-sectional area of the FWs, in order to maintain the slot filling ratio, the number of turns is proportionately changed. The stator is fixed during the whole optimal process of the motor. To further improve the torque performance, the optimization using the Kriging Method and Genetic Algorithm (GA), is then applied to the proposed model. Fig.3 (a), (b), (c) give the torque performances of three investigated machines, in which the point value is the torque values of each components when the total torque gets the maximum. The main specifications and FEM analysis results of the three investigated models are listed in the Table I. It is clarified that the torque is improved by 37.6% and the torque ripple is decreased by 18.8% without decrease efficiency, increase PM volume and motor size, compared with that the conventional machine. More detailed results and analysis will be presented in the full paper.

AT-13. Torque Ripple Improvement for Ferrite-Assisted Synchronous Reluctance Motor by Using Asymmetric Flux-barrier Arrangement.

M. Xu[1], G. Liu[1] and W. Zhao[1]
1. Jinagsu university, Zhenjiang, China

Introduction Ferrite-assisted synchronous reluctance motors (FASRM) provide high torque density and a wide range operation speeds for many applications, ranging from electric vehicle and electric home appliance [1]. Moreover, the ferrite magnet has received increased attention, following the increase of the price of rare earth magnet. However, the main drawback of the FASRM is the high torque ripple which will lead to serious vibration and acoustic noises [2]. Therefore, it is greatly significant to research the torque ripple suppression strategy for FASRMs, thus improving the smoothness of the torque [3]. This paper introduces a low torque ripple FASRM with asymmetrical flux barrier, which can reduce the torque ripple effectively. Novel Topology Fig. 1 shows the structure of the proposed FASRM. This motor has 48 slots and 8 poles, with two flux barriers per poles. The detailed configuration of the asymmetrical flux barrier is shown in Fig. 2. There are two kinds of flux barriers with different opening angle, and the changing of the angle based on the original flux barriers B_1. The opening angle of flux barriers B_2 is enlarged θ based on original flux barriers B_1. In this way, a shift of the torque waveform phase can be achieved, and the torque amplitudes offset each other. In addition, the amount and location of ferrite magnets have not changed, and reduce the torque ripple effectively without sacrificing the average torque. Results The proposed method is evaluated by a theoretical analysis and finite-element method (FEM). Fig. 3 shows the no-load field distribution and on-load flux density of the proposed FASRM. It can be seen that the magnetic fields are symmetrical distributions, and the asymmetrical flux barriers will not affect the electromagnetic performance of the proposed FASRM. Fig. 4 shows the reluctance torque waveforms and harmonics. As adopted the asymmetric flux barrier arrangement, a shift of the torque waveform phase can be achieved, and the torque amplitudes offset each other. It can be seen that the reluctance torque ripple is reduced from 85% to 24%, approximately. Fig. 5 shows total torques waveform and their harmonics. It can be seen that the total torque ripple is reduced to 14%, and the 6th and 12th harmonics have been successfully eliminated.

AT-14. Influence of Magnetic Saturation and Rotor Eccentricity on Back-EMF of Novel Hybrid-excited Stator Slot Opening Permanent Magnet Machine.

M. Zheng[1], *Z. Zhu*[1], S. Cai[1], H. Li[1] and Y. Liu[1]
1. Department of Electronic and Electrical Engineering, University of Sheffield, Sheffield, United Kingdom

Abstract—This paper introduces a novel hybrid-excited stator slot opening permanent magnet (PM) machine (HSSPMM). The operation principle of the machine is investigated and the effects of magnetic saturation due to PMs and rotor eccentricity are analyzed by finite element method (FEM). It shows that different from the conventional PM machines, the open-circuit back-EMF in this novel HSSPMM should be zero but may become non-zero if significant magnetic saturation exists, and further, the rotor eccentricity has a detrimental effect on the waveforms, amplitudes and symmetries of 3-phases back-EMFs, as confirmed by FEA and tests. I. Introduction The idea of locating PMs in the stator slot opening area comes from [1, 2] which places PMs between adjacent stator teeth on switched reluctance machine to enhance the torque. The conventional hybrid-excited stator slot opening PM machine (HSSPMM) can be modified by adding PMs between adjacent stator teeth in variable flux reluctance machine (VFRM) [3]. The PMs are used to reduce the magnetic saturation produced by current excitation and enhance the torque density. Moreover, the HSSPMM maintains good flux regulation capability as the VFRM due to DC excitation. In this paper, a novel HSSPMM is developed by placing PMs in the slot opening area of the stator slots for field windings of a DC-excited switched flux machine (DC-SFM) [4]. The novel HSSPMM has a coil span of one slot pitch for field windings (F1) while a coil spans over three slot pitches for the armature windings (A3), as shown in Fig. 1(a). The stator DC-SFM can be easily magnetically saturated due to both armature and DC excitations. However, the magnetic saturation can be reduced since the PM flux direction is opposite to that produced by current excitation, and meanwhile, the torque of the HSSPMM can be increased. The operation principle of the F1A3 HSSPMM is similar to that of the conventional HSSPMM. When the machine has no current excitation, the PM flux will be shunted in the stator, and the PM flux can be pushed to the rotor via air-gap by the flux produced by current excitation. The PM volume, stator outer radius, stack length, air-gap length, and copper loss of the F1A3 HSSPMM are fixed during optimization and same as the conventional HSSPMM. The F1A3 HSSPMM is also prototyped, as shown in Fig. 1(b), and is tested with focus on the open-circuit back-EMFs to validate the finite element analysis (FEA) predictions. II. Open-circuit Magnetic Saturation and Rotor Eccentricity analysis Based on the machine operation principle, the F1A3 HSSPMM should have negligible open-circuit back-EMF since the PM flux is shunted in the stator. However, the machine with the stator and rotor material of laminated steel (non-linear material) is found to have a large amplitude of the back-EMF waveforms, while the back-EMF is negligible for that of linear material as shown in Fig. 2. The large PM flux leakage caused by stator magnetic saturation results in the significant back-EMF, which is validated by the measured results. Moreover, the waveforms and amplitudes of 3-phase back-EMFs are different, and further, those of each coils in the same phase are different as well. In addition, the back-EMF waveforms are asymmetric, indicating the prototype machine might have the issue of rotor eccentricity. Based on the measured results, 2D FEA is applied to determine the rough position of the rotor, and the FEA predicted and measured back-EMF waveforms are shown in Fig. 2. The amplitudes of measured back-EMFs for coils B1 and C1 are almost twice larger than those of B2 and C2, respectively, as shown in Fig. 2(c) and Fig. 2(d). Thus, the rotor of the prototype machine exhibits static eccentric towards the center of B1 and C1 of almost 50%. Since the measured back-EMF of coil A1 is slightly larger than that of coil A2, as shown in Fig. 2(b), the rotor eccentricity is found to be further 6% towards coil A1 which is selected according to the amplitude difference. The predicted and measured waveforms are of a good agreement but not perfectly the same since the exact eccentric position of the rotor is not sure and even 3D rotor eccentricity may exist which is quite different from the previous 2D FEA predicted rotor eccentricity. Moreover, the rotor shaft may also be slightly dynamically eccentric. III. Conclusion In this paper, a novel HSSPMM is proposed and the operation principle of the machine is introduced. It is found that the open-circuit back-EMFs of the machine are large, indicating the stator is severely magnetically saturated and large PM leakage flux exists. The prototype machine test results verified the existence of stator magnetic saturation. The predicted and measured open-circuit back-EMF waveforms show the prototype machine has rotor eccentricity and the eccentric rotor position is determined according to the measured amplitudes of coil EMFs. Good agreements exist between the 2D-FE predicted and measured results of open-circuit back-EMFs.

AT-15. Design and Analysis of Variable Flux Memory Motor with Series-Parallel Structure Considering Permanent Magnet Load-Line.

J. Song[1], Y. Kim[2] and S. Jung[1]

1. Department of Electronic, Electrical and Computer Engineering, Sungkyunkwan University, Suwon-si, The Republic of Korea; 2. Department of Electrical Engineering, Chosun University, Gwangju, The Republic of Korea

1. Introduction In order to achieve high efficiency over wide-speed operation, variable flux memory motor (VFMM) has been proposed. This new class of motor can control the magnetization state by applying direct-axis (d-axis) current pulses [1]. When designing VFMM, it is important to study nonlinear magnetization characteristics considering the electrical constraints, since the PM magnetization strength must be controlled only with limited current fed by inverter [2], [3]. Especially, in the process of re-magnetization, the magnetic circuit becomes highly saturated, so that large current is requisite. Meanwhile, the PM magnetization characteristics of VFMM are highly correlated with how PMs are arranged in the rotor. Therefore, it is important for designers to select proper structure topologies at initial design stage, in order to design a VFMM with outstanding magnetization performance while satisfying the current limit conditions of the inverter. According to conventional studies, VFMMs can be classified into series and parallel magnetic circuits according to how the PMs within rotor are arranged [4]. It is known that series type VFMM is superior to parallel type in terms of magnetization performance [5]. However, re-magnetizing current larger than demagnetizing current is still considered to be a drawback of series type VFMM with ferrite PM only. In this paper, we propose a VFMM with novel series-parallel structure, of which magnetization characteristic is superior to both series and parallel type VFMMs. We investigated PM load-lines via finite element analysis (FEA) to identify the magnetization characteristics for three types of VFMMs, which are series type, parallel type, and proposed model, respectively. We confirmed that the proposed model is suitable for VFMM by analyzing and comparing shapes and behaviors of the PM load-lines under no-load and loaded conditions. 2. Magnetic characteristics of the proposed model Prior to deriving PM load-line, we investigated the PM operating point under no-load condition. Generally, it is known that the PM operating point of general PM motor is positioned on the second quadrant of B-H characteristic curve under no-load state, which is because the PM motor has air-gap on the magnetic circuit. However, due to structural characteristics of the proposed model, in which the magnetic field generated by PMs arranged in parallel is applied to PMs arranged in series in forward direction, the no-load operating points of the PMs arranged in series are on the first quadrant. On the other hand, the operating points of the parallel PMs in the proposed model are on the second quadrant as of general PM motor. Accordingly, the external magnetic field for re-magnetizing the series PMs is less than the parallel PMs. In consideration of these magnetic characteristics of each PM, we employed two types of PMs for the proposed VFMM, which are low-coercivity (variable magnetized PM) and high-coercivity PMs (constant magnetized PM). The series PMs are low-coercivity and parallel PMs are high-coercivity materials, respectively. 3. Analysis of magnetization characteristics based on PM load-line For the comparison of series type, parallel type, and the proposed model, we derived the PM load-lines which are essential factors to examine magnetization characteristics of VFMMs. Theoretically, the PM operating point is the intersection point of PM load-line and B-H characteristic curve of the PM. Hence, the PM load-line can be inversely derived by connecting the calculated PM operating points in accordance with different values of remanence flux density, which have regular interval [5]. To consider magnetic saturation, the PM load-line is derived via nonlinear FEA in this study. Fig. 1 shows the PM load-lines under no-load condition, where the curved lines with triangular, circular, and rectangular symbols are the PM load-lines of series, parallel type, and the proposed VFMM, respectively. It can be observed that the PM operating points of the series and parallel type VFMMs (A and B in Fig. 1) are located on the second quadrant. On the contrary, the PM operating point of the series PM in the proposed model (C in Fig. 1) is on the first quadrant, as mentioned above. In the process of re-magnetization, the main magnetic circuit of VFMM is highly saturated, while it is relatively free of saturation in demagnetization process. For this reason, it is necessary to identify magnetization characteristics, so that it has been studied with the shifted PM load-lines owing to positive d-axis current input (Ni_d=4kAT) as shown in Fig. 2. Here, N denotes the number of armature turns and i_d denotes d-axis input current. It should be noted that the shifted operating point of the proposed model (C' in Fig. 2) is positioned above the point M in Fig. 2, which means the variable magnetized PM becomes fully re-magnetized. However, the PMs of series and parallel type VFMMs are not fully magnetized yet, under identical d-axis current condition (Ni_d=4kAT), because the shifted PM operating points (A' and B' in Fig. 2) are under the point M. The supplementary computation results, which are not represented in Fig. 2, indicate that 15kAT and 50kAT of Ni_d are requisite to fully magnetize the PMs of series and parallel type VFMMs, respectively, which are 3.75 and 12.5 times larger Ni_d compared to that of proposed model.

I. Motor Specification and Initial Design The 80kW traction motor which is designed in this thesis is an interior permanent magnet synchronous motor. Table 1 indicates the design specification of the 80kW traction motor. In order to increase the saliency ratio, distributed winding was decided and in order to increase the winding factor, full pitch was decided. The driving method is sinusoidal wave driving with space vector(SV) PWM applied. The TRV and SR have to be decided first for the initial design [1,2]. In this paper, the traction motor which is applied to Nissan LEAF which has the same output power was referenced. Figure 1 demonstrates the magnetic reluctance curve following the stator tooth width. In the magnetic reluctance curve, the minimum point is small so the stator tooth width was determined. When the magnetic reluctance is the minimum, the no-load back EMF and torque density become the maximum. In traction motor for EV, improving the torque density is one of the important objectives. If the torque density of the motor is improved, the motor volume and the weight can be reduced [3]. If the motor weight is reduced, it can enhance the fuel efficiency of the electric vehicle. Therefore, in this paper, the shape of the rotor was changed just like Figure 2 with regards to the initial model. Figure 2 (a) is the initial model. It is a shape of which the motor dimension calculated previously has been applied. If the cross section area of the permanent magnet is increased, the air-gap flux density is increased and finally, torque density improves. In the case of (b) model, the cross section area of the permanent magnet is enhanced, increasing the torque density. In the traction motor for EV, the input current is big so the reluctance torque can be increased by enhancing the saliency ratio. If the reluctance torque is enhanced, the torque density is improved. If the thickness of the permanent magnet is increased, the saliency ratio is increased. However, the amount of usage of permanent magnet also increases simultaneously. In order to increase the saliency ratio without increasing the usage amount of the permanent magnet, the permanent magnet was allocated with 2-layer just like Figure 2 (c). Figure 2 (c) is a structure with a bridge added in order to disperse the stress in the magnetic rib. The bridge was inserted between the permanent magnet of the lower part and a flux barrier was inserted between the magnetic ribs to add the bridge. Figure 2 (c) is a structure that has 3 more bridges when compared to (a) and (b) model and by doing so, (c) model can disperse the stress of rotor core when compared to (a) and (b) model. Figure 3 demonstrates the 2D-FEA stress analysis with regards to the 3 types of model in Figure 2. It can be seen that the stress of magnetic rib in (a), (b) model has exceed the yield strength(410MPa). However, in (c) model, the yield strength is not exceeded. *II. Optimum Design and Characteristic Analysis* In order to reduce the input current and torque ripple and the induced voltage in the high speed operation, optimum design was conducted. As it can be seen in Figure 4, the objective functions are input current, torque ripple and induced voltage. Figure 5 demonstrates the optimum model. With regards to optimum model, motor parameter such as d, q-axis inductance and no-load phase back EMF, core loss resistance and others are calculated and by applying equivalent circuit of IPMSM, the characteristic analysis was conducted. Figure 6 (a) demonstrates the torque curve, line to line voltage curve and others in maximum power condition. If the no-load phase back IMF is not selected appropriately and in case it is designed bigger in the initial design, the field weakening current increase in high speed area and the copper loss increases. Figure 6 (b) demonstrates the efficiency map. *III. Experimental Verification* The Load test was conducted with regards to the motor that was fabricated. Through the load test of the fabricated motor, the current and the inductance per current angle were measured and the characteristics of efficiency, input current line to line voltage and others were measured following the torque and speed. Figure 7 demonstrates the experiment composition for the load test. The d, q-axis inductance was measured following the current and the current angle. Through no-load test, the winding resistance and no-load back EMF were measured and through the load test, the input current, line to line voltage and power factor were measured. The measured value was applied to the vector diagram to calculate d, q-axis inductance. Such method used to calculate the inductance ignores the core loss which could lead to deviation. Figure 8 compares the test result and the analysis result with regards to d, q-axis inductance. Figure 9 demonstrates the test result and the analysis result of the efficiency. As it can be seen in the figure, the efficiency map exhibits similar patterns from each other. In the base rpm, Maximum torque sector, the test result and the analysis result with regards to efficiency have deviation of approximately 2%. Figure 10 demonstrates by comparing the test result and analysis result of line to line voltage. The measured line to line voltage is the effective value of fundamental components. It can be seen that the deviation of test result and analysis result of line to line voltage is not big.

AU-01. Design of slit-like flux barriers to improve space harmonic distribution in a slit stator motor.

Y. Yokoi[1], R. Hashizume[1] and T. Higuchi[1]
1. Nagasaki University, Nagasaki, Japan

1. Introduction Space harmonic distribution of magnetic flux density across the air gap governs torque and iron loss in electrical machines. Fractional-slot concentrated winding (FSCW) configurations generate several dominant space harmonics. One of them produces the drive torque. The others increase undesirable effects such as iron loss in cores and eddy-current loss in magnets and do not contribute to the torque production. In the design of FSCW machines, the space harmonic distribution is improved with many design methods [1-4]. A slit stator motor (SSM) has been proposed to improve the space harmonic distribution for 12-slot 10-pole motors [5]. In general, the fundamental, 5th, and 7th space harmonics generate as dominant space harmonics in conventional 12-slot 10-pole motors. The 5th space harmonic produce the drive torque. The other space harmonics increase losses. For this reason, the space harmonic distribution can be improved by increasing the 5th space harmonic and decreasing the fundamental and 7th space harmonics. In the SSM, the stator has slit-like flux barriers that are located at the center of alternate teeth to separate the stator core. The stator winding coils are wound around the slit teeth to arrange single-layer windings. This stator design, which is called slit stator, improve the space harmonic distribution. Hence, the slit stator increases the 5th space harmonic and decreases the fundamental and 7th space harmonics. As the result, the SSM achieves more torque production and high efficiency than a conventional stator motor (CSM). In the SSM, the width of the slit-like flux barriers determines the space harmonic distribution and the motor performance. The effect of slits to barrier magnetic flux across the slits is enhanced with the increase of the slit width. However, the stator teeth width and/or the slot area decreases as the slit width increases. In addition, the flux density drops at the air gap faced by the slits. This influences the space harmonic distribution. Therefore, the design of SSMs requires the dependence of the space harmonic distribution on the slit width. In this digest, the slit-like flux barriers are designed to improve the space harmonic distribution of the air-gap flux density in the SSM. The influence of the slit width on the space harmonic distribution is investigated through a finite element method (FEM) analysis. The improved space harmonic distribution is verified experimentally. 2. Structure and Performance This section briefly describes the structure and the performance of a SSM. Fig. 1 shows the cross section of the SSM. The motor configures a 12-slot 10-pole permanent magnet motor with single-layer windings. Slit-like flux barriers are located at the center of the wound teeth in the stator. The dimensions of the SSM and a CSM are presented in Table 1. The width of teeth with slits is greater than that of teeth without slits by the slit width. All the teeth have the identical width of iron core not to enhance magnetic saturation at the slit teeth. The width of the yoke in the SSM can be less than that in the CSM. In the SSM, the width of the yoke is set at half of the teeth width because the magnetic flux across the slits should be suppressed. Table 2 presents the performance of the SSM and the CSM. The SSM requires smaller current than the CSM to produce the identical torque. The losses in cores and magnets are decreased by the slit arrangement. The enhanced performance is due to the space harmonic distribution improved in the SSM. 3. Numerical and Experimental Space Harmonic Distribution The slit width is determined to improve the space harmonic distribution of the air-gap flux density in the SSM. The influence of the slit width on the dominant space harmonics is investigated at a fed current of 10 A through an FEM analysis, as shown in Fig. 2. The 5th space harmonic is maximized at a slit width of 2.3 mm. The fundamental and 7th harmonics are decreased with the increase of the slit width. These results clarify that the slit arrangement can increase the 5th space harmonic and decrease the fundamental and 7th space harmonics. For the slit width that is greater than 2.3 mm, the 5th space harmonic decreases gradually in comparison with the other harmonics. For this reason, the slit width can be greater than 2.3 mm to improve the space harmonic distribution. However, the slit width is restricted because an increase of the slit width decreases the area of slots. Here, it is noted that the yoke width of the slit stator can be decreased from that of the conventional stator. The decreased yoke width contributes to the increase of the slot area. In SSM, the slit width is determined at 2.5 mm not to decrease the slot area from that in the CSM. The improved air-gap flux density distribution is verified through the FEM analysis and an experiment performed with a prototype. In the prototype, the gap corresponding to each slit is maintained at 2.5 mm by inserting a nonmagnetic material plate. Both ends of each slit have a gap of 1.5 mm to support the plate. Fig. 3 shows the air-gap flux density distribution at a current of 10 A. The numerical and experimental results are consistent with each other. The harmonic components in the distribution are shown in Fig. 4. It is numerically and experimentally confirmed that the slit stator increases the 5th harmonic and decreases the fundamental and 7th harmonics. The slight difference between the numerical and experimental results is caused by the difference in the shape at the ends of slits.

AU-02. A New Modular Flux-Concentrated Doubly Salient Machine with PMs in Both Stator Yoke and Slot Openings.

Q. Wang[1] and S. Niu[1]
1. Department of Electrical Engineering, The Hong Kong Polytechnic University, Hung Hom, Hong Kong

Abstract: This paper proposes a new modular flux-concentrated doubly salient machine(MFCDSM), in which the PMs are employed in both the stator yoke and the slot openings. The magnetic flux excited by the PMs in the stator yoke will be pushed by the PMs in the slot openings to pass through the air-gap and link the rotor, hence the leakage flux is reduced consequently. Meanwhile, the PMs in the stator yoke can act as magnetic reluctance, so the magnetic flux excited by the PMs in the slot openings will also pass through the air-gap and link the rotor, not short-circuited by the salient stator poles. Therefore, the magnetic flux excited by the PMs in both the stator yoke and the slot openings can be concentrated to the air-gap and link the rotor, and the torque capability of the proposed machine can be improved. With slot PMs, the electromagnetic torque of the proposed machine can be increased with 62%. Modular design of the stator can be achieved, which can simplify the manufacturing. Finite element method coupled with an improved Tabu search algorithm, namely FEM-ITS coupled method, is used to optimal design the proposed MFCDSM machine. Its electromagnetic performances are studied in detail using FEM. *Index Terms*—Doubly salient, flux-concentrated, modular design, optimal design, Tabu search. I. Introduction Doubly-salient machines have been extensively researched due to their robust rotor structure, high reliability and easy cooling with most of the heating sources located on the stator [1-3]. In order to achieve high torque density, doubly salient permanent magnet machines(DSPMM) have been investigated for many decades [4]. In this paper, a new modular flux-concentrated doubly salient machine(MFCDSM) is proposed, in which the PMs are employed on both the stator yoke and the slot openings. High torque density can be achieved because the PM flux can be concentrated to pass through the air-gap and link the rotor, so the leakage flux can be reduced. With the merits of modular stator design, the manufacturing cost of the proposed machine can be reduced. Finite element method coupled with an Tabu search algorithm [5], which is referred as FEM-TS coupled method, is used to optimize the design of this proposed machine. The electromagnetic performances are investigated in detail using FEM. II. Machine Configuration Fig. 1 shows the configuration of the proposed MFCDSM and its stator module. The stator consists of T-shaped modular segments, between which are mounted with PMs. The armature windings are concentric wound on the stator teeth. Each stator module consists of one stator tooth and one tooth-wound coil, the total number of stator modules is equal to the number of stator teeth. PMs are employed on both the stator yoke and the slot openings, and the adjacent PMs are magnetized in opposite direction, so the PM flux can be concentrated to the air-gap and link with the rotor. The rotor is simply made up of salient poles, which is mechanically robust. Various combinations of the stator slot number and rotor pole number can be used in the MFCDSM. In the proposed design in this paper, the stator slot number and rotor pole number is 12 and 11, respectively. The stator and rotor pole numbers are differed by one, which can result in sinusoidal back-EMF and reduce the torque ripple [6]. III. Design Optimization and Torque Characteristics A. Multi-Objective Optimization Before investigating the electromagnetic performances, the proposed MFCDSM is optimally designed using FEM-TS coupled method. Three objectives are investigated, which include the average output torque, the torque ripple ratio, and the efficiency. During the optimization process, the proposed machine is applied with a fixed current density 8A/mm^2 and rotates at rated speed 818rpm. Fig. 2(a) shows the optimization results of the efficiency and the average output torque, it can be observed that the efficiency is positive correlated with the average output torque, which means the proposed machine can work with high efficiency when designed with large output torque. The relationship between the torque ripple ratio and the average output torque is given in Fig. 2(b). One can find that there is no clear relationship between the torque ripple and average torque. The torque ripple ratio varies almost randomly during the optimization process. B. Single-Objective Optimization After the multi-objective optimization, the proposed machine is optimized through single-objective optimization. The objective is to achieve the largest output torque when applied with a fixed current density 8A/mm^2, and the constraint is the torque ripple ratio should lower than 12%. The average output torque versus iterative number is shown in Fig. 2(c), one can see that the optimization can converge within 20 iterations, which shows the effectiveness of the optimization method. C. Torque Characteristics Fig. 2(d) shows the torque angle waveforms of the proposed MFCDSM when the current density is 8A/mm^2. The electromagnetic torque generated by the slot PMs and yoke PMs are calculated separately. The total electromagnetic torque of the proposed machine is 20.4Nm, in which 7.8Nm is generated by the slot PMs and 12.6Nm is generated by the yoke PMs. Therefore, with the PMs in the slot openings, the electromagnetic torque of the proposed machine can be increased with 62%.

AU-03. Rotor Structure for Reducing Demagnetization of Magnet and Torque Ripple in a PMa-synRM with Ferrite Permanent Magnet.

Y. Kong[1], M. Lin[1], G. Yang[1] and K. Liu[1]
1. Engineering Research Center for Motion Control of MOE, Southeast University, Nanjing, China

Abstract—A rotor structure of permanent magnet assisted synchronous reluctance motor (PMa-synRM) with ferrite permanent magnet is presented in this paper, in which the irreversible demagnetization of magnet and torque ripple are reduced. The bypass-rib is proposed and added to the flux barrier of the rotor. The path for the demagnetizing field of armature windings are provided and the torque ripple can also be reduced by the bypass-rib. Based on the 2-D finite element analysis (FEA), the location and dimensions of the bypass-rib are investigated and improved. A PMa-synRM with the proposed rotor structure is designed and compared with the PMa-synRM with a conventional rotor. A prototype of the PMa-synRM is manufactured and tested to validate the FEA results. I.Introduction The magnetless machines and non-rare-earth machines are attracting more and more attention in recent years due to the high and dramatic rise price of rare-earth [1]. The PMa-synRM with ferrite permanent magnet is a good alternative machine to replace the machine using rare-earth permanent magnet. But the coercivity of the ferrite permanent magnet is weaker than that of the rare-earth permanent magnet. The operating point of the ferrite permanent magnet will pass over the knee point of the demagnetization curve under the large magnetomotive force of the armature reaction which lead to the irreversibly demagnetization [2]. Another drawback of the PMa-synRM is the large torque ripple [3]. Many research works have been done to solve these problems [4-8]. The tapered flux barrier is used to improve the antidemagnetization ability [4]. While the saliency ratio is decreased due to the decrease of the barrier thickness which leads to the output torque capacity reduction. The antidemagnetization ability can be obviously improved by using more permanent magnet to increase the thickness along the magnetization direction [5]. But this will make the costs increased. The asymmetrical flux barrier design was proposed to reduce torque ripple [6-7]. However, the asymmetrical structures increase the complexity of the initial design. This paper proposes a rotor structure to reduce the irreversible demagnetization of magnet and torque ripple without discounting the output torque. The complexity of the design is not increased owing to the symmetrical structure. The influences of the bypass-rib on the saliency ratio, no-load back electromotive force and antidemagnetization ability of the PMa-synRM are investigated in section II. In section III, the performances of the machine, especially the antidemagnetization ability, are analyzed and compared to that with the same design dimensions but without the bypass-rib structure. A prototype is manufactured and tested. Experiments results will be shown in the full paper. II.Rotor Design Fig.1 illustrates the topology and parameters of the bypass-rib. The bypass-rib structure is composed of two unconnected ribs and the permanent magnet is located in the flux barrier between the two bypass-ribs. The influences of the parameters on the saliency ratio, no-load back electromotive force and antidemagnetization ability are investigated which will be shown in the full paper. A PMa-synRM with the proposed rotor structure is designed and compared with a PMa-synRM with a conventional rotor. A series of demagnetization currents is applied to the PMa-synRMs from small to large. Fig.2 shows the demagnetization characteristics of the two PMa-synRMs. Most of the magnets in the conventional rotor structure are irreversibly demagnetized when the applied current is 15A while the irreversibly demagnetization rate in the proposed rotor is less than 10%. Experiments results based on the prototype will be shown in the full paper. III. Conclusions To improve the antidemagnetization ability of the PMa-synRM, the bypass-rib structure is proposed and added to the flux barrier of the rotor. The main parameters of the bypass-rib are studied based on the 2-D FEA. The saliency ratio and the antidemagnetization ability is mainly influenced by the length and width of the bypass-rib respectively. A PMa-synRM with the bypass-rib is designed and compared to a PMa-synRM with conventional rotor. A prototype is manufactured and tested. The results demonstrate that the PMa-synRM with the bypass-rib has almost the same output torque and much higher antidemagnetization ability and lower torque ripple than that of the PMa-synRM with conventional rotor structure.

AU-04. Electromagnetic Performance Analysis of Hybrid Excited Segmental Rotor Flux Switching Machine.

Y. Yang[1], J. Chen[1], B. Yan[1], X. Wang[1] and C. Zhu[1]
1. Shandong University, Jinan, China

I. INTRODUCTION Due to high torque density, simple rotor structure and good heat dissipation, the electrically and permanent magnet (PM) excited segmental rotor flux switching machines (SRFSMs) have attracted much attentions in recent years [1-2]. The machine topology [3], analysis method [4], and torque ripple reduction method [5] are studied in the literatures. In order to reduce the excitation loss of electrically excited SRFSM and increase the magnetic field regulation capacity of PM excited SRFSM, the new hybrid excited SRFSM is proposed and the analytical subdomain model is derived to calculate the magnetic field and electromagnetic performance. The magnetic field regulation capacity is verified with the results of finite element method (FEM) and prototype machine experiment. II. THE WORKING PRINCIPLE The hybrid excited SRFSM is shown in Fig. 1(a), and three N-pole PMs are replaced by three field windings F1-F3. The exciting magnetic flux will alternately go through the two adjacent stator teeth due to the segmental rotor core, so the flux paths of the two adjacent PM and field winding are parallel. Because the flux path of field winding doesn't include any PM, the magnetic field can be easily regulated by the field current due to the small reluctance, and the PMs have no risk of demagnetization. As shown in Fig. 1(b), the coil flux linkage is the summation of those produced by the adjacent PM and field winding independently. For the model, the flux linkages produced by the PM and field winding have nearly the same phase angles for the positive field current, so the total flux linkage is increased with the field current. For the negative field current, the phase difference between the two flux linkages becomes 180 electrical degrees, so the total flux linkage will be decreased with the increment of field current. By changing the value and direction of the field current, the flux linkage is also easily regulated. III. THE ANALYTICAL MODEL In order to study the magnetic field and electromagnetic performance, the analytical subdomain model is derived for the hybrid excited SRFSM. The inner part of rotor iron core (dotted portion in Fig. 1(a)) is to fix the rotor laminations to the rotor support, and has little effect on the magnetic field, so it is ignored in the analytical model. The rotor support is usually made of non-magnetic stainless steel, and is divided into two subdomains, i.e. the shaft and "rotor slot". The whole solving domain is divided into six subdomains, including the shaft, rotor slot, air gap, PM, stator slot opening and stator slot. The governing equations and general solutions of all the subdomains are obtained, and the equations including the integration constants are derived according to the boundary conditions, i.e. the magnetic vector potential and tangential magnetic field intensity should be continuous, respectively at the boundary between the adjacent subdomains. All the equations are transformed into matrix forms, and solved by the math software Matlab. With the magnetic vector potential, the magnetic field and electromagnetic performance including the flux linkage, back-EMF, cogging torque, electromagnetic torque and PM loss are calculated, and the regulation capacity of magnetic field is also analyzed. IV. THE RESULTS AND VALIDATIONS In order to verify the analytical model and performance of the hybrid excited SRFSM, one prototype machine with 12-stator-slot and 7-rotor-segment is designed and produced as shown in Fig. 2(a). In order to reduce the eddy current loss, every PM pole is consisted of three segments along the axial direction. The air gap flux densities with field current densities of 9A/mm^2, 0, and -9A/mm^2 are shown in Fig. 2(b). It can be found that the radial flux density is greatly increased corresponding to the flux path of field winding with the increment of field current density. The back-EMFs with different field current densities are calculated by the analytical model and compared with the experiment results. As shown in Fig. 2(c), when the field current density increases from -9A/mm^2 to 9A/mm^2, the back-EMF regulation ratio (defined by $(E_{pm}-E_{he})/E_{pm}$, where E_{pm} and E_{he} are the back-EMFs produced by the PMs and by the hybrid excitation) changes from -50% to 77%. In order to evaluate the torque capacity, the static torque is tested and the three-phase currents are set as $I_a=-I_b=0.866I_{amp}=17.32$A and $I_c=0$, where I_{amp} is the amplitude of phase current. It can be found that the torque can be easily regulated by the field current for the hybrid excited SRFSM.

Abstract:Due to the advantages such as high energy density, high power density, high cyclic-life, and environmentally friendly, flywheel have the potential to solve the problem of energy storage. In this paper, the interior bearingless permanent magnet synchronous motors (IBPMSMs) with V-shape permanent magnets (PMs) used for flywheel batteries of electric vehicles (EVs) is researched in detail. Especially, the influence of geometrical parameters of V-shape PMs on suspension force is investigated. Furthermore, the corresponding static electronic magnetic characteristics including inductances, electromagnetic torque is also studied. The finite-element method (FEM) is employed to evaluate the theoretical analysis. 1 *Introduction* Comparing with the traditional vehicles, electric vehicles (EVs) have advantages including low emissions, high energy conversion efficiency and multiple sources, and they are considered as an important way to deal with environment deterioration and energy shortage. As one of key technique of EVs, the power battery technique is extremely important. Comparing with conventional chemical battery, flywheel battery has relative advantages such as maintenance free, high energy density, high power density, rapid charge and discharge, high cyclic-life and environmentally friendly. The bearingless permanent magnet synchronous machine [1,2] (BPMSM) with the advantages of high efficiency, high power density, high power factor and friction-free is favourable for the flywheel battery [3,4]. In this paper, the structure and feature of proposed bearingless motor is introduced firstly in first part. Then the influence of V-shape PMs geometrical parameters on suspension force will be investigated. Furthermore, the electromagnetic performance, such as torques and inductances are analysed in following section. *Structure and features:* Fig. 1 illustrates the proposed IBPMSM with V-shape PMs. From the front view, it can be seen that the proposed motor has a similar structure with permanent magnet synchronous machine (PMSM), but the difference is the stator houses the torque winding and the suspension winding which fulfilled P_S=P_T±1 ω_S=ω_T (1) where P_T is the pole-pair number of the torque winding, ω_T is the current frequency of torque winding, P_S is the pole-pair number of the torque winding, and ω_S is the current frequency of suspension winding. The suspension force generation can be seen form[5]. 2 *Influence of PM Geometrical Parameters on Suspension Force* When the rotor is not eccentric, the suspension force F_p can be given as F_P=(F_x^2+F_y^2)^½(2) where F_x and F_y are suspension forces along x- and y-axes, respectively, and they can be written as F_x=$k_\alpha I_S I_{PM}$cos(θ_M-θ_S) F_y=$k_\alpha I_S I_{PMsin}$(θ_M-θ_S)(3) where I_S is suspension winding current, I_{PM} is the equivalent current of PM, θ_M and θ_S are the initial angle of torque winding current and initial angle of suspension winding current, respectively. In this part, the influences of two geometrical parameters (angle between two PMs *A* and number of segments *N*) on performances of suspension force and torque are investigated. It is not so easy to determine the angle between two PMs since there is currently no definite rule to choosing it, and it is usually determined according to the experiments. In this paper, keeping the length and width of magnetic bridge as a constant, and changing the angle between two PMs of one pole. Then the performance of suspension force and electromagnetic torque are obtained by using finite-element method (FEM). Fig. 2(a) shows the suspension force with different *A*. It can be seen that the angle between two PMs has a little influence on the amplitude of suspension. The suspension forces of the proposed IBPMSM with different *N* are shown in Fig 2(b), in which the segment gaps of PM is 0.5mm and the volume of PMs is fixed. It can be seen from Fig. 2(b) that the *N* has a significant influence on amplitude of suspension force. The large fluctuation of the suspension force occurs when *N* is equal to 5, and the suspension force is biggest when *N* is equal to 3. 3 *Electrical magnetic characteristic* Considering rotor strength and complex of process, two geometrical parameters are set *A*=20 and *N*=3. In this part, the corresponding results of torque characteristic and the inductance characteristic are calculated by using the FEM. The inductance is one of the important technical parameters for the proposed motor, and it will have an important effect on radial suspension forces and output power. In order to control motor easily, the two phase rotating reference frame d-q axis is widely used. According three phase inductance, the d-axis inductance L_d and q-axis L_q can be calculated $L(d,q,0)=C_{3/2}L(a,b,c)C^{\mathrm{T}}_{3/2}$(4) According to the simulation result, it can be found that the proposed motor has a large diffidence in d-q axis inductance, which can provide more reluctance torque. 4 *Conclusion* An IBPMSM with V-shape PMs used for EVs flywheel battery is proposed in this paper. The influences of two geometrical parameters on performances of suspension force and torque are investigated The performance are sensitive to those geometrical parameters The angle between two PMs influences the stability of suspension force, and the number of segments influences the amplitude of suspension force. Furthermore, according to electrical magnetic characteristic, the proposed motor can also provide large reluctance torque and low cogging torque.

Introduction Recently, the research on permanent magnet vernier machine (PMVM) is increasing due to its features of high power density and efficiency for low speed application. The machine utilizes slot harmonics of air gap permeance to develop the modulation flux, so it is beneficial to use of thin magnets in a surface permanent magnet(SPM) structure because it causes effective air gap shorter, resulting in the increment of slot harmonic of the stator permeance. Therefore, considering the demagnetization and torque density, it is hard to avoid using expensive Nd-magnets [1]-[4]. Meanwhile, a consequent pole machine has the advantage of being able to achieve nearly same levels of air gap flux density, although it reduce the used magnet quantity by half as compared to conventional machine [5]-[7]. If the consequent-pole structure is applied to a surface PMVM, the decrement of average air gap length is expected due to removal of half area of PM, resulting in increment of the air gap permeance harmonics as well. Consequently, even though thick ferrite magnet is used for the vernier motor, this motor is expected to resolve the problem of the average air gap length greatly and to get the higher vernier effect and demagnetization characteristics. In this paper, the characteristics of a consequent-pole motor with vernier structure using ferrite magnet analyzed and the characteristics are compared with those of general SPM and vernier machines by using finite element(FE) simulations in order to verify the advantages of proposed structure. Proposed Idea To get the vernier effects, common relation of Z_r-Z_s=-p is used, where Z_r is the number of rotor pole pairs, Z_s is the number of stator slots, p is the number of winding pole pairs. The vernier structure can be converted into consequence pole structure by replacing the S pole of magnet with iron core, which will reduce the average air gap length. Fig.1 shows general structure of a PM vernier machine and the proposed structure of the consequent pole vernier motor. The both prototypes given in Fig.1 are able to create vernier effect and the induced voltage can be expressed by (1) [1]. $E=N_{ph}D_il_c\omega_m(B_{g0}+(6q-1)B_{g1})\cos\{Z_r\theta\}$ (1), where N_{ph} is the number of turns in a phase, D_i is the inner diameter of stator core, l_c stack length of core, ω_m is the motor rotation speed, q is the number of stator slots/pole/phase. In addition, the expressions of B_{g0} and B_{g1} are given by (2) and (3). $B_{go} = B_{go.peak}\mu_0(1\text{-}1.6\beta(o/td))\cos\{Z_r(\theta\text{-}\theta_m)\}$ (2) $B_{g1} = B_{go.peak}\mu_0\pi\beta(0.39/(0.39\text{-}(o/td)^2))\sin\{1.6\pi(o/td)\}\cos\{\{Z_r\text{-}Z_s\}\theta\text{-}Z_r\theta_m)\}$ (3), where F_{1m} is the fundamental component of the MMF through magnet and can be obtained by using the magnetic equivalents circuit of the vernier and the proposed structures. Especially, the peak flux densities of (2) for both motors are given by (4) and (5), where g_a represents the air gap length, g_m represents the thickness of the magnets, A_m and A_g are the magnet and air gap area per pole respectively, and β is a non-linear function determined by the slot opening width and effective air gap length [5]. $B_{go.p.ver} = g_mA_mB_r/(\mu_0(g_mA_g+\mu_rg_aA_m))$ (4) $B_{go.p.prop} = g_mA_mB_r/(\mu_0(g_mA_g+2\mu_rg_aA_m))$ (5) The relation (4) and (5) shows that even if the number of magnets are reduced half but the main flux density B_{g0} of both motors are similar when g_m is quite larger than g_a. However, B_{g1} of the proposed vernier motor is greater than B_{g1} because the effective air gap length of the proposed structure is quite smaller, causing increases of the coefficient β. Therefore, when the machine has thicker g_m, it is possible to get the higher induced voltage due to the relationship (B_{g0}+(6q-1)B_{g1}. Therefore, the use of thick ferrite magnets can provide advantageous characteristics. Verification through FE simulations Three different prototypes of conventional, vernier and consequent pole type vernier motors with same geometric specifications are used for the FE analysis to verify the characteristics and are shown in Fig 2 (a), (b), and (c). In addition, fast fourier transform analysis is conducted to distinguish B_{g0} and B_{g1} from air gap flux density. Ferrite magnets with a thickness of 6mm is used for the analysis structures. The Fig 2 (f) shows that the magnitude of the fundamental component of Back EMF waveform given in Fig 2 (d), and it is proportional to the total combined composition of the air gap flux densities (B_{g0}+5B_{g1}, since q=1). As B_{g1} increases due to the reduction of the effective air gap length, the vernier effect is increased. Generally, the power density of a vernier motor is approximately two times that of conventional machines, but for the use of ferrite magnets, large thickness is required which reduces the advantage of the vernier effect, making the power density less than two times. On the other hands, the proposed structure has half number of magnets, but the power density is increased approximately 2.5 times. The use of ferrite magnets in proposed structure has shown an advantage in reducing the number of magnets and increasing the power density. Full paper further discusses detail analytical analysis of motor, the design limitations by considering demagnetization characteristics and reluctance effects.

AU-07. Static Characteristics of Hybrid Excitation Machine with Parallel Magnetic Path.

J. Zhang[1], Z. Xu[1], Y. Jiang[1] and W. Hua[1]
1. School of Electrical Engineering, Southeast University, Nanjing, China

Introduction: Electrical machine is the key component of power conversion systems where permanent magnet (PM) machine is popular due to its high efficiency and high power density. However, the airgap field of the PM machine could not be regulated and then it is not qualified in some applications, such as wide variable speed operation with high efficiency in whole speed range. According to the limitation of flux regulation for the PM machine, hybrid excited electrical machines are put forward and studied by many researches in recent decades, which combine both advantages of the PM machines and electrical excitation machines[1-4]. There are mainly two different hybrid excitation machines according to the relationship of PM and electrical excitation path, namely serial and parallel magnetic path. In the serial magnetic path, the PM is located and serial connected with the electrical magnetic circuit which has larger resistance of the magnetic circuit due to the PM has similar magnetic permenance as the air space, and then large excitation force is needed for flux regulation of the airgap field. An effective way to decrease the excitation force of the hybrid electrical winding, is adoption of parallel magnetic path, where the PM and electrical excitation in the magnetic circuit is paralleled. However, additional airgap has to be adopted in the hybrid excitation machine to avoid short-circuit of the PM flux. The introduction of additional airgap will lead to larger magnetic resistance for the electrical excitation and leakage flux of PM going through. *Topology*: This paper firstly proposes a new hybrid excitation machine with parallel magnetic path however without additional airgap and PM leakage flux. This machine has a novel compound structure with two salient-pole parts side by side, as shown in Fig. 1(a). Between two salient-pole parts, there is a PM ring with axis direction magnetization. It is shown in Fig. 1(a) that there are two serial airgaps in the PM flux path and both of them are the working airgap. Then the utilization of the PM is quite high since no leakage PM flux will be existed. The cross-section of the right salient-pole part with 12/8 stator rotor pole combination is shown in Fig. 1(b), where the PM flux will be in same direction for the stator teeth with armature windings. Three excitation windings are set on the stator teeth in which the flux direction and strength are determined by the current in the excitation windings. If the flux direction is shown as Fig. 1(b) then the magnetic strengthening is realized. Obviously the flux of excitation windings is not passed through the PM and then parallel magnetic path is achieved. It is inevitable the direction of PM flux in left and right airgap is different due to the side by side structure. So, if the rotor teeth of two sides are aligned shown as Fig. 1(a), the separate armature windings have to be used in the stator and it is not good since more terminal winding and accommodation space are required. Then the power density and efficiency will be low due to larger volume and winding resistance. However the rotor teeth in left and right side might be not aligned to avoid the PM flux cancellation and it is easy to produce due to the simple rotor structure. By shifting the rotor teeth in different side in a mechanical angle to make phase angle deviation of the flux in the stator, the armature windings in the side-by-side stator teeth may be combined into one due to the symmetrical structure. In this case the winding resistance is lowered and the power density is improved also. In order to verify the operation theory and obtain the static characteristics of this machine, 3D finite element analysis (FEA) tool is used for modeling of this machine. *Simulation Results*: By using 3D FEA, simulation results are obtained shown as Fig. 2. Fig. 2(a) shows the simulation results of different shifted angle for rotor tooth, where the excitation current and load current are zero. The no-load PM flux is varied according to the tooth shifted angle greatly. As mentioned before, the aligned rotor tooth will lead to reversal PM flux in two airgap fields and the total flux will be near zero if one combined armature winding is used. It shows the 22.5 degree is quite good for the tooth shifted angle and in this case the PM flux is positive added for right and left part. In Fig. 2(b) it shows the no-load PM flux under different PM thickness in axis direction while the rotor tooth shifted 22.5 degree with combined windings. The flux linkage is quite similar when the PM thickness is larger than 7.5mm. The flux linkage is related to the power density. However, larger PM thickness means consumptions of more rare-earth magnet and less iron at the situation of constant total stack length(75mm include PM). In this case, it is better the PM thickness is small at same flux linkage. So the optimized PM thickness is 10mm under the design parameters of this paper (outer dia. Φ128mm). The simulation results of co-action of excitation winding and PM are shown in Fig. 2(c). It shows very good magnetic field weakening and strengthening when the excitation winding is put into action. More details of machine design and characteristic analysis will be given in the full paper.

AU-08. A Double-Rotor Consequent-Pole Vernier Permanent-Magnet Machine with Toroidal-Winding Arrangement for Hybrid Electric Vehicles.

C. Lee[1]
1. Research Laboratory of Electronics, Massachusetts Institute of Technology, Cambridge, MA, United States

I. INTRODUCTION Due to the increasing concerns on energy utilization and environmental protection, the development of hybrid electric vehicles (HEVs) has been accelerating recently [1]. As one of key components in HEV systems, the electric machines have to offer several key features, including high efficiency, high power density, high controllability, wide-speed range, maintenance-free and fault-tolerability [2]. Since the permanent-magnet (PM) machines can fulfil most of the goals, this machine type has become the mainstream in the past few decades [3]. In particular, the Vernier permanent-magnet (VPM) machine, which utilizes the magnetic gearing effect to boost up the torque density, has been accepted as a very promising candidate for direct-drive HEV applications [4]. The VPM machine generally adopts the inner-rotor (IR) topology, such that its armature windings have to be installed with the distribution arrangement [5]. This conventional design suffers from two major disadvantages, namely the wastage of the inner machine space and larger end-winding length. To improve the situation, the outer-rotor VPM (OR-VPM) machine that adopts the toroidal-winding arrangement has been developed [6]. Upon the installation of the toroidal-winding arrangement, shorter end-winding length and better fill winding factor can be achieved. However, similar as the conventional IR-VPM design, the OR-VPM machine still suffers from the poor utilization of the inner space. The purpose of this paper is to artfully incorporate the concepts of double-rotor and consequent-pole into the VPM machine, and hence forming the proposed double-rotor consequent-pole VPM (DR-CPVPM) machine, purposely for HEV applications. With the implementation of the double-rotor structure, the toroidal-winding arrangement can be fully utilized to power up both rotors simultaneously. In the meantime, the consequent-pole topology can improve the PM utilization and hence further boosting up the power and torque densities. To illustrate the effectiveness of the proposed design, the proposed DR-CPVPM machine will be purposely compared with the well-known Prius HEV counterpart. II. MACHINE DESIGN The structures of the conventional IR-VPM machine and the proposed DR-CPVPM machine are shown in Fig. 1(a), and Fig. 1(b), respectively. Unlike the conventional IR-VPM machine that consists of only one rotor, the proposed DR-CPVPM machine instead utilize its inner space to accommodate the additional rotor. For simplicity, the pole arrangement of the outer- and inner-segments are purposely set equal. Since the proposed DR-CPVPM machine is derived from the IR-VPM machine, its design equations such as the pole arrangement can be extended from that of the profound ancestors. As mentioned, the traditional IR-VPM machine installs the armature winding with the distribution arrangement, such that it suffers from poor winding fill factor and larger end-winding length. On the other hand, the proposed DR-CPVPM machine instead artfully adopts the toroidal-winding arrangement, such that the armature winding can power up the two rotors simultaneously. Upon the employment of the toroidal-winding arrangement, better winding fill factor and shorter end-winding length can be achieved. Consequently, higher power and torque densities can be produced. To further improve the machine performance, unlike the conventional IR-VPM machine that equips with the alternating PM arrangement, the proposed DR-CPVPM machine instead employs the concept of consequent-pole for PM installation. With the consequent-pole arrangement, the leakage PM flux can be minimized. Consequently, even with a lower PM consumption, the proposed machine can still generate a larger PM flux-linkage. As a result, the proposed DR-CPVPM machine can potentially achieve a better cost-effectiveness than its counterparts. III. MACHINE PERFORMANCE ANALYSIS The no-load electromotive forces (EMFs) of the proposed DR-CPVPM machine at base speed of 500 rpm are shown in Fig. 2(a). It can be shown the two machine segments can produce the EMFs with same pattern, i.e., same polarity and same phase angle. Consequently, the feasibility of the toroidal-winding arrangement is verified. In the meantime, the results show the proposed machine can generate a very sinusoidal-like EMF waveforms, from both its outer- and inner-segments. With the bipolar brushless AC (BLAC) conduction algorithm, it can be expected that the proposed machine can produce a resultant torque with very little pulsation, which is highly desirable for HEV applications. The output torque waveforms of the conventional IR-VPM machine and the proposed DR-CPVPM machine are shown in Fig. 2(b). It can be found that the average torque of the IR-VPM machine and the proposed DR-CPVPM machine are 241.5 Nm and 376.3 Nm, respectively. In the meantime, their corresponding torque ripples are about 10.2 % and 12.3 %, respectively. As a result, with the double-rotor and consequent-pole structures, the proposed machine can achieve 56 % larger torque than its conventional counterpart, upon a comparable torque ripple value. All these values are very attractive for modern HEV applications [2]. The detail machine designs and comparisons based on the requirement of HEV applications will be included in the full paper.

AU-09. Efficiency-Enhanced Variable Flux Reluctance Machine with Reduced Excitation Coils for Electric Vehicles.

X. Zhao[1] and S. Niu[1]
1. Electrical Engineering, The Hong Kong Polytechnic University, Kowloon, Hong Kong

Abstract: Due to a limited source of rare-earth PMs, developing high-performance non-PM electrical machine is an important research topic for electrical vehicles. DC-excited variable flux reluctance machine is a promising candidate. However, conventional design of such machine suffers from large excitation copper loss and reduced efficiency, due to an identical distribution of excitation components at stator side. This paper aims to propose an efficiency-enhanced variable flux reluctance machine. The key is to reconstruct effective magnetic circuit with halved excitation coils, thus to reduce excitation copper loss while keeping the power density not sacrificed. A comparative study is performed between the proposed topology and existing counterparts, which reveals that, with the same machine size, slot factor and excitation copper loss, the proposed design provides higher power density and higher efficiency. Moreover, the proposed topology can also eliminate the mutual inductance. Therefore, this new design is a more competitive non-PM solution for electric vehicle propulsion. I.Introduction Due to the lack of rare-earth permanent magnet (PM) source, developing high-performance electrical machines with no PMs or reduced PMs is still an important research field for some industrial applications such as electric vehicles. Switching reluctance machine (SRM) is a promising solution, but it has severe torque ripple. Compared with SRM, DC-excited variable flux reluctance machine (VFRM) owns an excitation flux which is similar to traditional synchronous machine [1]. Therefore, it can obtain a smooth torque performance if driven by sinusoidal current. However, one of the most significant drawbacks in VFRM is its energy consumption in the DC field terminal, which leads to increased copper loss and reduced efficiency. This paper aims to propose a new VFRM with improved efficiency while maintains the same excitation ability compared with existing topology. With halved field coils, the copper loss in field terminal can be almost cut down and an efficiency-significantly-enhanced non-PM machine can be provided for electrical vehicle propulsion. II. Machine structure and magnetic circuit analysis. The machine structures of the existing and proposed design are shown in Fig. 1(a) and Fig. 1(b), respectively. One can see, both DC field coils and armature coils are located at stator side, with the rotor only consisting of iron materials, which makes VFRM a robust and cost-effective solution for EVs. Compared with existing design, the proposed topology cuts off the number of field coils and rearranges the armature coils as well, aiming to achieve a comparable performance with reduced excitation copper loss. The effective DC magnetic circuits of two designs are denoted and compared in Fig. 1 by yellow dash lines. One can see, the fundamental DC magnetic circuit of existing design starts from a wounded stator tooth, shunting into two adjacent teeth and coming back from the rotor part. Obviously, the effective magnetic circuit generated by each DC coil are coupled together. However, for the proposed design, the effective DC loop encircles only one DC component and there is no cross linking between different excitation coils. Hence, in the proposed topology, a modular magnetic circuit is actually built with halved excitation coils. III.performance comparison By using the finite element analysis, a comparative study is performed to verify the advantages of the proposed topology. For a fair comparison, FE models for two machines share the same outer dimension, axial length and air gap length. Besides a common design optimization is performed for two machines, considering the influence of structure parameters are different when the effective magnetic circuit is reconstructed. When the armature copper loss is fixed at 60W, the output torque curves for two designs with different excitation copper loss are presented in Fig. 2(a). With the same excitation loss, the proposed machine can achieve a higher output torque than the existing topology, which verifies that the proposed design owns a comparable excitation ability with halved DC coils. An improved efficiency can be aslo derived out from Fig. 2(a). Further, the inductance characteristic for two designs is also plotted in Fig. 2(b). Benefiting from a modular DC magnetic circuit as discussed in Part A above, the proposed machine has a negligible mutual inductance, compared with existing design, giving a fault-tolerance potential for high-reliability EV drives. IV.Conclusion This paper proposes an efficiency-enhanced variable flux reluctance machine. The key is by reconstructing effective magnetic circuit with halved excitation coils, aiming to reduce excitation copper loss while keeping the power density not sacrificed. By using finite element analysis, a comparative study is performed between the proposed design and existing counterpart, which reveals that with excitation copper loss, the proposed design provides higher power density and higher efficiency. Moreover, the proposed topology also eliminates the mutual inductance. Therefore, this new topology is more competitive non-PM machine for electric vehicles.

AU-10. Parametric Optimization of Flux Focusing Type Double Stator and Single Rotor Axial Flux Permanent Magnet Motor.

Q. Syed[1] and I. Hahn[1]
1. Electrical Drives and Machines, University of Erlangen-Nürnberg, Erlangen, Germany

Recently, great interest is developing towards axial flux permanent magnet motor (AFPM) for direct-driven in-wheel applications, due to their inherent multipolar disc-type structure and small axial length. Three-disc AFPMs have a high torque density because they effectively utilize the intermediate disc and are compact enough to be easily mounted in the wheel. Mechanical problems are also reduced because an intermediate disc is equally attracted in axial direction by its both sides. The slotted double stator and single rotor (DSSR) AFPM has more power and torque density and less cost, weight, volume, inertia and cooling problems in comparison to the single stator and double rotor (SSDR) AFPM topologies [1]. The flux focusing type slotted DSSR AFPM consumes a less amount of the permanent magnets (PMs) and has more torque density compared to the surface mounted permanent magnet (SPM) type slotted DSSR AFPM [2]. Therefore, in this paper flux focusing type DSSR AFPM is further investigated for parametric optimization. Initial dimensions of the flux focusing type DSSR AFPM are selected using the basic analytical modelling. A 3D finite element analysis (FEA) is utilized for its detailed characteristic analysis. The flux focusing type DSSR AFPM has 24 number of poles and 36 number of stator slots on each stator disc. Although it has a less winding factor (0.866), which decreases the output electromagnetic torque, it has a less total harmonic distortion (THD), zero fundamental or 1st harmonic, which reduces the losses, especially core losses. Due to the symmetry and its high periodicity of 12, 1/24th of each geometrical model of the flux focusing type DSSR AFPM is analysed using a 3D FEA, which decreases the computation time. The design of experiments (DoE) method is used for the parametric optimization of the flux focusing type DSSR AFPM. Although it is time-consuming due to the 3D FEA, it is suitable for the electromagnetic optimization of motor [3]. Initially, the full factorial design (FFD) is applied to analyse the effect of different design variables on the performance of the flux focusing type DSSR AFPM. With the help of the FFD, the significant design parameters can be identified easily. The FFD is very time-consuming, therefore, only the minimum, maximum and mean values of each design variable are considered, which limits the DoE. To extend the DoE and also to reduce the computation time compared to the FFD, the Latin hypercube sampling method (LHS) is used for the detailed characteristic analysis of the flux focusing type DSSR AFPM. The objective is to get best motor performance, such as high electromagnetic torque and back EMF and low torque ripple, cogging torque and total harmonic distortion (THD). The flux focussing type DSSR AFPM has constant outer radius length, current density, airgap, and stator yoke height. The design variables of the flux focussing type DSSR AFPM are shown in Fig. 1, where "*A*" is the ratio of the stator slot width and the slot pitch, "*B*" is the height of the stator slot, "*C*" is the ratio of the PM width and the pole pitch, "*D*" is the height of the PM, "*E*" is the ratio of the slot opening width and the slot pitch, "*F*" is the height of stator tooth tip, and "*G*" is the rotor's inner to outer radius ratio. Fig. 2, represents the output torque characteristics of the flux focusing type DSSR AFPM. Initially, a number of one hundred experiments were carried out for the LHS. The experiment "X" has the highest electromagnetic torque, however, it does not have the lowest torque ripple. Similarly, experiment "Y" has the lowest torque ripple but does not have the highest electromagnetic torque. Experiment "Z" has almost same torque ripple, as that of "Y" but has a higher electromagnetic torque. Therefore, the optimal solution is in between "X" and "Z". Interpolation between both geometrical models will provide an optimal solution of the flux focusing type DSSR AFPM. In the full manuscript, a detailed parametric optimization of the flux focusing type DSSR AFPM will be presented, based on the DoE method coupled with the 3D FEA. The effect of each design variable on the output characteristics, as determined by the analytical modelling and realized by the FFD will be presented and discussed. Along with the FFD, optimal design and a meta-parametric analysis of the flux focusing type DSSR AFPM will be carried out using the LHS.

Introduction: Recently, many flux-switching permanent magnet machine (FSPMM) topologies and their electromagnetic designs, winding layouts, and performance characteristics are broadly investigated [1]-[3]. For the potential applications onto a micro-sized vehicle with front and rear drives, with the desired continuous torque output of 35.5 Nm at a rated speed level of 1350 rpm, a comparative assessment of three different flux-switching permanent magnet motor topologies will be performed from the results calculated by detailed finite element method (FEM). The three FSPMMs that can meet their specific operational requirements will all be optimized based on their own features. The hardware constructions and the related experimental measurements will be supplied to validate the design adequacies. Model of the Proposed Motors: Fig. 1 illustrates the three proposed FSPMM topologies, they are respectively the conventional FSPMM with all poles wound (type A), the multi-tooth (type B), and the C-core (type C) FSPMMs. They have the same stator outer diameter of 140 mm, air gap length of 0.5 mm, rotor outer diameter of 91 mm, and stack length of 135 mm. The Results: For a fair comparison, the valid stator slot (S) and rotor pole (P) combinations for each topology with the same dimensions and operation conditions are designed and analyzed using FEM, and the one among each topology that has the best electromagnetic performance is selected. Then a design sensitivity analysis and the genetic algorithm are used to optimize the torque ripple whereas the desired torque for each selected topology being fixed. From the comparison results as provided in Table I, some of the key observations and features of these three FSPMMs can be summarized: 1) The conventional FSPMM (12S/13P of type A) is not a good candidate for use in EV applications among the three types as far as the usage of PM material is concerned. 2) The multi-tooth core FSPMM (6S/19P of type B) has a minimum usage of PM and copper materials, and hence a low manufacturing costs can be accomplished. However, design optimization must be performed to further increase the machine efficiency. 3) The C-core FSPMM (6S/13P of type C) has the highest average torque and efficiency. However, the two values are very close to the other two types. Also it will exhibit the largest value of torque ripple. Therefore, design modifications must be performed to further reduce the torque ripple for practical implementations.

Abstract—A variable flux hybrid-permanent-magnet synchronous machine (VFHPMSM) is propose in this paper, which is equipped with aluminum-nickel-cobalt (AlNiCo) PMs and neodymium-iron-boron (NdFeB) PMs. A prototype of VFHPMSM is built, and the experimental results are in good correlation with the FEA simulation. The simulation and experimental results show that VFHPMSM has a good flux adjusting ability and efficiency. *Index Terms*—hybrid-permanent-magnet, flux adjusting ability, finite element analysis (FEA), re- and demagnetization; I. INTRODUCTION Along with the development of rare earth permanent magnet materials, the permanent magnet synchronous motor is used in many applications, such as electric vehicles, industrial drive, domestic appliance and power generation. However, due to the constant of PM magnetic field, the motor flux is always difficulty to adjusting. And with the vigorous development of electric vehicles, a high-performance permanent magnet synchronous is urgent demanded. In this paper, a variable flux hybrid-permanent-magnet synchronous machine (VFHPMSM) is presented and a prototype is built. The operation principle of VFHPMSM is analyzed and the re- and demagnetization characteristics analysis is studied based on finite element analysis (FEA). II. TOPOLOGY AND OPERATION PRINCIPLE *Machine Topology* Fig.1 shows the topology of VFHPMSM, which is designed at 4-pole 24-slot. The rotor adopts with hybrid-permanent-magnet in each pole, and PMs are arranged in W-shape. The AlNiCo PMs mount on the middle of the pole, and NdFeB PMs arranged with V-shape in the side of AlNiCo PMs. *Operation Principle* The flux weakening principle of VFHPMSM is illustrated in Fig.2. According to the magnetization state of AlNiCo PMs, two typical states are defined: flux-enhanced (AlNiCo PMs identically magnetized with NdFeB PMs) and flux-weakened (AlNiCo PMs oppositely magnetized with NdFeB PMs). The magnetization state of AlNiCo PMs can be regulated by an impulse current in the stator coils. III. ELECTROMAGNETIC PERFORMANCE OF VFHPMSM *Magnetic Field Distributions* The magnetic field distributions of 1/4 motor model under different demagnetizing current *I* are shows in Fig.3. By applied the demagnetizing current of d-axis, the magnetic field distributions and magnetization state of AlNiCo PMs are changed. *Flux-Adjusting performance* The FEA predicted flux linkage and back EMF waveforms of the VFHPMSM at 1560 rpm under different magnetization state of AlNiCo PMs are compared in Fig.4 and Fig. 5. It is found that the amplitudes of the flux linkage and back EMF waveforms will decrease as the demagnetizing current increases. The weakening rate may increase with the demagnetizing current and it can be 51% when the demagnetizing current *I* reach 35A. As shown in the Fig.5, the changes of EMF are the same tendencies with flux linkage, and the waveforms had a distortion. The reason for this is that the air-gap magnetic density with the center of the pole is small or even negative when AlNiCo PMs demagnetization. *Efficiency Characteristics* The FEA predicted efficiency of VFHPMSM and general IPM at 1500 rpm are compared in Fig.6. It is found that the efficiency of VFHPMSM is improved with constant magnet IPM. IV. EXPERIMENTAL VERIFICATION The rotor lamination and photographs of the VFHPMSM are shows in Fig.7 and Fig.8. Fig.9 shows the machine testing setup. The test bench includes a voltage source inverter, a control board, VFHPMSM, load machine, Oscilloscope and a test cabinet. V. CONCLUSION A variable flux hybrid-permanent-magnet synchronous machine has been presented, which shows a wide range of flux-adjusting, and the flux linkage is varied obviously at different demagnetizing current. Furthermore, the results of FEA and experiments of VFHPMSM prove that the machine can change the flux of permanent magnet, and realized that the motor operate in wide speed areas with high performance.

I. INTRODUCTION Permanent magnet synchronous motors (PMSMs) have risen steadily in various industrial and domestic applications owing to their superior performance such as high power density and efficiency. According to the different winding type, PMSMs can be generally divided into distributed winding (DW) and fractional slot concentrated winding (FSCW) motors [1]. Compared with DW, FSCW motor own low cogging torque, compact structure, and convenient fabrication. However, FSCW contains abundant stator MMF harmonics, which results in a great deal of rotor eddy current loss. In consideration of heat dissipation difficultly within the rotor, a higher temperature rise of rotor can result in permanent magnets demagnetization and motor itself breakdown. Nationwide studies of the effects of pole-slot combination on stator MMF harmonics indicate that PMSMs with 1/2 slots per phase per pole are preferred due to a less MMF harmonics than others in order to lower rotor loss. Meanwhile, if interior permanent magnet (IPM) structure is selected for rotor, a better flux-weakening ability can be achieved [2-4]. However, a larger cogging torque and back EMF harmonics of IPM motors with 1/2 slots per phase per pole than the other FSCW motors results in greater torque ripple, which can further brings vibration and acoustic noise problem. When the motor load is small, cogging torque is the dominant source from all the components of torque ripple. The interaction of a few back EMF harmonics and input current generate torque ripple even if the injected current can be controlled as ideal sinusoidal wave. This paper investigates the rotor-shape optimization method for IPM motors with 16 poles/24 slots (1/2 slots per phase per pole) in detail to improve both cogging torque and back EMF wave, and finally achieve the purpose of optimizing torque ripple. Different from the previous contributions, a simplified rotor-shape optimization method for IPM motor is proposed by the combination both shape function optimization of rotor surface and PM shaping technology, which can effectively decrease the optimization parameters of rotor to improve the optimization efficiency. II. BACK EMF AND COGGING TORQUE ANALYSYS A.MMF harmonics and Back EMF analysis Based on the principle of winding function, the winding factor is analyzed for a unit motor with 2 poles/3 slots. It can be revealed that the winding factor of 5th and 7th order harmonic is 0.866 as equal to the fundamental order. Meanwhile, the notable 5th and 7th EMF harmonics are induced. Worthy of mention is that the MMF harmonics of 2 poles/3 slots are an integral multiple of the number of pole pairs. For motors with q less than1/2, excepting the MMF harmonics with an integral multiple of the pole pair number of the motor, the motor also contains rich non-integer multiple space harmonics called sub-harmonics, which is a significant characteristic of FSCW. B.Cogging torque analysis Based on the visual displacement approach, cogging toque order is the LCM of slot number and pole number. According to the orthogonality of trigonometric function, only when the indexes of two factors are identical to each other, the integral results are not zero. For the motor with 1/2 slot per phase per pole, the basic order of cogging torque is 6, so the 6th and 12th order can be as cogging torque dominant components. III.ROTOR-SHAPE OPTIMIZATION METHOD A. Optimization method A simplified rotor-shape optimization method for IPM motor is proposed by the combination both shape function optimization of rotor surface and PM shaping technology. For reducing the number of parameters and improving optimization efficiency, an modified inverse cosine function as the optimization function for rotor surface, at the same time, the PM shaping technology is employed to further improving the cogging torque and back EMF wave,and suppressing the torque ripple. The related structure and optimization parameters are illustrated in Fig. 1. During the optimization process, the stator is assumed to a slotless solid without regard for the slot effects. B.Optimization results The optimization results are summarized in Table I, and cogging torque for the IPM motors is shown in Fig. 3. Such results can indicate that the optimized machine owns the lowest cogging torque, agrees well with that the flux density analysis aforementioned. IV.EXPERIMENT VERIFICATION A prototype machine as the results of optimization is manufactured shown in Fig. 3, in which (a) shows the modified inverse cosine shape for rotor core and corner-cut permanent magnet poles. Back EMF waveforms @320rpm of measure and FEA are compared in Fig. 4. It can be found that the test result agrees with the simulation very well. The *THD* of the test EMF waveform is only 1.76%, conforming to the value of 1.8% in Table I. It is clear that the optimized rotor reduces the EMF harmonics obviously. More experiment will be listed in this Section. V. CONCLUSION 1) The 3rd, 5th and 7th harmonics of airgap flux density are the main cause of the cogging torque, among which the 3rd harmonic is the dominant for IPM motor with 1/2 slots per phase per pole. 2) The simplified optimization method can effectively improve the both back EMF and cogging torque problems, and further reduce torque ripple of IPM motor with 1/2 slots per phase per pole. The *THD* of no-load EMF is 1.76%, and the cogging torque is 0.687% relative to the rating torque.

AU-14. Design for an Six-Phase Synchronous Reluctance Motor Mounted with Centrifugal Compressor Using Multiobjective Optimization Methods.

C. Lin[1] and C. Hwang[2]
1. Electrical Engineering, National United University, Miaoli, Taiwan;
2. Department of Electrical Engineering, Feng Chia University, Taichung, Taiwan

This paper describes a two-step design using optimization method for a six-phase synchronous reluctance motor mounted with a centrifugal compressor to achieve minimum cost, lower torque ripple, maximum efficiency and higher power factor. In the first-step optimization, the multiobjective design of adopted altered bee colony optimization (BCO) and Taguchi method combined with finite element analysis (FEA) are used for optimizing the barrier shape and layer number in the rotor to reduce torque ripple and raise power factor. In the second-step optimization, the adopted multiobject design method can be emplyed for optimizing the geometry of stator to achieve minimum cost and maximum efficiency. Experimental results show that these techniques can not only improve the efficiency and power factor but also reduce the material cost and torque ripple. The multiphase machine offers numerous advantages over the conventional three-phase motor drives such as increased torque per ampere for the same volume machine, reduction of the stator current per phase, improvement of torque density and increase of the fault tolerance [1-2]. Some of the most suitable applications are electric, hybrid electric vehicles [3] and ship propulsion [4]. An multiobjective optimization design of a six-phase synchronous reluctance motor applied in a centrifugal compressor provides an important role in helping the consumption systems. The factors of design optimization in the six-phase synchronous reluctance motor are minimizing material cost, minimizing torque ripple, maximizing efficiency, and maximizing power factor. One of the popular design methods of the electromagnetic devices is the use of finite-element analysis (FEA) coupled with optimization algorithms. However, the classical optimization algorithms, such as deterministic and stochastic methods, seem to be not very efficient by using the FEA because it needs longer computing time. Therefore, a multiobjective optimization design of a six-phase synchronous reluctance motor used in both the altered bee colony optimization (BCO) [5], [6] and the Taguchi method [7], [8] with FEA [9], [10] in practical methodology is applied in a centrifugal compressor system. In this paper, the motor is rated at a power of 3kW, rotating at 1800r/min. The initial design of the motor consists of a stator having 36 slots that carry two-layer windings, as shown in Fig. 1 and Table I. The losses of the motor include iron loss in the stator, copper loss in the winding, eddy current loss in the rotor, and rotational losses due to friction and wind resistance. The iron and copper losses were the dominant contributor in a centrifugal compressor. The finite-element method with the measurement that combined the BCO and the Taguchi method is a very efficient and effective approach in the robust design of a high-performance motor. This paper presents the optimization design of a six-phase synchronous reluctance motor using two-stage optimization processes, which mainly depends on the stator and rotor regions between cost and efficiency. The stator region is applied to reduce the use of the iron and the winding to minimize cost and maxmimize efficiency in the first stage, while the rotor parameters are kept unchanged. An optimization design based on the altered BCO and the Taguchi method with FEA is employed to further enhance the machine performance. The Taguchi method can optimize the machine parameter of performance characteristics in electrical discharge machining. The experimental results are then converted into a signal-to-noise (S/N) ratio. The S/N ratio can be used to measure the deviation of the show characteristics from the desired values. In the second-stage optimization, the objectives are the maximization of power factor and minimization of toque ripple. while the stator parameters are kept unchanged. An optimization design based on the altered BCO and the Taguchi method with FEA is employed to further enhance the machine performance. In summary, it is seen that the two-stage optimization can reduce both cost and torque ripple, and further increase efficiency and power factor from the experimental values. Finally, the photo view of a six-phase synchronous reluctance motor is shown Fig. 2. The views of stator, rotor and winding combination in the six-phase synchronous reluctance motor mounted with a centrifugal compressor is shown in Fig. 2(a)–(b). This paper has presented an optimization design using the altered BCO and Taguchi method with FEA for tacking multiobjective optimization problems on a six-phase synchronous reluctance motor mounted with a centrifugal compressor compressor. The results of this paper confirm the effectiveness of the proposed technique for obtaining lower cost and better performance characteristics. This technique can be applied to solve multiobjective optimization problems of any electromagnetic devices.

Initial design of motor specifications

Parameter	Value
Rotor outer diameter [mm]	37.5
Stator outer diameter [mm]	72.5
Air gap length [mm]	0.5
Stack length [mm]	46
Layer number of barrier rotor	4
Stator slot number	36
Pole number	4
Steel material	50CS600

AU-15. Design and investigation of a V-shaped Permanent Magnet Vernier Motor with enhanced Flux-Modulated effect and Low Torque Ripple.

Y. Chen[1] and *L. Quan*[1]
1. Electrical Engineering, School of Electrical and Information Engineering,Jiangsu University, Zhenjiang, China

I. Introduction Vernier permanent magnet (VPM) machines have attracted more and more interest and attention, which have been considered as one of promising candidates for direct-drive applications, such as electric vehicles (EVs) and wind power generation [1]. As one of the new type of flux-modulated machines, the VPM machine not only has a relatively simple geometry structure of only single PM rotor and one modulating stator, but also possesses abundant harmonic contents in the air-gap magnetic field to realize the flux-modulated effect. Based on such concept of the flux modulation, many various VPM machine topologies are proposed and studied in recent years. Generally, the competitive torque characteristic can be achieved in existing studies, such as the surface-mounted VPM machine and spoke type VPM machine [2], [3]. However, because of the inevitable internal and external flux leakages in above mentioned VPM machines, the PM utilization and torque ripple of them will be affected to some extent. In addition, from existing studies, the utilization of fundamental and high-order harmonics in air-gap magnetic field are usually taken into consideration, while the low-order harmonics with high amplitude are neglected. It is worth noting that the effective utilization of low-order harmonics will more effectively enhance the machine toque capability, which offers a new path for further improving the torque density of the VPM machine. Hence, how to design a high torque density VPM machine with high performances is becoming a hot issue and research orientation in motor filed. In this paper, based on the design concept of flux modulation, a V-shaped permanent magnet vernier (V-PMV) motor is proposed, where the effective working harmonic are fully utilized. And by utilizing the unique V-shaped PM topology in rotor, the flux leakage phenomenon can be avoid effectively. It provides the possibility for the proposed motor achieving low torque ripple, high torque density and high efficiency. II. Motor Topology and Features To extensively explore the performance advantages of the V-PMV motor, the flux-concentrating VPM (FC-VPM) machine of [3] is selected purposely and designed with the same size for fair comparative analysis. The specific motor structures of the proposed V-PMV motor and FC-VPM motor are respectively shown in Fig. 1 (a) and (b). From the figures, the main differences between the two motors are the different PM topologies in rotor and different stator tooth designs. To the former, the spoke-type PM topology of the FC-VPM motor will bring up an external flux leakage, while the V-shaped one can artfully solve such problem. It contributes to improving the machine torque characteristics to large extent. For the latter, the V-PMV motor uses the split-slot design, which aims at changing the flux-modulated form for obtaining an enhanced flux-modulated effect and reducing the torque ripple. Fig. 1 (c) and (d) depicts the no-load flux distributions of the two motors. It can be found that, as expected, the external flux leakage is avoided in the proposed V-PMV motor. At the same time, the maximum flux density of stator teeth in the proposed motor is under 1.8T, while the local flux density of that in FC-VPM motor is exceeded 1.8T. It indicates that the proposed V-PMV motor has a relatively low magnetic saturation in operation. III. Results For obtaining optimal machine performances of the V-PMV motor, the influences of some key design parameters on output torque are investigated, such as slope angle of PMs s_v and slot width h_{slot}, as illustrated in Fig. 2 (a) and (b). After the parameter designs, the no-load air-gap flux density curves of the V-PMV motor and FC-VPM motor are calculated and compared in Fig. 2 (c). It can be seen that the peak value of the air-gap flux density in the V-PMV motor is 1.7T, while that of the FC-VPM motor reaches 1.9T. It agrees with the results from Fig. 1 (c) and (d). The corresponding harmonic spectrum analysis of air-gap flux density is given in Fig. 2 (b). Obviously, under the same volume of PM, the amplitude of the fundamental and high-order harmonic of the V-PMV motor are higher than the FC-VPM motor, and the low-order harmonic with high amplitude is also utilized in the V-PMV motor. It means that the PM utilization is improved effectively by an enhanced flux-modulated effect in the V-PMV motor. In addition, the no-load back-EMF and steady torque of the two motors are also compared in Fig. 2 (e) and (f). It can be seen from Fig. 2 (e) that the V-PMV motor possesses a symmetrical and sinusoidal back-EMF waveform, where its amplitude is larger than that of the FC-VPM motor. Then the comparison of the torque performances is presented in Fig. 2 (f). It can be observed that the average torque of the V-PMV machine is 102.9 Nm, which is about 24.4% bigger than that of the FC-VPM motor. Meanwhile, the torque ripple of the proposed design is only about 35.2% of the FC-VPM motor, achieving the small value of 0.012. In conclusion, the above study results reveal that the proposed V-PMV machine can offer a high PM utilization and low torque ripple. More detailed theoretical analysis and experimental results will be given in full paper.

AU-16. A Novel Wide Speed Range Permanent Magnetic Machine Based on Mechanical Flux Weakening Control.

Y. Mao[1] and *S. Niu*[1]
1. Electrical Engineering, The Hong Kong Polytechnic University, Hong Kong, Hong Kong

I. Introduction Permanent magnetic machine which has many advantages such as high power density, lower friction loss and fast dynamic response becomes very attractive in EVs propulsion [1-2]. For the purpose of entirely replace fuel cars by EVs, there are many things that to be improved. One of the most important issue is to increase EV's speed limit. If the machine need to run in a high speed level, two approaches can extend the maximum speed under constant power. One is to increase the drive's output voltage, another one is to carry out flux weakening controls to reduce the back emf. Since the drive's output voltage is limited by the DC source, usually the flux weakening control is adopted. But for the permanent magnetic machine, flux weakening control is very difficult because that permanent magnet provide constant flux distribution intrinsically. Nevertheless, many researches have been done to achieve flux weakening solution in PM machine. In [3] a hybrid-excited dual-PM machine for electric vehicle propulsion is proposed. In this design both ac current and dc current are employed where the ac component is used to produce the rotating armature field, and the dc bias current is used for the flux regulation. But in these designs, there exist the risk of demagnetizing the PM material irreversibly. More than that, the flux weakening effect is achieved at the expense of cutting down the torque density. To solve these problems, a novel wide speed range PM machine based on mechanical flux weakening control is proposed. In this machine, the flux weakening effect is achieved by adjusting the rotation angle of the inner rotor mechanically. To control the inner rotor, an extra machine can be employed and connected to the inner rotor. The electromagnetic characteristics of this machine are also analyzed. II.Configuration and Working Principle of The Proposed Machine The topology of this machine is shown in Fig. 1. The machine is composed one stator, where two armature winding are housed in, a common machine rotor, and an inner rotor for mechanical control. Wherein the Winding I interacts with the inner and outer rotor simultaneously due to flux modulation effect. Winding II interacts with the outer rotor only. When turning the inner rotor for a small angle, the initial phase of the back EMF of the Winding I is changed with its amplitude stays constant. The initial phase and amplitude of the back EMF of the second winding both remains unchanged. So after series connection of the two winding, the magnitude of the back EMF can be changed. By rotating the inner rotor little by little, the complex back EMF of two winding can change from 0 to the maximum value. Thus according to the speed requirement, it can be adjusted to realize the wide speed range control. The rotors of this machine have consequent-pole PM array which is constituted by radially outwardly directed magnetized permanent magnet segments and ferromagnetic segments. Wherein the number of the permanent magnets of the inner rotor $N1$, the number of the permanent magnets of the outer rotor $N2$, and the number of armature magnetic pole pairs of the Winding I $P1$ satisfy the equation:$N1 = N2\text{-}P1$.The number of the permanent magnets of the outer rotor $N2$ and the number of the armature magnetic fields of the Winding II $P2$ satisfy the equation:$N2 = P2$. The invention also discloses several methods for controlling the rotation of the inner rotor by applying the extra motor or by adding the inner stator. The invention provides a continuous and smoothed speed control for the hybrid electric vehicle and the wind power generation device. Fig. 2 shows some scheme of the complex machine. In Fig. 2 (a), an inner stator is employed. The inner stator winding can interact with the inner rotor so as to give electric control of the rotation of inner rotor. In Fig. 2 (b), the inner rotor may be stretched in the axial direction by a certain length with the axial lengths of the outer rotor and the outer stator stayed unchanged. The outer rotor is sleeved on the inner rotor and the outer stator is sleeved on the outer rotor. The inner stator is coaxial with the outer rotor and the outer stator and arranged side by side. The inner stator is sleeved on the inner rotor (elongated axial length portion). In Fig. 2 (c), the motor adopts a coaxial disc type structure. III.Performance Analysis The back EMF waveform of the machine is calculated based on finite element method. Fig. 3 shows the waveform of both winding, and the sum of the value are also depicted in the same figure. It can be seen that by rotating the inner rotor step by step, the back emf of the sum of Winding I and Winding II is changed. The back EMF spans from 10V to 40V. IV.Conclusion This paper proposed a wide speed range PM machine based on mechanical flux weakening control. The conventional field-weakening method for permanent magnet motors is by adding field windings which may cause demagnetization of the PM and add more loss. This invention neither involves any field windings nor a very complicated structure. More than that, this machine has a wider speed control range than traditional field excitation machine.

AV-01. CoFe–Based Amorphous Microwires for GMI Sensor Applications.

P. Sarkar[1,2], F. Yuan[3], M. Lai[2], J. Jeng[4] and C. Lu[1]
1. Department of Mechanical Engineering, National Taipei University of Technology, Taipei, Taiwan; 2. iSentek Inc, Taipei, Taiwan; 3. iSentek Inc., New Taipei City, Taiwan; 4. Department of Mechanical Engineering, National Kaohsiung University of Applied Sciences, Kaohsiung, Taiwan

Magnetic sensors and transducers play an essential role in modern technologies involving self-monitoring and control. They are widely used in fields including Non-Destructive Testing and Evaluations and Bio-magnetic inspections etc. A wide range of magnetic sensors, such as fluxgate sensors, induction sensors, Hall Effect sensors, Giant magneto-resistive (GMR) sensors and superconducting quantum interference device (SQUID) gradiometers are available. Recently, the area of sensor development traversed a new milestone with the introduction of Giant magneto-impedance (GMI) based sensors. It has attracted considerable scientific and technological interest especially because of its ultra-high sensitivity allowing high precision magnetic field sensing and as an additional tool to investigate soft magnetic materials properties of other materials, e.g. ferritic steel. Amorphous materials with tunable shapes and magnetic properties can be designed for a wide range of applications. In this regard, amorphous alloys are studied in different forms including thin films [1], ribbons [2], wires [3], powders [4] and recently in the form of rods [5]. The characteristics which make the amorphous alloy superior magnetic materials compared to their crystalline counterpart are: (i) high magnetic permeability due to the negligible magnetocrystalline anisotropy which is closely related to the small coercive force, (ii) high electrical resistivity that reduces the eddy current losses and (iii) low magnetic noise owing to the absence of grain boundaries. Moreover, excellent corrosion resistance makes it a perfect candidate for uses in tough environments. In the present work, investigation has been carried out on the development of amorphous metallic materials in the form of microwires having diameter of around 100 micrometer for GMI magnetic sensing applications. The wires are fabricated through rapid solidification route using in-rotating water quenching technique. The objective of the work is to optimize CoFe-based amorphous microwires for GMI sensing applications. Alloy compositions $(Co_{94}Fe_6)_{72.75}Si_{12.25}B_{15}Cr_0$, $(Co_{94}Fe_6)_{72.75}Si_{12.25}B_{12.75}Cr_{2.25}$, $(Co_{94}Fe_6)_{72.75}Si_{12.25}B_{11.25}Cr_{3.75}$, $(Co_{94}Fe_6)_{72.75}Si_{12.25}B_{10}Cr_5$ having nearly zero-magnetostrictive microwires were designed to develop highly magnetic sensitive wires. The alloy was prepared from pure materials by vacuum arc melting technique. The developed wires have diameter of 110 μm. The Curie (730K) and crystallization temperature (762K) were measured via standard measuring units while amorphous nature of as-quenched materials was confirmed through X-ray diffraction and Differential Scanning Calorimetry observations. The GMI property of as-quenched and annealed wire was investigated using an automated computer-controlled GMI measurement system with conventional four-probe technique. The GMI profile was measured for different driving frequency (0.5-10MHz) at driving current amplitude 3 mA. The GMI studies have been performed with variation of driving frequency at a fixed driving current of 3 mA. The maximum GMI ratio was observed at 5 MHz about 125% with Cr=0 sample with single peak structure (Fig-1 Inset). The GMI ratio has increased with the content of Cr. A maximum GMI ratio of about 430% was achieved in the wire with Cr = 2.25 with double-peak structure (Fig-1). The coercivity also reduced from 0.687 A/m to 0.389 A/m. Post annealing were found to further enhance the GMI ratio. The annealing temperatures 650K, 750K, and 800K were selected based on the Curie temperature of the material 730K: below T_C the wires remains amorphous only strain relaxation or recovery takes place, nano-crystallization occurs in wires annealed at temperature around T_C. The maximum GMI ratio for the wire with Cr = 2.25 at 5 MHz enhanced from 430% to about 650% when annealed at 750K for 5-minutes. In terms of GMI ratio, the sensitivity of 9.47% per A/m has been obtained in as-cast condition which improved to 14.5% per A/m for annealed sample. The sensitivity of around 802 V/T has been achieved as the maximum with the optimized frequency of 5 MHz and driving current amplitude of 3 mA. The Noise level of the microwires measured around 10 nT/√Hz at 1Hz. Features of high GMI ratio, high operating frequency, high sensitivity and low noise of the developed microwires highlight the potential of the presented wires for magnetic field sensor with ultra-high sensitivity.

AV-02. Stress Induced Domain Wall Motion in FeCo microwires for Energy Harvesting.

S. Bhatti[1], C. Ma[2], X. Liu[2] and S. Piramanayagam[1]
1. School of Physical and Mathematical Science, Nanyang Technological University, Singapore, Singapore; 2. Department of Electrical and Computer Engineering, Shinshu University, Nagano, Japan

In spintronics, the motion of domain walls is usually governed by applying external polarized currents [1] or magnetic fields [2]. Such domain wall motion is used mainly for logic or memory applications [3]. Domain wall motion can also be used for energy harvesting by converting stress into changes in magnetization and thus into electrical voltage. In the energy harvesting investigations reported so far, domain wall motion by stress is accomplished only in multiferroic structures, where stress was induced by providing an electrical energy to the ferroelectric layers [4]. A peculiar method exhibiting mechanical stress regulated motion of domain walls in a pure magnetic structure has been proposed by us. This approach relies on the deposition of magnetostrictive FeCo with induced magnetic anisotropy on a polyimide flexible thin film. The use of flexible substrates with low Young's modulus and the special magnetic stack enabled us to achieve significant magnetization rotation or domain wall motion. The changes in the magnetization angle or the domain wall motion induced voltage in the pickup coils. In order to induce the efficiency of such devices, an increase in thickness is speculated to give a higher induced voltage in the pickup coils. However, at the same time, it warrants a detailed study, as increasing thickness could lead to circular magnetization and contrarily, a reduced flux. Therefore, we have carried out a detailed study on the effect of thickness of FeCo microwires on the extent of change in magnetic properties under applied stress. For the experiment, microwires of the type CoNi/FeCo/CoNi with different thicknesses were deposited by facing targets sputtering (FTS). Using FTS, an anisotropy was induced in transverse direction to the length of the microwires. We also deposited microwires of FeCo with different thicknesses varying as 30, 40, 50 and 60 nm to measure the effect of thickness in the extent of change of magnetic properties. We pasted the samples to concave or convex curved surfaces with the radii of curvature of 16 mm and 18 mm to measure the effect of stress under different compressive and tensile stresses, respectively. Bitter Patterns technique using Kerr microscope was used to observe the domain wall motion in the microwires. To understand the effect on the magnetic properties of the microwires with different thicknesses under applied stress, a custom made micro-MOKE was used. Figure 1 (a) shows the bitter patterns of the 30 nm thick as deposited FeCo microwires and Fig 1 (b) shows the microwires with applied stress. Under small stress, rotation of domain walls was observed, whereas application of large stress resulted in diminishing of domain walls, as can be seen from fig. 1(b). Figure 1 (c) to (e) show the hysteresis loops of 30 nm thick microwires, measured using the micro-MOKE. Alteration of axial magnetization anisotropy was noticed under applied stress, changing easy axis to hard axis and vice-versa, as shown in fig. 1. From the micro-MOKE results, it can be inferred that the motion of domain walls under applied stress results due to the stress induced shifting of the easy axis. To understand the effect of the varying thicknesses of FeCo on M_rt (product of the magnetic remanence and thickness), we measured the hysteresis loop of as deposited samples. We observed an increase in the M_rt value (as expected) and coercivity at larger thickness of the sample. Then we measured the effect in the coercivity of FeCo microwires with different thicknesses under same stress values. It can be seen from the fig. 2 that the change in the coercivity of FeCo microwires increases as the thickness of the FeCo increases. Moreover, the effect of applied stress induced to the microwires increases as the thickness of the deposited FeCo increases, which can be calculated by the Stoney's formula[5]. We speculate this enhancement in the induced stress is the reason behind the increase in coercivity change with thickness. Such enhancement in the magnetic properties is speculated to give rise to a higher induced voltage in the pickup coils. The results of this experiment open the gateway to stress controlled motion of domain wall, which in future, can be used for energy harvesting.

AV-03. Magnetic Property of Amorphous Magnetic Thin Ribbon and its Laminated Bulk under the Tensile and Compressive Stress.

T. Mizuta[1], Y. Tani[1] and K. Fujiwara[2]
1. Mitsubishi Electric Corporation, Amagasaki, Japan; 2. Doshisha University, Kyotanabe, Japan

In the context of energy conservation, it is required to enhance the efficiency of electrical motor in recent years. The magnetic property is closely related to the efficiency of the electrical motor, thus it is necessary to clarify the magnetic property for the design of energy-efficient motor. It's known that the magnetic property deteriorates under distortion and residential stress by punching, press fitting and lamination process. Therefore, there is a large difference between the efficiency of design and that of actual measurement. To reflect the influence of distortion and residential stress, there are several reports of measuring magnetic properties of Fe-Si steel sheet under stress condition[1]-[2] and of estimating motor characteristics taking account of stress distribution[3]. On the other hand, amorphous magnetic materials have been attracting a lot of attention as a core of motor because of its high permeability and low iron loss. There are some reports of applying amorphous magnetic thin ribbon to motor core[4]-[5]. Although it is more sensitive to distortion and residential stress because of its high magnetostriction, magnetic property of single amorphous thin ribbon is not measured under tensile and compressive stress without loading any unnecessary stress. There is the report of measuring magnetic property of amorphous alloy under stress[6]. However, bending stress is not taken into account. In this paper, we develop the measurement device with stress loading mechanism for magnetic thin ribbon and laminated bulk. We measured magnetic property of amorphous thin ribbon and laminated bulk under up to 40MPa tensile and compressive stress. The increase of iron loss by compressive stress and lamination is discussed. Fig.1 shows the measuring device with stress loading mechanism for magnetic thin ribbon. The size of specimen is W30mm×t0.025mm×L220mm. Specimen is set on the holder which is grooved as much as thickness of magnetic thin ribbon and pressured by surface pressure load mechanism(surface pressure load mechanism 1) through the holder to prevent the specimen from buckling during measurement. There is another surface pressure load mechanism(surface pressure load mechanism 2) that pressure the specimen through the york. The direction of loading stress is the same with the direction of magnetization. The loading stress is controlled to the command value by feedback regulation. We also develop the measuring device with stress loading mechanism for the laminated bulk. The size of specimen is W10mm×t10mm×L100mm. The specimen is laminated of which around 400 pieces of magnetic thin ribbons are stacked and glued. The only tensile stress can be applied by the measuring device for the laminated bulk. We measured the magnetic properties of amorphous thin ribbon and its laminated bulk under stress by our developed measuring devices. Fig.2 shows the iron loss results of the thin ribbon and laminated bulk at 0.5T and 50Hz. The plus stress means tensile stress and the minus stress means compressive stress. The iron loss of thin ribbon increases with the compressive stress and decreases with the tensile stress. Comparing the iron loss of thin ribbon and laminated bulk at no stress, the iron loss of laminated bulk is twice larger than that of thin ribbon. It is inferred that approximately 10MPa compressive stress is caused by gluing and it deteriorates the magnetic property of laminated bulk. The iron loss increase ratio of laminated bulk under the compressive stress is larger than that of thin ribbon. More detailed results will be presented in the conference.
ACKNOWLEDGMENTS This paper is based on results obtained from the Future Pioneering Program "Development of magnetic material technology for high-efficiency motors" commissioned by the New Energy and Industrial Technology Development Organization(NEDO).

Application of silicon carbide (SiC) and gallium nitride (GaN) based power devices with lower on-resistance and higher switching frequency, compared to the silicon(Si)-based power devices to DC-DC converter, enables to realize a compact, lightweight and high efficient switching converter at a switching frequency beyond 1 MHz [1], [2]. To realize such a DC-DC converter, magnetic components with small core loss are strongly required. We developed a composite magnetic core consisting of 2.56 μm-diameter iron-based amorphous alloy (Fe-AMO) powder and epoxy–resin, which had low core loss at MHz band [3]. In addition, we proposed the method of forming the surface-oxidization layer for Fe-AMO powder to decrease the eddy current overlapped between adjacent Fe-AMO powders in the composite magnetic core [3]. The fabricated 91.5 wt.%-AMO (2.56 μm-diameter)/epoxy composite magnetic core exhibited low core loss at MHz band but low relative permeability of about 10. The purpose of this study is to increase the permeability of such the composite magnetic core with low core loss, we investigated an effect of mixing Fe-AMO powder at different particle size distribution on the increase of packing density of Fe-AMO powder in the composite core. By using a hexagonal closely-packed (hcp) structure model, the appropriate different Fe-AMO particle diameter was estimated to obtain higher volume fraction of Fe-AMO powder for the fabrication of higher permeability composite core. When the spherical shape Fe-AMO particle with a single-size particle is assumed to be located according to the hcp structure in the composite core, there are two kinds of gaps (octahedral and tetrahedral gap) in the hcp structure. When the appropriate single-size Fe-AMO particles with smaller size are located at both octahedral and tetrahedral gap of the hcp structure, a theoretical volume fraction of the Fe-AMO powder in the composite core is estimated to be 76 %. We used a 2.56 μm median-diameter Fe-AMO powder (2.56 μm Fe-AMO) as the particles located at both octahedral and tetrahedral gap of the hcp structure because it was finest atomized-powder avaliable, where the particle size of Fe-AMO powder for making the hcp structure was calculated to be 11.39 μm from the hcp structure model. We used 10.94 μm median-diameter Fe-AMO powder (10.94 μm Fe-AMO) for making the hcp structure, which was closest to the calculated one. Fig. 1 shows the volume fraction and the permeability of a composite magnetic core with alternating mixing rate of 2.56 μm Fe-AMO and 10.94 μm Fe-AMO. The maximum volume fraction of Fe-AMO powder in a composite magnetic core was 71 vol.% when the Fe-AMO powder weight ratio of 25 wt.% of 2.56 μm median size and 75 wt.% of 10.94 μm median-size, which was 5 % lower than the theoretical volume fraction of 76 % because of the particle size distribution of Fe-AMO powder not having single-size particle. The relative permeability of the composite core with the maximum volume fraction of Fe-AMO powder was 21, which was 2.1 times higher than that of compsite core using 2.56 μm Fe-AMO only. The core losses were also evaluated using a BH analyzer (IWATSU, SY-8218). Since the dynamic losses, namely the eddy current loss in the composite magnetic core and residual loss in the Ni-Zn ferrite core, were dominant at around MHz band or above, where the dynamic loss was defined as W_{c0}-W_{h0}, W_{c0}; core loss per cycle and W_{h0}; hysteresis loss per cycle. In this study, the dynamic losses were evaluated for three kinds of the composite magnetic core with the maximum volume fraction 71 % of Fe-AMO powder, with 2.56 μm Fe-AMO only and with 10.94 μm Fe-AMO only. For comparison, the residual loss of the Ni-Zn ferrite core made by Fair-Lite was also evaluated. Fig. 2 shows frequency versus the dynamic losses per cycle of four kinds of the magnetic core under the constant maximum flux density B_m of 20 mT. From Fig. 2, at around 1MHz the composite magnetic core with the maximum volume fraction of Fe-AMO powder or with 2.56 μm Fe-AMO only exhibited the smallest dynamic loss than those of others. At 3 MHz frequency, the composite magnetic core with 2.56 μm Fe-AMO only exhibited the smallest dynamic loss. On the other hand, it was found that the dynamic loss of the composite magnetic core with the maximum volume fraction of Fe-AMO powder was closed to that of the composite core with 10.94 μm Fe-AMO only at 3 MHz. Such a dynamic loss measured at 3 MHz in the composite magnetic core with the maximum volume fraction of Fe-AMO powder was considered to be dominated by 10.94 μm Fe-AMO with larger eddy current inside. At around 1 MHz or below, the composite magnetic core, with the Fe-AMO powder maximum volume fraction and consisting of 2.56 μm and 10.94 μm Fe-AMO powder, had both 2.1 times higher permeability and the dynamic loss was similar to the conventional 2.56 μm Fe-AMO composite magnetic core [3].

AV-05. Analysis of cutting technology influence on the magnetic anisotropy in grain-oriented steel based on the orientation distribution functions.

G. Paltanea[1], V. Manescu (Paltanea)[1], L. Dumitru[1] and H. Gavrila[1]
1. Electrical Engineering Department, University Politehnica of Bucharest, Bucharest, Romania

Grain-oriented electrical steel alloys have superior magnetic properties in the rolling direction (RD), due to its metallurgically induced Goss texture. The increased number of grains that have their easy magnetization axis of [001], oriented parallel to the RD, determines high values of the magnetic permeability and low energy losses. Anisotropy of their magnetic properties is intensively exploited nowadays, in order to manufacture electrical devices with high-energy efficiency [1, 2]. The magnetic cores of these electrical devices have parts with different orientations with respect to the RD, so the electrical engineers require knowing the path, where the magnetic reluctivity has a minimum value. A drawback of this approach is that the anisotropy of the grain-oriented silicon iron alloys is usually neglected and the catalogs provide only measured data for the RD and for the direction perpendicular to the rolling direction (TD) [111], in a good accordance with the international standards (EN 10107, JIS C 2553 and ASTM A876) [3]. The grain-oriented electrical steel sheets are generally cut through mechanical punching technology, which leads to induced mechanical stresses near the cut edge that influences the crystallographic texture and the magnetic properties of the device cores. The laser technology determines a burr free cut edge, which does not present mechanical deformations, while the magnetostrictive effect is absent in this area. The main disadvantage of the laser cutting is the induced thermal effect in the cutting zone that could have a negative influence on the grain orientations and, an unwanted oxidation could appear at the cut edge [4]. In the paper there were analyzed MOH commercially grain oriented samples with a thickness of 0.27 mm. Strips of 300 mm × 30 mm were cut through mechanical punching and laser at different angles ϕ with respect to the rolling direction, from 0° to 90° with a step of 15°. The samples were characterized with a unidirectional Single Strip Tester at a measuring frequency of 50 Hz. Pole figures and orientation distribution functions (ODFs) are considered today important in the polycrystalline material texture theory. It becomes almost a rule the fact that the magnetic properties of the crystalline materials are directly linked to their crystal structure and the crystal orientation is very important. The grain-oriented silicon iron strips are characterized by orthorhombic symmetry of body centered cubic crystals and the Goss texture (110)[001] samples could be analyzed with the ODFs theory. In [5, 6] it is put in evidence that all magnetic properties A could be described with three ODF parameters as $A = A_0 + A_1\cos(2\phi) + A_2\cos(4\phi)$, because they are usually a 4th order properties [5, 6, 7]. In [5, 7] is proposed a method to determine these three ODF coefficient, by considering the experimental data for the strips cut at 0°, 45° and 90° in the following assumption: $A_0 = 0.25[A(0°) + A(90°) + 2A(45°)]$, $A_1 = 0.5[A(0°) - A(90°)]$, $A_2 = 0.25[A(0°) + A(90°) - 2A(45°)]$. In the paper were determined the normal magnetization curves at a frequency of 50 Hz and at imposed values of the magnetic field strengths H ranging from 50 A/m to 10000 A/m, in the case of each angle ϕ and both cutting technologies. The model input data were experimental values of the magnetic polarization J at fixed H in the case of ϕ equal to 0°, 45° and 90°. In Fig. 1 are presented the polar diagrams $J(\phi)$ at 200 A/m and 2500 A/m; the last value is very important, because the magnetic polarization J_{25}, measured for H = 2500 A/m, is a direct function of the crystallographic texture, and the grains are monodomenial [7]. It can be noticed that the magnetic polarization distribution versus the cut angle has a 2nd fold variation, in the case of low magnetic field and a 4th fold distribution for high field strengths, fact that make very suitable the equation presented in [5, 6, 7]. The worst magnetic properties are observed at ϕ = 60°, which is in a good accordance with the theory that indicates an angle of 54.7° [8]. For both cutting technologies, the best magnetic properties are observed in the case of samples cut parallel to the rolling direction. It is obvious that the magnetization process is influenced by the cutting technology: the laser cut samples magnetize harder than the punched ones. In Fig. 2 there is presented the reconstructed normal magnetization curves, for punched strips, in the case of ϕ = 30°, 60° and 75° for both cutting technologies. The three computed ODF parameters lead to a good approximation of the experimental data and the cutting process affects in a substantial amount in low magnetic field region. The power losses evaluation is also performed based on the same algorithm. Finally, a prediction of the power losses for different angles at an imposed applied magnetic field strength is presented in the paper. AV-06. Effects of Annealing in Magnetic Field or under Tensile Stress on the Magnetic Properties of Fe-based Amorphous Magnetic Material.

T. Todaka[1], I. Uesugi[1] and T. Sato[1]
1. Division of Electrical and Electronic Engineering, Faculty of Science and Technology, Dept. of Innovative Engineering, Oita University, OIta, Japan

I. Introduction: Amorphous magnetic materials have been widely used as a core material of power transformers to reduce iron loss due to their excellent soft magnetic properties [1]. Also, from recent requirements of low loss and high speed electrical motors, considerable attention has been given to the amorphous magnetic materials that the iron loss is about 1/10 of one of the electrical steel sheets. However they have issues that the building factor (B.F.) and the magnetostriction are very large in comparison with those of the grain-oriented electrical steel sheets. As a solution of these issues, it is known that magnetic annealing after the magnetic-core processing is effective for reduction of B.F. of amorphous magnetic materials. However, reports on the magnetic annealing conditions of amorphous magnetic materials are very few and in the present circumstances they have been decided with intuition or experience of engineers. In order to effectively utilize the amorphous magnetic materials, we have tried to make clear a suitable magnetic annealing condition in a magnetic field, such as the temperature and the retention time. Furthermore, effects of a tensile stress adding during the heat treatment on the magnetic properties of the amorphous magnetic materials are examined. In this paper, knowledges about the annealing retention time to reduce the B.F. and the effects of annealing under tensile stress are reported. II. Measurements: Fig. 1 shows a schematic view of a special apparatus, which can apply a magnetic field and a tensile stress to a piece of 60 mm x 305 mm amorphous sheet, during annealing. The apparatus was put into an electric furnace as it is and heat treatment was performed. The amplitude of the exciting magnetic field strength in DC was controlled to be 800 A/m, the temperature was 320 degree-C. The retention time was changed from 0 min to 150 min with 30 minute step. The tensile stress depending on the attached weights was also changed from 9.8 MPa to 49.0 Mpa with 9.8 MPa step. The measurements of magnetic properties of the amorphous sheet (2605HB1M, Fe-Si-B) were conducted with a shingle sheet tester (H-coil method). Sinusoidal magnetic flux density conditions from 0.1 T to 1.55 T per 0.05 T at 50 Hz were kept during the measurements. III. Results and discussions: Fig. 2 shows an example of the iron loss reduction after magnetic annealing (320 degree-C, 150 min, 800 A/m) comparing with as cast one. As shown in this figure, the iron loss could significantly reduce after the magnetic annealing. Amorphous state after the magnetic annealing was also conformed from the XRD pattern. Fig. 3 (a) shows the iron loss as a fiction of the alternating magnetic flux density of 50 Hz and the annealing time (retention time) and Fig. 3 (b) shows the iron loss as a fiction of the alternating magnetic flux density of 50 Hz and the tensile stress. As shown in Fig. 3 (a), the iron loss became smaller with the retention time. As for the hysteresis loops, it was observed that the coercive force became smaller after the magnetic annealing. The reason can be considered as position stabilization of magnetic domain walls during the magnetic annealing [1,2]. Similar tendency should be observed for the annealing under tensile stress without magnetic field. As shown in Fig. 3 (b), the iron loss became smaller by adding only tensile stress. In this case, an optimal stress condition was observed at 32.9 MPa. The tensile stress was also effective to stabilize domain walls; however too much stress became a cause to increase pinning sites. The detailed results for the conditions mentioned above will be shown at the presentation and in the full version of paper.

AV-07. Analysis of dynamic permeability and energy loss of ring-shaped Fe-Ga alloy.

L. Weng[1], W. Li[1], X. Cao[1], S. Liang[1] and B. Wang[1]
1. The State Key Laboratory of Reliability and Intelligence of Electrical Equipment, Hebei University of Technology, Tianjin, China

0. Introduction The dynamic permeability and loss of Fe-Ga alloy is an important index to determine the performance of Fe-Ga alloy. Permeability represents the ability of Fe-Ga alloy to conduct magnetic flux, and loss is the key factor affecting the operation performance of Fe-Ga alloy devices[1-2]. The high frequency-dependence characterization of ring-shaped Fe-Ga alloy including coercivity, loss and residual induction response to applied AC magnetic field is studied by Weng Ling[3]. The eddy current model to analyze the coercivity of ring-shaped Fe-Ga alloy at different heating temperatures is established by Grossinger R [4]. While they didn't analyze dynamic permeability which is important to design the Fe-Ga alloy transducers. In this paper, the dynamic permeability and loss model of ring-shaped Fe-Ga alloy based on the principle of electromagnetic is established. The results provide guidance for the design of high frequency Fe-Ga alloy transducers. 1. Dynamic Permeability and Loss Model of Ring-shaped Fe-Ga Alloy By the alternating magnetic field in the excitation coil induced electromotive force and Ohm's law can be obtained: $e=\mu_0N^2A\mu_m(\sin\delta+j\cos\delta)\omega I/l=(R+j\omega L)I$(1) From formula (1) can be obtained: $\mu'=\mu_m\cos\delta=Ll/\mu_0N^2A$(2) $\mu''=\mu_m\sin\delta=Rl/\mu_0N^2A\omega$(3) Where: *A* is the cross-sectional area of the ring-shaped sample,μ'is the real part of the complex permeability, it also known as elastic permeability. μ''is the imaginary part of the complex permeability, it also known as viscous permeability. As the phase difference between the voltage and current caused by the loss of magnetic core is δ, the loss factor, $\tan\delta=\mu''/\mu'=R/\omega L$(4) Through the above deduction, if the equivalent inductance and resistance of the ring-shaped Fe-Ga alloy are known, the variation of dynamic permeability and loss factor with frequency can be calculated by formula (2), (3) and (4). 2. Results and Analysis Using the equivalent inductance obtained experimentally, the elastic permeability of the ring-shaped Fe-Ga can be calculated from formula (2). The comparison between the model calculated value and the experimental measurement value is shown in Fig.1(a). When the magnetic field frequency is 1~12 kHz, the elastic permeability decreases greatly. When the magnetic field frequency is 12~28 kHz, the elastic permeability increases. Elastic permeability reflects the storage capacity of magnetic medium for magnetic energy. The calculated results of the model are basically consistent with the measured results, which verify the correctness of the model. Using the equivalent resistance obtained experimentally, the permeability of the ring-shaped Fe-Ga can be calculated from formula (3). The comparison between the model calculated value and the experimental measured value is shown in Fig.1 (b). As the frequency of the magnetic field increasing, the viscous permeability increases continuously. Viscous permeability characterizes the magnitude of the magnetic energy loss of the magnetic medium. The calculated results of the model are basically consistent with the measured results, which verify the correctness of the model. The loss factor that can be calculated from the formula (4). The change of the loss factor and relative loss with the frequency of the magnetic field is shown in Fig.2.As can be seen from Fig2, with the increase of the magnetic field frequency, the loss factor increases firstly and then decreases, finally it tends to be stable. While the relative loss shows a decreasing trend. The loss factor represents the size of the magnetic energy loss. The greater the loss factor, the greater the loss of magnetic energy in the magnetic medium. The intersection point of the relative loss and the loss factor curve represents the best working point of the Fe-Ga alloy device. It can be seen in Fig.2 that Fe-Ga alloy devices are at the best working efficiency when the magnetic field frequency is 3~4 kHz. Working in this frequency range, the ring-shaped Fe-Ga alloy device can minimize the loss of magnetic energy, Fe-Ga alloy medium magnetic energy storage capacity will not be too much. While the loss factor and relative loss are also in a balanced state, so Fe-Ga alloy devices maximizing the conversion of magnetic energy to other forms of energy can improve Fe-Ga alloy devices working efficiency. 3. Conclusions The elastic permeability, viscous permeability and loss factor of ring-shaped Fe-Ga alloy are calculated by the model. The correctness of the permeability model of ring-shaped Fe-Ga alloy is also verified by experiments. Finally, the optimum working magnetic field frequency of the ring-shaped Fe-Ga alloy device is about 3~4 kHz by analyzing the change of the loss factor and relative loss with the frequency of the magnetic field. The above theoretical analysis and experimental research provide a basis for the design of ring-shaped Fe-Ga alloy devices.

Introduction Helical nanostructures such as nanosprings (NSs) attract enormous attention owing to wide applications. In particular, magnetic helical nanosprings are promising among different systems, because of their additional advantage their motion can be controlled by magnetic field. As an example of application, under an external field, the helical NSs can be used as sensors, rotors and actuators [1]. We have presented the brief synthesis method for helical nanostructures and the difference of magnetic hysteresis behaviors [2]. In this study, we report magnetization reversal processes and magnetostatic interactions characterized of Co and CoFe NSs by first order reversal curves (FORCs) and micromagnetic simulations. Co and CoFe nanowires (NWs) were also fabricated and analyzed for comparison purposes. Experimental The NSs and NWs are fabricated by electrodeposition method utilizing anodized aluminum oxide nanotemplates which have nominal pore size of approximately 200 nm. Ag of 300 nm was deposited as a working electrode. The precursor solution is composed of cobalt sulfate heptahydrate, iron sulfate heptahydrate, vanadyl sulfate hydrate, L-ascorbic acid and a small amount of nitric acid to adjust acidity. However, Fe precursor was excluded for Co NSs and NWs. The NSs and NWs were synthesized under a constant current density. Magnetic properties were measured by vibrating sample magnetometry (VSM). Especially FORC analyses were employed to understand further magnetization reversal processes. Results and discussion A collection of electron microscopy images in Fig. 1 shows that NWs and NSs were uniformly synthesized into the nanotemplates [2]. To understand the interactions between neighboring NWs or NSs, the FORC method was used to observe the coercivity (H_c) and interaction field (H_i) distribution patterns. Magnetic fields in the parallel and perpendicular directions were applied. Compared to the NW array, the NS array shows unique distribution. The FORC diagram of parallel field to CoFe NS array has no distribution in H_i direction since there are a few interactions between neighboring NSs. In addition, defects, different length, and different H_c values of each NSs are responsible for long tail along the H_c direction. However, there is a large distribution in H_i direction due to interactions between the layers of the NSs themselves. The gaps between layers has more influence on magnetization reversal when perpendicular direction fields were applied to NSs.

Shaping of laminated magnetic cores always implies cutting of the sheets and ensuing degradation, via localized plastic deformation, of their soft magnetic properties. The performances of fully processed non-oriented (NO) Fe-Si laminations can, in particular, be seriously impaired by the cutting operations required to form the slotted stator core of rotating machines. Because of its applicative impact, this problem has been amply treated in the literature, with focus on the specific magnetic properties of the mechanically damaged band at the cut edge [1] and on the phenomenological retrieval of the overall loss behavior, either by numerical methods [2] or analytical formulations [3], employing a suitable high number of parameters, to be found by experiments. These reveal somewhat awkward procedures, often limited to the assessment of the degradation of the quasi-static magnetic behavior of the material. In this work, which provides an extensive set of experimental results on different types of non-oriented Fe-Si sheets, we aim at a simple phenomenological assessment of the degradation of magnetization curve and magnetic losses enforced by cutting. This is based on the idea that, although the induction in a cut strip sample is not uniform, we can nevertheless invoke an equivalent uniform induction for the dynamic magnetic behavior, while providing simple relationships for the evolution of magnetization curve and losses with strip width. Four types of commercial non-oriented Fe-Si sheets, of thickness 0.192 mm $\le d \le$ 0.638 mm were cut as strips of different widths (5 mm $\le w \le$ 60 mm), using both guillotine punching and water-jet method. The measurements were performed under controlled sinusoidal flux by means of a calibrated single-strip tester, from DC to the maximum frequency f_{max} = 2 kHz, at the peak polarization values J_p = 0.5 T, 1.0 T, and 1.5 T. The normal magnetization curve (J_p, H_p) exhibited, in all materials, the expected rightward shift in the *J-H* plane upon decreasing strip width, with coercivity and hysteresis loop area correspondingly increased. By using a simple scheme, where the work-hardened region of the strip is identified with two defined bands of width L_c running along the cutting line at the edges, we can express the dependence of the magnetization J_p on the strip width w under an applied field H_p as $J_p(w) = J_{p0} - (J_{p0} - J_{pc})\times 2L_c/w$, $(w \ge 2L_c)$, where J_{p0} and J_{pc} are the magnetization values associated with the undamaged and damaged bands, respectively. It turns out that, by measuring the complete normal magnetization curves at two different w values, we can estimate the width of the damaged bands L_c and, for any H_p value, the associated magnetizations J_{p0} and J_{pc}. The full evolution of the curves with w is then obtained and found to agree with the experimental curves, in spite of the somewhat crude scheme involved. This is equally true for the hysteresis loss W_{hyst}, the area of the quasi-static loop, now evolving with w as $W_{hyst}(J_p, w) = W_{hyst}(J_{p0}) + (W_{hyst}(J_{pc}) - W_{hyst}(J_{p0}))\times 2L_c/w$, $(w \ge 2L_c)$. We show in Fig. 1 an example of energy loss versus frequency $W(J_p, f)$ behavior measured up to f = 400 Hz for J_p = 1.0 T on a 0.470 mm thick Fe-(2.6%)Si sheet and a 0.192 mm thick Fe-(3.5%)Si sheet. It is apparent that both the quasi-static (W_{hyst}) and the dynamic losses, the sum of the classical W_{cl} and the excess W_{exc} loss components, are affected by the cutting-induced strain hardening. Having estimated the quantity $2L_c$ through the previous analysis of the normal magnetization curves, we can immediately predict by the previous equation and knowledge of a couple of values of $W_{hyst}(J_p, w)$ at two strip widths, the whole $W_{hyst}(J_p, w)$ behavior versus w. This is observed in Fig. 2 to closely fit the experimental data, concerning the example shown in Fig. 1. It is also shown in Fig. 2 that a same inverse dependence on w as for $W_{hyst}(J_p, w)$ applies to the excess loss $W_{exc}(J_p, w)$. In deriving this quantity from the experimental $W(J_p, f)$ curve, we calculate the classical loss $W_{cl}(J_p, f)$ using the standard formula for uniform induction J_p. In fact, W_{cl} is chiefly associated with the macroscopic eddy current patterns circulating close and at the sheet surface, related to the time derivative of the flux averaged over the sample cross-section. W_{exc} has instead a local character, over distances basically connected with the grain size. It quite naturally follows a same dependence on w as $W_{hyst}(J_p, w)$, as illustrated in Fig. 2. It is understood, however, that the averaged sinusoidal $J(t)$ results from the composition of non-sinusoidal contributions from the damaged and undamaged regions. Actually, this appears to have a minor impact on the overall behavior of $W_{exc}(J_p, w)$, which is shown to be well described, up to the frequency limit imposed by skin effect, by the standard formulation provided by the statistical theory of losses [4], the effect of local distortion being in any case accounted for by the statistical parameter V_0. I. INTRODUCTION Soft magnetic materials are widely used in magnetic devices such as transformers, reactors and sensors. For application of the soft magnetic films to magnetic sensors, we have investigated Fe-Ni films prepared by an electroplating method and confirmed their good magnetic properties [1-3]. In general, the materials with high saturation magnetization are effective to reduce size of the devices. For Fe-Ni-system films, the increase in the Fe content of the films or substitution of Co for Ni is typically applied to increase the saturation magnetization. In the present study, we focused on magnetic exchange coupling as another method to increase the saturation magnetization, and considered that the total Fe contents in the films can be increased without abrupt increase in coercivity by preparing exchange coupled Fe-Ni/$Fe_{22}Ni_{78}$ multilayered films. This contribution reports the soft magnetic properties of double-layered Fe-Ni/$Fe_{22}Ni_{78}$ films prepared by an electroplating method. II. EXPERIMENTAL PROCEDDURES We carried out the electroplating to obtain the Fe-Ni double-layered films using two plating baths with different Fe ion concentration. The electrolyte of the plating bath contained the following: 20~117 g/L of $FeSO_4{\cdot}6H_2O$, 275 g/L of $NiSO_4{\cdot}7H_2O$, 10 g/L of $C_7H_4NNaO_3{\cdot}2H_2O$ (Saccharin), 15 g/L of NH_4Cl, 0.5 g/L of $C_6H_8O_6$ (Ascorbic acid), 3 g/L of $C_{12}H_{25}OSO_3Na$ (Sodium lauryl sulfate). $Fe_{22}Ni_{78}$ films were electroplated on the Cu plate from a plating bath with 53 g/L of $FeSO_4{\cdot}6H_2O$, and then Fe_xNi_{100-x} films were electroplated on the $Fe_{22}Ni_{78}$ ones using another plating bath. Bath temperature was set at 50°C during the plating, and current density was kept at 200 mA/cm^2 by using a computer-aided dc current source (Matsusada P4K-80). The dc-hysteresis loops of the Fe-Ni films were measured with a B-H tracer (Riken Denshi BHS-40), and the coercivity was determined from the loop. III. RESULTS AND DISSCUSSION Figure 1 shows the coercivity of the double-layered Fe-Ni/$Fe_{22}Ni_{78}$ films a function of total Fe content in the films. In this experiment, we controlled the thicknesses of each layer at 12 μm (total thickness: 24 μm) by the change in the plating time. As the Fe content in the Fe-Ni layer varied from 0 at. % to 68 at.% by the change in the $FeSO_4$ concentration, the total Fe content in the multilayered film consequently varied from 11 at.% to 40 at.%. For a comparison, the result for single-layered films (thickness: 24 μm) are also shown in Fig.1. As shown in Fig.1, all the double-layered films showed lower coercivity compared with the single-layered films. This result implies that the exchange coupling effectively works to reduce the coercivity. To confirm the effect of the exchange coupling on the coercivity, we changed layer thickness for the $Fe_{22}Ni_{78}$ magnetic phase from 1 to 18 μm. Figure 2 shows coercivity of the double-layered $Fe_{10}Ni_{90}$/$Fe_{22}Ni_{78}$ films as a function of thickness of the $Fe_{22}Ni_{78}$ layer. Since large variation of coercivity enables us to easily confirm the effect of the exchange coupling when the exchange coupling becomes weak, we determined the Fe content of the Fe-Ni layer at 10 at.% in this experiment. Total thickness of the double-layered $Fe_{10}Ni_{90}$/$Fe_{22}Ni_{78}$ film was kept at 24 μm. As shown in Fig.2, the coercivity dramatically decreased with increasing the thickness of $Fe_{22}Ni_{78}$ layer from 1 to 6 μm. This result implies that and $Fe_{10}Ni_{90}$ phase is effectively exchange coupled with $Fe_{22}Ni_{78}$ one to improve magnetic properties when the thickness of the $Fe_{22}Ni_{78}$ layer is more than 6 μm. From these results, we conclude that exchange coupled Fe-Ni/$Fe_{22}Ni_{78}$ multilayered films are one of attractive soft magnetic materials due to their improved magnetic properties.

Non-oriented steel (NO) sheets are materials with great engineering significance used in AC applications where the direction of magnetic flux is circular, such as electric motors and generators [1]. As an aspect of the worldwide trend towards energy consumption decrease and preservation of the environment, the reduction of electricity consumption has become an extremely crucial matter in recent years. The understanding of the dependence of power losses in electrical steels on frequency is of great importance [2]. Core losses are structure sensitive and depend on several metallurgical factors; such as chemical content, grain size, crystallographic texture, cleanliness and stress states in NO electrical steels. [3]. The aim of this work was to investigate the influence of dynamic and continuous heat treatment on the soft magnetic properties of NO electrical steels. The used experimental material was a NO electrical steel grade M530 – 50A after primary recrystallization. Experimental samples were temper rolled under laboratory conditions. The value of reduction was less than 8 %. After this the samples were subjected to dynamic or continuous annealing according to the patent SK 288322 [4] and European Norm EN 10126, respectively. The samples with primary recrystallized microstructure (R1) were characterized by average grain size about 20μm. The annealed samples at dynamic (R5 dyn) and continuous conditions (R6 cont) were characterized by coarse grained microstructure with average grain size 120μm and 100 μm, respectively. The strips of the NO electrical steels were used for the measuring of the specific electrical resistivity by the direct method and for the measurement of the coercivity by the Foerster Koerzimat HCJ 1.097. The ring samples were used for magnetic measurements. The AC/DC hysteresis loops were measured by the Permeameter AMH-1K-S at the frequency range from DC to 400 Hz at maximum induction of 1.0 T and 1.5 T, respectively. Fig.1 shows the differences between *B(H)* loops for 3 different samples for 1.0 T magnetic induction amplitude. These curves were obtained at 50 Hz. There is, clearly, enlargement of the locus area for sample R6 cont, which is related to the increase on the coercivity. The R1 sample requires higher field strengths to achieve the induction of 1.0 T in comparison to other samples, for 1.5 T sample R6 cont requires the highest field strength of the three samples. These steels are compared to find out the effect of thermal treatment on magnetic losses. Fig. 2 plots magnetic losses vs. frequency measured at 1.0 T inductions. It is evident from the Fig. 2 that sample R5 dyn has lowest core loss at all frequencies. The core losses dependences show the different ranking of the studied samples for 1.0 T and 1.5 T. The results show that the varied thermo-mechanical treatment affects the magnetic losses in NO electrical steel laminations and the comparison of the magnetic properties depends on the value of magnetic induction.

AV-12. $NiFe_2O_4$ Nano-Hollow Spheres with Improved Magnetic and Dielectric Properties.

D. Mandal[1] and K. Mandal[1]
1. Condensed Matter Physics and Material Sciences, S.N.Bose National Centre for Basic Sciences, Kolkata, India

$NiFe_2O_4$ (NFO) is one of the most significant spinel ferrites due to its specific qualities such as low coercivity (H_C), high saturation magnetization (M_S) and Curie temperature (T_C), high electrical resistivity, low eddy current loss, and remarkable thermal and chemical stability [1]. Among the various morphologies of magnetic nanomaterials, nano-hollow spheres (NHS) are found to be very promising [2] because of their high M_S, large surface area and pore volume, low density, and ability to withstand volume changes due to temperature and pressure, which enable them to be used in wide varieties of applications in the fields of biomedical research, energy storage, high frequency magnetic devices and chemical sensors. The cavity inside and large surface enhances their capability of capturing and delivering drugs and also repeated internal reflections increase their applicability as microwave absorbers. Herein, the excellent properties of $NiFe_2O_4$ nano-hollow spheres (NFO NHS) synthesized in solvothermal method are reported. Figure 1(a) shows the X-Ray Diffraction plot of NFO NHS comparing with NFO Bulk indexing the crystal planes present and also confirming the single phase inverse spinel face centered cubic structure. Average crystallite size (= 23.5nm) and lattice constant (= 8.35Å) are calculated from Debye-Scherer formula and Bragg's law respectively from XRD spectra. The morphological analysis evidences the sample to be NHS with an average size of 200 nm, shown in SEM (Fig. 1(b)) and TEM (Fig. 1(c)) micrographs. EDX spectra (Fig. 1(d)) prove the constituents (Ni, Fe and O) present in the sample. M-H hysteresis loops of NFO NHS with maximum applied field up to 2kOe at temperatures 100K, 200K, 300K, 400K are described (Fig. 1(e)). At room temperature (300K), H_C and remnant magnetization (M_R) of NHS are 122Oe and 10.5emu/g respectively, displays the soft ferrimagnetic nature of NFO. The increase in H_C and magnetization on lowering temperatures are related to a growth of magnetic anisotropy preventing the alignment of the moment spins in an applied field [3]. A comparison between magnetic properties of NFO NHS, NFO nano particles (NPs) and Bulk NFO has been depicted in Fig. 1(f). It is found that T_C, H_C, and M_S values are increasing from bulk (H_C=78Oe, M_S=48.5emu/g) to NPs (H_C=93Oe, M_S=58.3emu/g) to NHS (H_C=122Oe, M_S=63.5emu/g). Both the increase in anisotropy and cationic movements are responsible for the higher H_C and M_S values of NPs than bulk NFO [3-4]. High temperature needed in solvothermal method to synthesize NHS and large surface to volume ratio of NHS are responsible for higher H_C and M_S values than NPs. The study of the dielectric properties (calculated from impedance (Z) – phase (θ) data [4]) gives information about the polarization behavior, conduction mechanisms and dielectric relaxation. Their variation with frequency (f) and temperature influences their applications for microwave devices e.g. in isolators, circulators etc [5]. Figure 2(a) shows the variation real (ε') and imaginary (ε'') values of dielectric constant with frequency (log(ω), ω=2πf) from 40 Hz-110 MHz at different temperatures from 30°C to 300°C. As the frequency increases ε' sharply falls and approaches to almost frequency independent nature due to inability of electric dipoles to comply with variation (i.e. frequency) of applied ac electric field, and increase in temperature facilitates more and more dipoles to be oriented along the field. The variation of ε' as well as ac conductivity ($\sigma_{ac}= \omega\varepsilon_0\varepsilon''$) (Fig. 2(b)) with frequency can be explained on the basis of Maxwell-Wagner two layers model for space charge, where ferrimagnetic materials are assumed to have larger grains and smaller grain boundaries as conducting and insulating layers, respectively. Dielectric loss ($\tan\delta = \varepsilon''/ \varepsilon'$) (absorption of energy) decreases with the increasing frequency of the applied electric field as after a certain frequency σ_{ac} increases and relaxation time constant also shrinks. Impedance spectra (Fig. 2(c), (d)) follows the above results and dielectric relaxation peak (80 kHz for 100°C) observed for each temperature shows its non-Debye type nature [4]. These improved properties [1, 3-5] make them suitable for uses in high-frequency devices as well as in bio-medical applications.

AV-13. Magnetic material deterioration of non-oriented electrical steels as a result of plastic deformation considering residual stress distribution.

N. Leuning[1], S. Steentjes[1], H. Weiss[2], W. Volk[2] and K. Hameyer[1]
1. Institute of Electrical Machines (IEM), RWTH Aachen University, Aachen, Germany; 2. Institute of Metal Forming and Casting (utg), Technische Universität München, Munich, Germany

It is well known that magnetic properties of electrical steel are highly sensitive to mechanical stress [1-4]. Processing and manufacturing of magnetic cores lead to complex stress and strain distributions within the material. The stress covers different scales, i.e., residual stress within and between grains, local stress variations over several grains and global residual stress. The residual stress interacts with elastic stress due to magnetic and external forces during the operation, i.e., centrifugal forces. To account for the alteration of magnetization and loss due to mechanical stress in actual electrical machines, the basic relations have to be understood. A comprehensive description, respectively characterization of the magneto-elastic-plastic coupling is still missing in scientific literature. With a profound knowledge of the interrelations, improved material modeling and therefore the simulation of electromagnetic energy converters, such as electric motors or generators can be enabled. This study is aimed at the identification of the effect of plastic deformation and concurrent impact of residual elastic stress in this context. Previous research indicated that the magnetic deterioration through plastic deformation is caused mainly by elastic stress and not by the mechanism of dislocation formation [1,2]. Therefore, this study contributes to the general magneto-elastic as well as the magneto-elastic-plastic coupling. In contrast to complex processing impacts, for example cut edge effects, this study is performed on rectangular samples with a defined uniaxial tensile mechanical loading. The magnitude of the loading causes a homogenous stress state that is above the elastic limit and thus, leads to plastic deformation. The results of the experiments by reloading the material samples allow one to consider the different contributions of dislocations and internal stress. Further, mechanical finite-element (FE) simulations are conducted to evaluate the residual stress distribution in detail and link as well as quantify the magnetic deterioration with the integral components of the residual stress. Experimental The study is performed on samples of a conventional 0.35-mm, 2.4 wt.% FeSi, in rolling (RD) and transverse direction (TD). Three samples in each direction are stressed beyond the elastic limit with different maximum stress values. Next, the external force is removed and finally, the deformed samples are stressed again in the same direction as the initial deformation. The magnetic properties are characterized during the initial deformation process, and then again at reloading. With this approach, the effect of plastic deformation on the resulting magnetic property changes can be considered. In this consideration the different contributions of dislocations as the underlying mechanism of deformation and residual stress distribution as a direct consequence of plastic deformation, can be incorporated. Mechanical FE-simulations are used to correlate the global stress distribution with the elastic residual stress in the deformed samples. Results The presented work is based on the observation that the magnetic properties of uniaxially tensile-stressed samples above yield strength, deteriorate strongly when the external loading is removed [2, 4]. In [1] this effect is linked to long-range internal stress. In Fig.1 results are displayed for 1.0 T at 100 Hz. The experimental succession is represented by the path from 1→2→3. Here, two samples were tested with different peak stress σ_{max}. For the required magnetization H_{max} a linear increase with applied tensile stress at initial deformation is observed. The exceeding of the elastic limit is not perceived in the magnetization. When the external loading is removed a strong rise of H_{max} occurs. For the magnetic loss the behavior is similar, however the exceeding of the elastic limit can be observed in form of a steeper slope of the curve. A gradual reloading, path 3→4 shows an approximation of the reloading curve to the initial curve which results in the same behavior at peak stress. This indicates that the magnetic deterioration, e.g., of the magnetization ΔH_{max} between the initially deformed loaded and unloaded state due to the distribution of residual tensile and compressive stress as a consequence of plastic deformation is explainable as an equivalent tensile stress of σ_{max}. A comprehensive observation of the polarization dependence as well as a coupling to the residual stress distribution obtained from mechanical FE-simulations (comp. Fig. 2) is presented in the full paper. Conclusions The presented work highlights the necessity to improve the basic understanding of the magneto-elastic-plastic-coupling. This allows to incorporate the actual material behavior in material modeling, especially for models predicting the mechanical processing of NO electrical steel sheets. Even though the experimental study was performed on plastically deformed samples, vital information of elastic residual stress can be deduced. It was shown that the integral mechanical stress from mechanical simulations correlate with the magnetic deterioration and that a coupling of mechanical and magnetic simulations could be a promising approach to estimate magnetic deterioration. This work serves as a contribution towards the understanding of material deterioration on a physical level and for the development of quantification methods.

Introduction Electromagnetic steel sheets are used for iron core materials of various electric devices, and their performance improvement leads to high energy efficiency. Typically, electromagnetic steel sheets are based on Fe-Si alloys, and it is reported that purification of Fe-Si alloys is effective for improving their properties. Kaido et al. proposed the effectiveness of purification by high-purity Fe-3.1 mass%Si alloy by making a prototype motor and studying it.[1] Based on this research, Lei et al. fabricated high-purity Fe-(5, 6) mass%Si alloys with high concentration. Additionally, Lei et al. reported that the hysteresis loss of Fe-6 mass%Si is lower than Fe-5 mass%Si at low magnetic field, and increases more quickly at a high magnetic field.[2] From these results, it can be seen that as the amount of Si increases, the soft magnetic characteristics become better, but interest is given to what kind of magnetic behavior the high-purity Fe-Si alloy shows in the 6.5 mass%Si, which shows the best magnetic characteristics with Fe-Si alloy. The purpose of this study is to investigate the magnetic properties around the 6.5 mass%Si on the high-purity Fe-Si alloy and the crystal structure change by further increasing the amount of Si. Experiment and Calculation High-purity Fe-(6.5, 7) mass%Si ingots were made of 99.99 mass% electrolytic iron and 99.999 mass% silicon in a CCLM (Cold Crucible Levitation Melting) furnace in a high vacuum atmosphere. Samples with Si content of 6 mass% were those of a previous study. Ring samples were cut out from the manufactured ingots, and measurement was performed with a maximum applied magnetic field of 5000 A/m by using an Automatic DC Magnetization Analyzer. Magnetic domain behavior was observed with a Kerr effect microscope using a part of the ring sample used for magnetic property measurement. The crystal grains observed with the Kerr effect microscope have identified the crystal orientation by EBSD (Electron Back Diffraction Patterns). A sample for TEM (Transmission Electron Microscope) observation using samples with a diameter of 3 mm was prepared by ion milling. Magnetic domain behavior was observed with a Lorentz electron microscope using a sample for TEM. Additionally, an electron diffraction pattern was observed using TEM. Results Fig. 1 shows half hysteresis loops of high-purity Fe-(6, 6.5, 7) mass%Si alloys at a magnetic flux density of 1.5T. Coercivities of high-purity Fe-(6, 6.5, 7) mass%Si alloys are Hc=9.31 A/m, Hc=7.64 A/m, and Hc=7.92 A/m, respectively. Permeabilities of high-purity Fe-(6, 6.5, 7) mass%Si alloys are μ=12.3, μ=36.5, and μ=3.9, respectively. Hysteresis losses of high-purity Fe-(6, 6.5, 7) mass%Si alloys are Wh=0.27 W/kg, Wh=0.39 W/kg, and Wh=0.48 W/kg, respectively. The permeability and coercivity show the best values for high-purity Fe-6.5 mass%Si alloy shown in Fig. 1. Conversely, for hysteresis loss, high-purity Fe-6 mass%Si alloy shows the best value. Remarkably, there are large differences in the magnetic hysteresis loops behavior between the high-purity Fe-6.5 mass%Si alloy and the high-purity Fe-7 mass%Si alloy, but the hysteresis loss of the high-purity Fe-7 mass%Si alloy indicated good value. Compared with high-purity Fe-6.5 mass%Si alloy with the best soft magnetic properties and with commercially available Fe-6.5 mass%Si alloy, the high-purity Fe-6.5 mass%Si alloy we made had lower coercivity and lower hysteresis loss. From this result, it can be seen that soft magnetic characteristics are improved by purification. In the observation with the Kerr microscope, the high-purity Fe-(6, 7) mass%Si alloys have a single magnetic domain with the applied magnetic field of 120 kA/m (1.5 kOe). Additionally, the high-purity Fe-6.5 mass%Si alloy has a single magnetic domain with the applied magnetic field of 88 kA/m (1.1 kOe). In the observation with the Lorentz electronic microscope, movement of the domain walls is observed at the applied magnetic field of 24 kA/m for the high-purity Fe-7 mass%Si alloy. Furthermore, migration of the domain walls are confirmed at the applied magnetic field of 17 kA/m for the high-purity Fe-6.5 mass%Si alloy. Moreover, migration of the domain walls is confirmed at the applied magnetic field of 16 kA/m for the high-purity Fe-6 mass%Si alloy. Because the magnetic permeability is higher, the domain wall is more likely to move, so it can be said that the result is almost in agreement with the result of the magnetic characteristics from the results of the Kerr effect microscope image and the Lorentz electron microscope image. Fig. 2 shows the electron diffraction pattern of the high-purity Fe-7 mass%Si alloy. Fig. 2 also shows that the B2 and D03 structures appear. As a result of comparing the three compositions, it can be seen that the high-purity Fe-7 mass%Si alloy has the largest amount of B2 and D03 structures because the spots of B2 and D03 were diffracted more strongly as the Si amount was increased. It is argued that these structures may affect the large difference in magnetic properties of high-purity Fe-6.5 mass%Si alloy and high-purity Fe-7 mass%Si alloy.

AV-15. Soft Magnetic Thin Films Laminations on Various Silicon Wafer Trench Geometries.

D.J. Cronin[1,2], P. McCloskey[1], A. Masood[1] and C. O'Mathuna[1]
1. Integrated Magnetics, Tyndall National Institute, Cork, Ireland; 2. University College Cork, Cork, Ireland

The recent surge in demand for miniaturisation of power transformers and inductors requires magnetic core materials with low energy loss, high saturation flux density, medium to high permeability, low coercivity and high operating frequency. With increasing switching frequencies for power supplies, the size and storage requirements for passive components is significantly lower. This is where the opportunity lies in using soft ferromagnetic thin films. Recent developments in magnetic materials such as CoZrO granular films, thin films and CoNiFe alloys have been evaluated by research groups such as George Loizos et al [1] for the next generation of integrated magnetic devices for high frequency applications. This work will focus on the development of thin film magnetic laminations for integrated magnetic trenches for applications to inductors on silicon. Lamination structures of CZTB magnetic material and an AlN insulator onto various microscale deep trenches were deposited onto silicon wafers by several fabrications processes and their properties analysed. These new trench shapes with an efficient magnetic material are expected to reduce eddy current and hysteresis losses compared to traditional cross-sectional shapes. Different trench designs were characterised for both magnetic and physical performance. The physical characterisation would include SEM and FIB imaging for layer uniformity of the magnetic material. Magnetic characterisation includes using a BH loop tracer to produce hysteresis loops in both easy and hard axes of the trenches to determine magnetic properties such as Coercivity (H_c) and anisotropy energy (H_k), the field required to fully magnetise the material in its hard axis. A permeameter was used to obtain its relative permeability vs frequency, μ_r vs f. Intrinsic properties of the material such saturation flux density and resistivity will not change with shape, whereas properties such as permeability or coercivity can be influenced by shape, surface structure and roughness etc. The shape designs fabricated were semi-circular, rectangular and quadrilateral. The fabrication processes used to etch the trenches were KOH bath, DRIE dry etching RF plasma and a dry vapour XeF_2 etch. A 'sandwich' of 10 layers of CZTB 200nm thick, each separated by a layer of 10nm was deposited into each trench. This lamination arrangement reduces eddy current losses. A profilometer was used to scan each trench to ensure the projected depth of 100 µm was observed. This work was done to see how coating trenches before copper deposition would influence their magnetic characteristics and efficiency when applied in integrated devices. Although defects and non-uniformity was seen in the SEM and FIB images, very promising results were obtained in particular for the rectangular shaped trench with H_c as low as 0.5 Oersteds. However after improving the fabrication process and eliminating defects and non-uniformity, H_c is expected to be even lower. Combined with a high B_{sat} of 1.3 T, this trench design is a favourable starting point for applications on a larger more complex scale. The full results show that the lamination coating could also be extended further to the surface of silicon wafers in inductor designs where flux lines are boosted through the components where inductance, L and permeability are increased. As cross-sectional area has a major role in increasing the inductance of a component, where is the magnetic path length, the shape of these trenches can play a major part in increasing its magnetic performance without changing its magnetic path length. Upon finding an ideal shape such as a rectangular trench, CZTB laminations can be applied to these magnetic components to improve their performance compared to their conventional cross-sectional geometry.

AV-16. Effect of growth conditions on the Soft Magnetostrictive properties of thin Fe-Co-Cr films.

S. Baco[1], Q.A. Abbas[1], Z. Leong[1], T. Hayward[1], N. Morley[1] and T. Thomson[2]
1. Material Science and Engineering, The University of Sheffield, Sheffield, United Kingdom; 2. School of Computer Science, University of Manchester, Manchester, United Kingdom

Soft magnetic materials with low anisotropy and coercive fields, large magnetostriction constant and saturation magnetisation are required for microelectromechanical systems (MEMS) such as sensors and actuators [1]. One promising material for MEMS devices is FeCo, as not only is it cost effective compared to the rare earth element alloys but also has a high saturation magnetisation and magnetostriction constant [2]. Although FeCo has a high saturation magnetisation and magnetostriction constant, it can also have large coercive and anisotropy fields for as deposited films [3], which affect the performance of MEMS devices. One solution to produce soft magnetic FeCo films with small coercive and anisotropy fields is to alloy with other elements, such as B [4], Ni and Al [5]. The magnetostrictive properties of Fe-Co-Cr thin films in particular have not yet been reported, therefore the aim of this study was to investigate the magnetostrictive properties and microstructure of FeCoCr films. Since growth conditions strongly affect the microstructure, hence the magnetic properties, FeCoCr films were fabricated as a function of thickness and sputtering power by the RF Sputtering technique. The first film set varied the film thickness from 56nm to 165 nm, at constant power (75W) and pressure (4.8 mTorr). The second film set varied the sputtering power between 75 W and 150 W, with film thickness ~100nm and pressure (4.8 mTorr). The microstructure and magnetic properties were investigated by Atomic Force Microscopy (AFM), X-Ray Diffraction (XRD), and High-Field MOKE magnetometer respectively, while the Villari technique was used for the magnetostriction measurement. AFM analysis revealed that 56nm film had a rougher surface compared to the thicker films. For the first film set (different film thickness), all the films exhibited a wide XRD peak at 2θ ~44^0 associated with FeCoCr bcc (110). The same broad peak at 2θ ~44^0 was observe for the films grown at the lower powers (75W and 100W), while for the films grown at higher sputtering power (125W and 150 W), two sharp peaks were observed corresponding to FeCoCr bcc (110) at 2θ ~44^0 and bcc (211) at 2θ~82$^{0.}$ This indicates that crystallinity improved as the sputtering power increased. From the magnetisation hysteresis loops measured on the MOKE magnetometer, the soft magnetic properties of FeCoCr as function of thickness were observed, with the coercive fields reduced to H_c = 1.5 kAm^{-1} at 100nm and anisotropy H_k = 12 kAm^{-1} at 120 nm (Fig.1a). While the anisotropy and coercive fields were H_k <20 kAm^{-1} and H_c < 2 kAm^{-1} for the films grown at sputtering power between 75 W to 125 W, but rapidly increased for the films grown with 150W (Fig. 1b). This is likely to be due to the change in microstructure of the films at the highest sputter power. The magnetostriction constant of FeCoCr films was found to be the highest at 100 nm (λ = 28ppm) however it was significantly independent on film thicknesses (for all thicknesses λ was between 22 and 28 ppm). This means that the interfacial magnetostriction constant does not strongly influence the effective magnetostriction constant of these films. The magnetostriction constant decreased from 28ppm to 5 ppm, as the sputtering power increased for the 100nm films, which can be related to the changes in the microstructure of the films, as observed in XRD. For comparison, a 100nm FeCo film was grown at the same sputtering power (75W) and pressure (4.8 mTorr). The FeCo film had isotropic behaviour, with a considerably larger coercive field (H_c= 9.2 kA/m) (Figure 2) and slightly smaller magnetostriction (λ=25ppm) than the 100nm FeCoCr film. In summary, FeCoCr films have been successfully fabricated with remarkable good soft magnetostrictive properties. By adding Cr, the coercive fields reduced by factor of 6 compared to FeCo. The suitable sputtering parameter to produce the soft magnetic properties with low coercive and anisotropy fields, while maintaining high magnetostriction constant were grown at thicknesses between 100 and 125nm at a power of 75 W. Growing films at higher sputtering powers (150 W) resulted in better crystallinity, but with large coercive fields and low magnetostriction constant, due to their strong dependence on the microstructure.

AW-01. Effect of Magnetic Annealing on Magnetic Characteristic of Amorphous Wound Core.

T. Sato[1] and T. Todaka[1]
1. Oita University, Oita, Japan

In this paper, an effect of a magnetic annealing on magnetic characteristics of an amorphous wound core is shown. Amorphous magnetic materials have been widely used as a core material of power transformers to reduce iron loss due to their excellent soft magnetic properties [1]. The amorphous core for transformer is wound core formed by stacking a plurality of amorphous sheet materials. Because a bending stress is generated at each of the corners of the wound core, the magnetic characteristic is deteriorated at the corners as shown in Fig.1 (a). As the result, the iron loss of the wound core becomes larger due to the effect of the bending stress. In order to remove the residual stress that is generated in the wound core including the bending stress, the wound core must be annealed in magnetic field by an electric furnace [2]. However, it hasn't become clear the effect of the magnetic annealing to the amorphous wound core in detail. Thus, we studied about the effect of the magnetic annealing to the bending stress. To express the bending stress at the corner of the wound core, 4 kinds of model wound cores formed by stacking the amorphous sheet were made. The model cores were formed by folding a cylindrical form, and the bending stress of model cores were adapted by changing the radius of the cylindrical cores. The values of radius of the model wound cores are 25mm, 35mm, 50mm, and 100mm. The bending stress was calculated by equations of shearing stress as shown in Fig.1 (b). When the bending stress is calculated by these equations, the value of the bending stress of the short radius model core becomes larger. The model wound cores were annealed by using the electric furnace as shown in Fig.2 (a). The holding time of the annealing conditions were adapted among 30 minutes to 480 minutes under annealing temperature 320 degree and the magnetic field 640 A/m. The magnetic characteristics of the model wound cores were measured by the system as shown in Fig.2 (b). The magnetic characteristics were measured before the magnetic annealing and after. Fig.2 (c) shows the iron loss curves of the model wound cores before the magnetic annealing. The iron loss increased in the bending stress applied state and the model core of higher bending stress became lager. It made clear that the iron loss of the wound core at the corner of inside in the non-magnetic annealing condition becomes lager than the outside due to the bending stress. Fig.2 (d) shows the relationship of iron loss between before and after the magnetic annealing. The iron loss after the magnetic annealing is smaller than before, the values of iron loss in the different bending stress conditions reduced to about same value 0.8 W/kg. These results show the effect of the magnetic annealing to the bending stress.

AW-02. Numerical Simulation of Particle Motion Inside Nano-Modified Transformer by Multi-Scale LBM-FDM Method.

L. Xuan[1], F. Zeng[1], X. Guan[1] and H. Peng[1]
1. School of Electrical Engineering, Wuhan University, Wuhan, China

1. Introduction Applications of nanofluid has become more and more widespread. Then there's an idea of adding nanoparticles into transformer oil to form a stable suspension colloid. The method can improve heat transfer characteristics and insulating properties of transformer oil [1]. But it is inevitable that nanoparticles and inherent metallic particles inside transformer move continuously and have different electric charges in electric field, reducing insulation performance of transformer oil, even causing breakdowns [2]. Therefore, particle motion and distribution problems have received more and more concerns. Fu et al. presented a theoretical model for analyzing the movement of the conducting particles inside transformer oil [3]. Kumar et al. carried out simulation on particle movement with balanced and unbalanced voltages in a three phase common enclosure gas insulated busduct [4]. They proposed that a moving conducting particle in an external electric field will be subjected to a collective influence of several forces including electrostatic force, electrostatic force and drag force. Cui et al. proposed a novel particle tracing method to estimate the moisture in transformers [5]. Ma et al. simulated the distribution state of metal particles in the oil tract of traction transformer with the method of computational fluid dynamics [6]. However, the traditional calculation methods previous researches used have evident deficiencies, such as low calculation accuracy and enormous calculation quantity. After years of development, the lattice Boltzmann method (LBM) has become a promising method for fluid flows and heat transfer simulation [7]. The method is based on mesoscopic scale and has advantage of simplicity and high computational efficiency, which makes it popular and has been applied to many simulations of two-phase fluid flows. But owing to limit of its present application range, the algorithm has trouble solving macro problems such as analysis of electric field. In this study, a multi-scale LBM-FDM calculation model has been built. Motion characteristics of nanoparticles and metallic particles in a nano-modified transformer have been calculated. First, distributions of temperature rise and fluid flow inside transformer were calculated by mesoscopic LBM method. Secondly electrical field inside transformer was calculated by macro FDM method. Lastly movements of nanoparticles and metallic particles were simulated using results from previous analysis. 2. Numerical calculation method 2.1 Force analysis To figure out how a particle moves, force of a particle should be analyzed. In this study, it was enough for us to just consider gravity, viscous resistance and electric force, because magnitude of other forces was far smaller than those three forces. The motion equation is given by $ma+F_e+F_g+F_v=0$ where m is the mass of a particle, a is the acceleration, F_e is the electric force, F_g is the gravity, F_v is the viscous resistance. 2.2 Calculation process The numerical calculation process is shown in Fig. 1. As is shown, we firstly build a 2-D axisymmetric thermal-fluid and flow particle tracking multi-scale model. To get viscous resistance, velocity and temperature field is analyzed by LBM in mesoscopic dimension. To get electric force, electric field is analyzed by FDM in macroscale dimension. Then we should also consider gravity of a particle. Combining all three forces, movement tracks of a particle is finally obtained. 3. Results and discussion In the multi-scale calculation model, the iron core, primary windings and secondary windings were taken account for heat source, with transformer oil filled as medium. Distributions of temperature and velocity fields by LB analysis are shown in Fig. 2(a) and Fig. 2(b). At the time the voltage of primary winding access the peak, the distribution of electric field computed by FDM is shown in Fig. 2(c). Two nanoparticles of different positions were set as the research objects. Movement tracks of the nanoparticles under forces at 1500s are shown in Fig. 2(d). Blue lines represent the movement tracks and red circles represent the initial positions of one particle. As is shown, no matter where the starting position is, the nanoparticles will follow the flow of transformer oil, moving clockwise and cycle. In essence, it is found that the magnitude of viscous resistance is much larger than electric field force, thus the nanoparticle is mainly affected by the force of viscous resistance. Likewise, two metallic particles at different positions were set as research objects, and movement tracks of them at 3000s are shown in Fig. 2(e). As the figure shows, the movement tracks of the metallic particles differ from those of nanoparticles. Similar to the nanoparticles, the particles follow the flow of transformer oil at the place where the flow velocity of the oil is high. But at the place where the flow velocity of the oil is low, the particles are mainly affected by the gravity and may sink down. This is because the mass of a metallic particle is much larger than that of a nanoparticle. In addition, when a particle is near the windings, the effect of electric field force is obvious, and the alternating sinusoidal electric field under the power frequency causes a serious cyclic swing presents in the movement track of the particles (dense tracks in the figure).

AW-03. An Efficient Finite Element Modeling for Stray Loss Calculation in Power Transformer Tank Using Impedance Boundary Condition.

K. Park[1], S. Hahn[1] and H. Ahn[2]
1. Electrical Engineering, Dong-A University, BUSAN, The Republic of Korea; 2. R&D Center, Power & Industrial Systems Performance Group, Hyosung Corporation, Changwon, The Republic of Korea

1. Introduction A power transformer is one of the important power apparatuses for electric power transmission. Over the world, high efficient and low loss power transformer is widely studied. In a transformer, the electric power loss generated in the transformer is classified into copper loss, core loss, stray loss, and etc. The stray loss account for about 20% of the total loss in a power transformer. Especially, in case of a power transformer with large % impedance, the ratio of stray loss may be about 30~50% of the copper loss. The stray loss due to the eddy current induced by the leakage flux is occurred in the tank, steel structure, and localized part of whole winding. Previous work concerning the stray loss calculation of steel structure in a power transformer has been published by many researchers. Although many researchers produced some interesting results, they spent a lot of computing time in order to compute the stray loss of steel structure in a power transformer. To calculate the eddy currents, the skin effect must be considered. The transformer tank has a size of several meters, but the thickness of the tank is about ten millimetres and the skin depth of the tank is several millimetres. Therefore, a large number of meshes and a lot of calculation time are required to calculate the eddy current using FEM. Therefore, it needs to study the method to shorten computing time while maintaining the accuracy of analysis. In this paper, we propose the application of impedance boundary conditions to solve this problem. 2. Stray Loss Analysis 2.1 Stray Loss The transformer tank loss generated by the leakage flux from the windings are called stray loss. The losses on the transformer tank surface are as follows [1]. Loss = $\sqrt{(\omega\mu/8\sigma)}\int_s H_t H_t^* ds$ Where ω is the angular frequency, σ is the conductivity, μ is permeability, H_t is the tangential component of the magnetic field vector at the surface, *denotes complex conjugate. 2.2 Inpedance Boundary Condition If the skin depth is much thinner than the thickness of the conductor, the boundary condition for rough calculation without considering the effect inside the conductor is called the impedance boundary condition. At the surface of good conductors the tangential component of the electric field (E) is approximately proportional to the tangential component of magnetic field (H). This boundary condition can be written as the following equation [2]. $n \times E = Z_s n \times (n \times H)$ Where Z_s is the complex surface impedance. 3. Results and Discussion In our study, we proposed an efficient numerical method using the impedance boundary condition to reduce the computing time for the stray loss. The proposed method applies the impedance boundary condition to the tank wall that the leakage flux is penetrated into its surface. With this analysis method, we could calculate stray loss generating on 3-D transformer tank. The computation time of 3-D model depends on the number of mesh that one of several reasons. Therefore, in order to shorten the computation time, the number of mesh should be reduced. This result was compared with the number of shooters and the analysis time in case of applying the impedance boundary condition and considering the skin effect. Table 1 compares the total number of meshes and the computation time. In order to verify validity of proposed impedance boundary condition, compared with the computation value of stray loss for skin effect. Figure 1 shows the loss distribution of the two cases in the transformer tank. The proposed method is expected to be useful to reduce the computing time and to give the accurate results.

AW-04. Relationship Between Drive Frequency and Load Characteristics in Bidirectional Contactless Power Transfer for Electric Vehicles.

T. Takura[1] and H. Matsuki[2]
1. Tohoku Institute of Technology, Sendai, Japan; 2. Tohoku University, Sendai, Japan

1. Introduction Recently, with the advent of vehicle-to-home (V2H), storage batteries of electric vehicles (EVs) have some roles of shifting the peak of electric power, making effective use of renewable energy, supplying the power in a disaster, and so on. In V2H, it is necessary to realize bidirectional power transfer between EVs and homes. Already, bidirectional power transfer can be realized by the plug-in method. The next generation V2H requires integration with bidirectional contactless power transfer (BCPT) technique in order to improve durability and convenience. BCPT needs to maintain the transmission performance even if the relationship between the power supply and the load is switched. By connecting the capacitor on the primary side and the secondary side symmetrically, the difference in performance depending on the direction can be reduced. In this study, SS method[1] is adopted as a symmetrical resonance circuit. However, SS method under the constant input voltage has a problem that, at light load, the current on the primary side increases to increase the voltage on the secondary side. Therefore, when the load fluctuates depending on the state of charge of the storage battery or the state of power usage at home, the strength of electromagnetic field leaking from the primary coil and the output voltage rise. In this study, we demonstrate suppressing the coil current and stabilizing the output voltage at the time of load fluctuation by changing the drive frequency that can be easily controlled from either the vehicle side or the home side. 2. Theory and experimental method The cause of the above problem in SS method is related to the reduction in the input impedance of the circuit. When driven at the resonance frequency, the input impedance approaches the winding resistance of the primary coil at light load. And, the current on the primary side becomes excessive. In order to solve this problem, changing the drive frequency is one of the effective ways. So, we confirmed the load characteristics to clear the effects of the drive frequency on the coil current and the output voltage. The specifications of the coils show Table I. The input voltage was constantly adjusted to 1 V (root mean square value), the resonance frequency was set at 86.6 kHz, and the secondary coil was located 100 mm vertically from the primary coil. 3. Results and conclusion The results of the load characteristics of the coil current and the output voltage when the drive frequency is changed to 86.6, 91.6, and 96.6 kHz are shown in Fig.1. At the resonance frequency, both the coil current on the primary side and secondary output voltage increased at light load. These results suggest the increase of leakage electromagnetic field and the risk of overvoltage at high power. On the other hand, by increasing the drive frequency, we succeeded in suppressing the coil current on the primary side and the output voltage. In particular, when transmitting at 96.6 kHz, the input voltage and the output voltage at light load are nearly equal, and the output voltage was stabilized. Therefore, the method of changing the driving frequency is extremely effective in suppressing leakage electromagnetic field and stabilizing the output voltage at the time of load fluctuation.

Abstract. The insulation system of one 330kV Inverted-type Oil-immersed Current Transformer (IOCT) has broken down recently. In order to find the cause of the accident, the dielectric parameters of the IOCT insulation materials with different moisture content were tested at different temperature. Then, the electric field distribution of the IOCT insulation system was calculated using the data measured. The strongest electric field strength of main insulation was analyzed, and the extreme operating environment of IOCT was obtained. Keywords: IOCT, dielectric parameters test, moisture content, temperature, electric field strength 1. Introduction The IOCT working in the outdoor is a series device used in transmission network for measurement and protection purposes. The insulation system of one 330kV IOCT has broken down recently. This broken-down IOCT operates in high-speed rail traction network system in high latitudes, where the diurnal temperature variation is large and the air is humid. The polarization loss generated during IOCT operation will increase the temperature of the insulation system. As presented in previous research, with increase in temperature, greater dispersion of dielectric parameters of oil-paper were noticed [1,2]. With the increase of temperature, the average kinetic engergy of the conductive particles in the oil-paper samples increases, resulting in a larger dielectric loss factor [3], and the rising temperature will aggravate insulation aging [4,5]. During the IOCT operation, the moisture content of the insulation system will increase due to the insulation aging degradation and humid air invasion, and the insulation performance of oil-paper will deteriorate with the increase of moisture content [6]. The significance of water content is paramount: a humidity of 4% can shorten a transformer's operational lifetime by a factor of 40 (i.e., by 97.5%) [7]. The condition of oil-paper insulation is one of the basis factors determining the condition and life expectancy of many professional power appliances, including IOCT [8]. Therefore the temperature and moisture content dependence of the insulation materials should be taken into account in the calculation of the IOCT electric field distribution. In this paper, the relative permittivity of the IOCT insulation system with different moisture content was measured at different temperature, firstly. Then the IOCT FEM models were established according to the broken-down 330 kV IOCT. Finally, the data measured were taken into the material parameters of the models, and the electric field distribution of the IOCT was obtained at different temperature and moisture content. The strongest electric field strength of IOCT main insulation was analyzed, and the extreme operating environment of IOCT was obtained. 2. Measurement of the Dielectric Parameters The dielectric parameters (relative permittivity) of Minsk oil-immersed paper, and German semi-conductive paper with different moisture content were measured at different temperature, at 50Hz, using the Alpha-A broadband dielectric spectrometer. The results are shown in Fig. 1. More results will be shown in the full paper. 3. Calculation and Analysis The main insulation system of IOCT is consisted of Minsk oil-immersed insulation paper, German semi-conductive paper, and mineral oil. The outermost layer is oil storage tank. The innermost layer is shielding case, which is connected with ground, it is low potential. The conductive rod is connected in series in the traction system bus. Between the oil storage tank and the insulation system is the equalizing cage, which plays a role in balancing the voltage. The oil storage tank and equalizing cage are connected to the conductive rod, and they are high potential. The mineral oil filled in the gap in the oil storage tank, play insulation and heat dissipation. According to the structure of IOCT, the electric field distribution was obtained. The main results are shown in Fig. 2. Since the condition of the oil-immersed insulation paper determines the service life of the IOCT, the maximum electric field strength of each insulation layer is analyzed. More results will be shown in the full paper. 4. Conclusion The dielectric parameters of oil-immersed paper, and semi-conductive paper with different moisture content were measured at different temperature. Then, the IOCT model was established considering the temperature and moisture content dependence of the insulation materials. The influence of temperature on the electric field distribution of IOCT is more significant than that of moisture content. Although the temperature and moisture content rising is beneficial to equidistribution of the IOCT electric field, the too high temperature and moisture content will reduce the service life of insulation materials. The oil-paper damage of IOCT insulation system is generally not caused by electric breakdown but heat aging in high temperature. Therefore, the IOCT recommended operating temperature should not be higher than 383 K, and the moisture content should not be higher than 0.7%.

AW-06. A Study on Increase of Core Loss Ratio and Inductance According to Construction of Induction Heater for Electric Vehicle.

J. Kang[1], Z. Wang[1] and K. Kim[1]
1. Dept. of Electrical Engineering, Hanbat National University, Daejeon, The Republic of Korea

In the automotive industry, PTC devices is used as a heat source for air conditioning systems. However, PTC devices have a disadvantage of high cost and heavy weight. On the other hand, Induction heater are characterized by faster heating rates and lower cost than conventional PTC devices [1]. However, in the automotive industry, research on induction heaters has not yet been conducted. At sub-zero temperatures, EV batteries have a feature of drastically decreasing capacity. The EV starts to operate without a separate preheating time at the start [2]. Therefore, the heating time is one of the most important factors for maintaining the battery temperature in winter. Therefore, induction heaters are more suitable than PTC devices as components for maintaining battery temperature in electric vehicles [3]. Important design parameters of the induction heater are the inductance and the loss. Increasing the inductance is an element to reduce the capacitance of the capacitor connected to the circuit. The price and size of the capacitor are proportional to the capacity. Therefore, reducing the capacitance is important to reduce fabrication cost and weight. The loss is largely divided into core loss from the work piece and copper loss form the coil. The ratio of core loss to total loss is very important. If the copp er loss is large, the coil generates a lot of heat, which is not good in durability and heat transfer. Therefore, it can be seen that high loss in the work piece is the most important factor for the efficiency of the induction heater. In this paper, we studied the improvement of the proportion of the core loss in the total loss and the inductance according to the structure of induction heater by using FEM. Analysis models are divided into three models in the paper. For comparison, the analysis models used the same turns of coil, wire diameter and used the Litz wire to reduce the skin effect and proximity effect of the coil at high frequency. Fig. 1 shows three proposed models. As shown in the figure, SUS430f is used as the material of the work piece. To reduce the skin effect and proximity effect of the coil, Litz wire(0.1 mm X 80reels) is used. The number of turns is 65 turns. Fig. 1-(a) shows a case where only one inner work piece and only an external coil are used. Fig.1-(b) shows a structure in which a work piece is formed inner and outer, and a coil is located therebetween. Fig. 1-(c) shows that the structure of the work piece is the same as Fig.1-(b), but the coil consists of the inner and outer parts. The three models are chosen to have the same number of turns and the size of inner work piece. To reduce the capacitance of the capacitors connected to the circuit, designing the induction heater to have large inductance is more advantageous for the manufacturing cost and weight. The capacitance for LC resonance can be estimated in advance by accurate inductance derivation. Therefore, it is one of the most important factors in design to accurately derive the value of inductance by simulation, magnetic equivalent circuit calculation, and actual measurement data. Fig. 2 shows the magnetic equivalent circuits of proposed models. As shown in the figure, the inductance value calculated by using the the magnetic equivalent circuit. Fig. 3 shows the magnetic flux distribution in the FEM simulation. As shown in Fig.3-(a), the magnetic flux leaks into the air. Thus, it can be seen that the inductance decreases due to leakage flux. On the other hand, Fig.3-(b) shows that the outer work piece blocks magnetic flux leaking into the air. Therefore, it can be seen that inductance is higher than model 1. Fig.3-(c) shows the magnetic flux leaking from outer to the air. Based on the above results, inductance analysis for three proposed models is conducted. As a result, we intend to derive a structure favorable to inductance among the three model structures. Fig. 4 shows the magnetic flux density distribution. As shown in the figure, model 2 has a small amount of magnetic flux leaking into the air and most of the flux flows through the work piece. Therefore, core loss is higher than model 1. Thus, when the number of turns and diameters of the coils are the same and the input power is the same, the copper loss of both models is the same, but the core loss ratio changes. As mentioned above, the output of the induction heater is divided into core loss and copper loss. Therefore the ratio of these losses is important to the design. If the copper loss ratio is high, the coil generates a lot of heat. However, coils are coated for insulation purposes. Therefore, when a large amount of heat is generated in the coil, the efficiency is low due to the durability of the coil and the low heat transfer rate. Therefore, FEM simulation has been carried to increase the ratio of core loss to tatal loss.

AW-07. A Novel Magnetic Valve Structure for Magnetically Controlled Reactor.

M. Liu[1,2], S. Wang[2], Y. Li[1] and J. Li[2]
1. State Key Laboratory of Reliability and Intelligence of Electrical Equipment, Hebei University of Technology, Tianjin, China; 2. State Key Laboratory of Control and Simulation of Power System and Generation Equipments, Tsinghua University, Beijing, China

Abstract— Magnetically controlled reactor (MCR) is one type of saturable reactors (SR) that is based on the working principle of a magnetic magnifier, which is widely used in ultrahigh-voltage (UHV) power systems. The reactance of an MCR is changed by controlling the DC current through the control winding, to saturate the iron core by changing the thyristor conduction angle. In the traditional design, the valve structure has two different sections in MCR's magnetic valve, which leads to the increasing of the current harmonics. In the whole range of capacity adjustment (from the minimum to the rated capacity), only a small area of the reactor core is saturated, and the rest is working in an unsaturated state. The capacity of the reactor can be changed by changing the saturation degree of the magnetic path in the small section segment. Therefore, structure design of the magnetic valve is the key role for the MCR, which affects the adjustment performance directly. In this paper, a buffered structure and a mathematical model of the slope-stage saturable MCR (SSMCR) are proposed. This novel magnetic valve structure is shown in Fig. 1. There is a ramp in the middle of the valve core, which can compensate current harmonic generated by the main iron core when it is beginning to saturate. As a result, the total harmonics of the output current is reduced. The mathematical model that reveals the equivalent *B-H* characteristics of magnetic valve for the SSMCR is also presented. The deduction of the mathematical model indicates that there are two key factors affecting the total output current harmonics of the SSMCR. One is the parameter θ, which represents the slope of the ramp. The other one is the parameter *k*, which represents the ratio between the minimum length l_1 and the total length (l_1+l_2) of the magnetic valve. Meanwhile, the equivalent *B-H* curve is related to the two parameters, as shown in Fig. 2. Comparing the traditional magnetic valve structure, nearly 50% current harmonics amplitude is reduced during reactance adjustment according to the simulation. To calculate the equivalent *B-H* curve easier, the slope part of magnetic valve is divided into many stairs, as Fig.3a shown. The calculation is based on the two assumptions: (1) The magnetic flux density is uniform along the section of core. (2) Fringing and magnetic flux leakage is negligibly small. So the expression of equivalent *B-H* characteristics for the novel magnetic valves, as a function of *B*, can be written. The core is discretized into k elements (normally m=8 elements will suffice). The equivalent *B-H* characteristics is presented in Fig.2b. The simulation of SSMCR is presented that the 3rd current harmonic is maximum when t=0.1. Compared to the traditional MCR, the maximun current harmonic of SSMCR is 4.82% better than traditional MCR.

1. INTRODUCTION Considerable efforts have been made to improve the performance of power systems. In particular, the emphasis is on the power density, efficiency, and reduced passive elements in the inverter. A common method to reduce the size of passive elements is to increase the switching frequency of the inverter.[1] With the development of digital home appliances and renewable energy sources, interest in DC-based transmission and distribution has increased. Commonly used systems are based on alternating current. Therefore, the DC power generated from the renewable energy source is converted into the AC power and converted to another DC power for use in the digital device. The use of DC distribution reduces the unnecessary power conversion steps and improves the efficiency of power distribution. On the other hand, in the case of direct current distribution, the conversion from DC to a set DC voltage level is required. To achieve high efficiency in this process, the role of the DC / DC converter for distribution is important. The design of a high-frequency transformer, which is the main component of a DC / DC converter, is very important.[2] The transformer used in the current system, however, uses a high power and low frequency. In the case of a DC transmission system, such as HVDC, the transformer should use high power and high frequency, but there have been few studies in this area. Therefore, this study examined the design of the high frequency transformer. When a high frequency is used in a transformer, the magnetic flux is small. hence, the magnetic flux density, which is the magnetic flux passing through the same unit area, becomes small, which means that the size of the passive element can be reduced. When designing the transformer covered in this paper, it is necessary to consider the frequency components differently from a general transformer design. As a design method, the magnetic equivalent circuit method was used to simplify the design, and finite element method (FEM) analysis and comparative analysis were conducted for validation. The FEM analysis tool in MAXWELL was used. 2. MAIN SUBJECT 2.1 Structure and specification of transformer Fig. 1 (a), (b) presents the shape, specification and magnetic flux density of the 100kVA high frequency transformer model discussed in this paper. The shape of the transformer is a core type transformer: Across is the width of the core; Height is the height of the core; Lamination is the lamination thickness; Path is leg of the transformer; and is the amination length times the path is the cross-sectional area. 2.2 Magnetic equivalent circuit of the transformer The proposed method magnetic equivalent circuit provides the convenience of an analysis of the transformer. Fig. 2 (c), (d) presents the magnetic equivalent circuit. The reluctance, R_m, is caused by the resistance component in the relative magnetic field lines in the magnetic circuit, and corresponds to the electrical resistance in the electrical circuit. $R_m = F/\Phi = MPL/\mu_r\mu_0 A_c$ [A/Wb] (1) where F is the magnetomotive force; Φ is the magnetic flux; A_c is the effective cross section; μ_r is the relative permeability; μ_0 is the vacuum permeability; and MPL is the magnetic field pass length. The magnetic flux is bundle of magnetic lines, corresponding to the current in an electric circuit. $\Phi_m = V_1/4.44fN_1 = F/R_m$ [Wb] (2) f is the frequency; N_1 is the number of turns in primary; and V_1 is the input voltage. The magnetomotive force is a force for generating a magnetic field, and corresponds to the electromotive force in an electric circuit. $F = NI = \Phi_m R_m$ [AT] (3) The excitation current, I_0, at no-load of the transformer can be calculated by considering Φ_m in terms of the frequency in eq. 3. The magnetic flux density, B_m, will determine the design of the transformer material information in a magnetic flux passing through per unit area to be designed so that the core is not saturated. $B_m = \Phi_m/A_c$ [$T, Wb/m^2$] (4) The Composite magnetic reluctance, R_{mt}, $R_{mt} = 2*(R_{m1}+R_{m2})$ (5) 2.3 Analysis Results B_m and μ_r are determined by the core material properties; Φ_m is calculated using eq. 2; and R_m is calculated using eq. 1. Considering the frequency, I_0 can be derived from eq. 3. Φ_m and B_m can be calculated considering the frequency. Table 1 shows the comparison results of FEM and magnetic equivalent circuit. The exciting current and the error rate calculated by the magnetic equivalent circuit method in (c) was 3.5%. Fig. 1 (b) confirms that local saturation occurred only at the inner corner, which is the shortest path through which the flux of the transformer could flow, and the rest of the iron core was operated with a flux density < 0.4 [T]. This confirmed that it had been designed properly. 3. CONCLUSION In this study, a magnetic circuit equivalent method was applied to calculate the transformer characteristics more accurately considering the frequency. The validity of the proposed magnetic equivalent circuit method was confirmed by the FEM and comparative analysis. The proposed magnetic circuit equivalent method is a useful method for interpreting the fundamental characteristics of high-frequency transformers more efficiently. The electromagnetic characteristic of power transformers is a dynamic phenomenon. It is characterized by changes in current and magnetic flux state over time. Mathematically, the dynamic process of power transformers can be described by nonlinear differential equations. Analysis of electromagnetic equipment performance and accurate calculation of the magnetic field must consider the core nonlinear magnetic properties. By adding Jiles-Atherton (JA) model as shown in Fig. 1, the characteristics of transformer surge, including magnetic nonlinearity under transient conditions are simulated. In the final stage, the magnetizing inrush current is identified by the various characteristics of the fundamental wave amplitude, and the corresponding fundamental wave amplitude curves under different remanent fluxes are analyzed. To determine the effect of remanent flux on the inrush current, the single-phase and three-phase transformer no-load closing transient process is simulated. This paper has practical significance to provide an adequate theoretical basis for the identification and suppression of the inrush current. By reducing the remanent flux, the performance of the transformer, and furthermore the quality of the power system can be improved.

Abstract - In this paper, we analyze the loss of a device depending on the switching state of a 3kW solar inverter circuit. IGBT and diode conduction losses and switching losses use PSIM's thermal module function and inductor loss analysis uses PSIM's MagCoupler function for more accurate analysis. 1. Introduction Power semiconductor losses take a lot of time to calculate using formulas. To solve these problems, various simulation tools such as PSIM, Jmag, and MATLAB have been developed and can easily and quickly analyze the loss using these simulation tools [1]. In this paper, a method for analyzing losses of power semiconductor devices and losses of diodes and inductors according to switching state of 3kW solar inverter circuit was studied. Power semiconductors and diodes are modeled by PSIM's Device Database Editor function using the information provided in the data sheet of the actual device to analyze the loss due to the switching state of the inverter using the thermal module function of the PSIM. The inductor is modeled as Jmag and combined with Psim to analyze losses[2][3]. 2. Analysis of solar inverter loss 2.1 inverter circuit Table 1 shows the specifications of the transformer type 3kW solar inverter circuit. Figure 1 shows the circuit constructed by PSIM according to this specification. It consists of Boost converter part and radio bridge type inverter part. The Boost converter part boosts the voltage input to the inverter and adjusts it to the inverter operating voltage range. The output voltage is always greater than the input voltage and when the switch is on, the diodes are reversed and disconnected from the output stage. The input supplies energy through the inductor, and when the switch is off, the output is supplied with energy through the inductor. The output filter capacitors are also very large to maintain a constant output voltage. The bridge type inverter consists of four IGBTs and controls the switch by PWM method [1]. 2.2 Inverter Loss Formula Inverter losses occur primarily in power semiconductor devices. The loss of the power semiconductor device IGBT is dispersed by conduction loss and switching loss. When the semiconductor switch element is OFF, current does not flow through the switch in the blocking area, so there is no loss of the element. When the switch is turned on, current flows through the switching element, and a voltage is applied to both ends of the element to cause a loss. The loss of the power semiconductor switching device is the sum of the conduction loss and the switching loss as shown in Eq. (1) [2] [3]. $P_{IGBT(loss)}=P_{c(IGBT)}+P_{sw(IGBT)}=P_{c(IGBT)}+P_{sw-on(IGBT)}+P_{sw-off(IGBT)}$ (1) $P_{c(IGBT)}$: Conduction Loss of IGBT $P_{sw(IGBT)}$: Switching Loss of IGBT The conduction loss of the IGBT is a loss occurring in the saturation region when the IGBT is ON, and is the value obtained by multiplying the current flowing through the switching element by the voltage across the device. $P_{c(IGBT)}=V_{ce(sat)}\times I_c$ (2) $V_{ce(sat)}$: Collector-Emitter Saturation Voltage I_c : Collector Current The switching loss of the IGBT is the loss caused by passing through the active region when the IGBT is turned on or off. It is the product of the current flowing through the switching element and the voltage across the IGBT. $P_{sw(IGBT)}=(E_{on}+E_{off})\times f_{sw}\times V_{cc}/V_{cc-datasheet}=1/T\int^{tr}V_{ce}(t)\times I_c(t)dt+1/T\int^{tf}V_{ce}(t)\times I_c(t)dt$ (3) E_{on} : Turn-on Energy Loss E_{off} : Turn-off Energy Loss f_{sw} : Switching Frequency V_{cc} : DC Input Voltage $V_{cc-datasheet}$: DC Input Voltage on Datasheet The loss of the diode is the sum of the conduction loss and the switching loss, and most of the switching loss is the turn-off loss. $P_{Diode}=P_{c(Diode)}+P_{sw(Diode)}+P_{c(Diode)}+P_{sw-off(Diode)}$ (4) $P_{c(Diode)}$: Conduction Loss of Diode $P_{sw(Diode)}$: Switching Loss of Diode The conduction loss of a diode is given by equation (5) as the product of the forward voltage drop of the diode and the current. $P_{c(Diode)}=V_F\times I_F$ (5) V_F : Foward Voltage Drop of Diode I_F : Foward Current of Diode The turn-off switching loss of the diode is determined by the reverse recovery current and the reverse recovery time of the diode and is given by Equation (6). $P_{rr(Diode)}=E_{rr}\times f_{sw}\times V_r/V_{r(datasheet)}=(1/4)\times Q_{rr}\times V_{rr}\times f_{sw}=(1/8)\times t_{rr}\times I_{rr}\times V_r\times f_{sw}$ (6) E_{rr} : Reverse Recovery Energy Loss V_r : Reverse Blocking Voltage $V_{r(datasheet)}$: Reverse Blocking Voltage on Datasheet Q_{rr} : Reverse Recovery Charge t_{rr} : Reverse Recovery Time I_{rr} : Reverse Recovery Current The loss of the Inductor is the sum of the iron loss and the copper loss, as shown in Equation (7). $Pt=P_c\times P_{cu}$ (7) P_c : Iron Loss P^{cu} : Copper Loss 2.3 IGBT and diode loss analysis The Thermal Module is a function that can simulate the loss of each device by inputting the value informed from data sheet of Diode, IGBT, MOSFET, Inductor etc through PSIM's Device Database Editor [5]. Figure 1 shows the circuit diagram of PSIM's thermal module to simulate the loss of the solar inverter. Figure 1 (d) is a thermal equivalent circuit with added thermal resistance to estimate the IGBT loss. 2.4 Modeling and Co-Analysis of Inductor Table 2 shows the simulation specifications. Figure 4 shows the inverter co-analysis results. 3. conclusion Through the PSIM and JMAG, the inductor design and the loss analysis for the solar inverter were obtained. Based on the results of this analysis, it is expected that it will be very helpful to design the inductor that can predict the loss and reduce the loss. AW-11. Design and Fabrication of Rotary Magnetostrictvie Energy Harvester for Knee-joint wearable applications.

B. Yan[1], J. Hong[1] and C. Zhang[2]
1. Guangdong University of Technology, Guangzhou, China; 2. Harbin Institute of Technology, Harbin, China

Energy generator used to harvesting the rotation of human knee-joint has got more attention, which has good application in self-powered design of wearable electronic devices. Consider the characteristics of human knee joint rotation, its rotation always appear as low frequency (1-2Hz), small angle deflection (0-90°) and huge drive torque (>50Nm) [1-2]. Traditional hybrid structure of electric machine and gearbox are always accompanied by high power density, but the size and mass are larger for its wearable. Harvesters based on piezoelectric ceramics exist smaller size and mass, but with lower output electricity. Magnetostrictive materials, such as TbDyFe alloy, shows relatively high power density and efficiency, also can be used to design of magnetostrictive/electromagnetic hybrid structure, which can help to improve the power density and output electricity. This paper presented an interest rotary magnetostrictive energy harvester, which is introduced in Fig.1. The harvester has two parts: stator and rotor. Six flat Terfenol-D rods surround by the picked up coils respective, are set in the stator uniformly. Rotary permanent magnet array are fixed in the rotor. The harvester rotates like as a stepper motor, which has rotary electromagnetic power generating effect and impacted magnetostrictive power generating effect in its rotation. Magnetic field and electromagnetic force in presented harvester are analyzed, rotary permanent magnet array and principal design parameters of harvester are optimally optimized. Then, the respectively harvesting effect of Terfenol-D rod induced by single ΔH and $\Delta\sigma$ are calculated, and its predicted hybrid harvesting effect is concluded. Lastly, a prototype of harvester is fabricated and tested. The size of proposed structure is control as 77cm^3, and its mass is about 0.21kg. The rotational harvester exists larger power density at 1-2Hz low frequency situation, can be generated up to 7.6V peak value voltage. Also more interest results will be introduced in our recently papers.

BA-01. New opportunities for characterizing magnetic systems using next-generation synchrotron radiation sources.

J. Lang[1]
1. X-Ray Science Division, Argonne National Laboratory, Argonne, IL, United States

The world-wide proliferation of synchrotron x-ray radiation light sources over the past 30 years has led to their routine application in investigations of the magnetic behavior of a wide-range of technologically relevant devices. The intense highly collimated x-ray beams with tunable polarization properties that these sources provide have enabled the development of various x-ray spectroscopic and scattering techniques, such as X-ray Magnetic Circular/Linear Dichroism (XMCD/XMLD) and X-ray Resonant Magnetic Scattering (XRMS), which have been applied to obtain key structural, electronic, and magnetic information from a variety of systems. Near core-shell resonances, such x-ray measurements probe particular electronic orbitals within individual atomic species, thereby offering unique insights into the multiple interactions present in multi-constituent materials. The current so-called "third-generation" synchrotron sources, such as the Advanced Photon Source in Chicago, USA, provide highly stable x-ray beams that can be focused to probe magnetic structures from a few hundred nanometers to microns. The evolution of modern technology, however, has led towards more complex hierarchical magnetic systems at much smaller length scales. Further, many correlated electron systems possess magnetic textures that order on the nanometer length scales. Over the next decade, many of the world's synchrotron sources will undergo significant upgrades and entirely new sources will be built as "fourth-generation" light sources in order to address these challenges. These machines will leverage new accelerator technologies to dramatically decrease the size of the electron bunches that produce the x-rays, which in turn will greatly increase the brightness of the available x-ray beams by factors of 50 or more. This will enable focusing of the full x-ray intensity to nanometer dimensions, and also greatly enhance the degree coherence of the x-ray beam. These vast improvements in photon beam properties, combined with rapid, ongoing advances in x-ray optics, insertion devices, and detectors, will provide transformative capabilities for utilizing x-rays to understand magnetic systems at unprecedented spatiotemporal time and length scales. Furthermore, it will enable studies of magnetism in the most extreme conditions such as high pressure, temperature, and applied fields. This talk will present examples of how synchrotron radiation light sources are currently applied understand magnetic systems, and the transformative capabilities that will be enabled by the new light sources on the horizon.

BA-02. Ultrafast and Very Small: Discover Nanoscale Magnetism With Picosecond Time Resolution Using X-Rays.

H. Ohldag[1]
1. Stanford Synchrotron Radiation Lightsource, SLAC National Accelerator Laboratory, Menlo Park, CA, United States

Today's magnetic device technology is based on complex magnetic alloys or multilayers that are patterned at the nanoscale and operate at gigahertz frequencies. To better understand the behavior of such devices one needs an experimental approach that is capable of detecting magnetization with nanometer and picosecond sensitivity. In addition, since devices contain different magnetic elements, a technique is needed that provides element-specific information about not only ferromagnetic but antiferromagnetic materials as well. Synchrotron based X-ray microscopy provides exactly these capabilities because a synchrotron produces tunable and fully polarized X-rays with energies between several tens of electron volts up to tens of kiloelectron volts. The interaction of tunable X-rays with matter is element-specific, allowing us to separately address different elements in a device. The polarization dependence or dichroism of the X-ray interaction provides a path to measure a ferromagnetic moment and its orientation or determine the orientation of the spin axis in an antiferromagnet. The wavelength of X-rays is on the order of nanometers, which enables microscopy with nanometer spatial resolution. And finally, a synchrotron is a pulsed X-ray source, with a pulse length of tens of picoseconds, which enables us to study magnetization dynamics with a time resolution given by the X-ray pulse length in a pump-probe fashion. For this purpose we designed and employed a dedicated scanning x-ray microscope at SSRL [3]. Over the past few years this microscope has been used to address spin transport across FM/NM interfaces [1], spin current induced dynamics [2,5] as well as controlling magnetic order in complex oxides with electric voltages [4]. In this presentation several examples will be given of how synchrotron based x-ray spectroscopy and microscopy can be used to directly address issues in magnetism research on fundamental length scales that are otherwise only accessible via indirect measurements. One important area for example is the field of interface magnetism. Complex magnetic multilayers have become more and more important over the past decade and are now an integral part of essentially every magnetic device. Often, we use structural characterization tools like high energy x-ray diffraction or transmission electron microscopy to quantify the quality of such interfaces. However, these methods only tell half of the story in the case of magnetic interfaces, since structural and magnetic interfaces can have a significantly different profile. To illustrate this issue figure 1 is shows magnetic domain images obtained using a Photoemission Electron Microscope at the Co and Cu L-resonance in a Cu(1nm)/Co(3nm) bilayer grown on a NiO(100) single crystal. The image of the left side shows rather large black and white areas representing magnetic domains in the Co layer. Corresponding Co soft x-ray absorption and circular dichroism spectra obtained from a single domains are shown in the lower half of the figure. These spectra can be used e.g. to quantitatively determine the number of holes in the 3d band as well as the spin and orbital momentum of Co in this sample. In this case, however, we would like to focus on the element specificity and the sensitivity to small magnetic moments of this technique. The panel on the right side shows an XMCD image acquired at the Cu absorption resonance at the same location. Surprisingly the Cu layer exhibits a net magnetization leading to an XMCD effect and the magnetization mimics the domain structure of the Co layer underneath. In this case the magnetization originates from Cu sites at the interface to the Co layer, that exhibit a small proximity moment of the order of 0.01 Bohr Magneton aligned with the Co layer. This means that the spontaneous magnetization does not abruptly end when moving across the interface from a ferromagnet into a non-magnet, but that the transition is rather gradual and may depend on the actual hybridization between ferromagnet and non-magnet at the interface. In any case the structural and magnetic profile of such an interface is different, which has implications for a wide area of effects, e.g. spin transport across interfaces [1]. Another area in which x-ray microscopy has made a significant impact is the field of magnetization dynamics, e.g. spin transfer torque oscillators. Figure 2 shows an image of a localized spin wave – or spin wave bullet – observed in a Co/Ni multilayer with perpendicular magnetic anisotropy. A spin polarized current is injected into the Co/Ni multilayer from an underlying FeNi film, which leads to localized precession of the magnetization in the Co/Ni layer that is restricted to the area of the current injection, roughly 150 nm in diameter. The magnetization precession leads happens on a cone-like orbit, which causes the projection of the magnetization along the surface normal to be reduced. This reduction of the projection can be detected in an x-ray microscope and leads to the contrast shown in the figure. The size of the contrast suggests that the opening angle of the precession cone is of the order of 30 degree. Here the fact that x-rays are able to penetrate different materials and one can chose to address the dynamic behavior of a particular layer via element sensitivity, allows us to study the dynamics of buried layer in a "real" multilayer structure. While transport measurements on these samples suggested the existence of a spin wave bullet, only the microscopic observation can conclusively confirm this behavior.

BA-03. Neutron Scattering on Magnetic Thin Films.

Y. Liu[1]
1. Neutron Sciences Directorate, Oak Ridge National Laboratory, Oak Ridge, TN, United States

Neutron scattering has played decisive roles in elucidating magnetic structures of crystalline materials in the last several decades, thanks to the relatively weak nature of the neutron scattering from materials and well-understood neutron-material interactions [1]. Historically, neutron scattering has dealt mostly with bulk magnetic materials, and magnetic thin films pose challenges because of their inherently small scattering volumes. With the advance in neutron sources and instrumentations, neutron scattering is more and more employed on magnetic thin film researches. Particularly, thanks to the increased flux and the reduced background, the critical mass of films has been pushed down to be less than 0.05 mg to use neutron diffraction to investigate atomic scale spin orders of functional antiferromagnetic oxide films. At the same time, polarized neutron reflectometry (PNR) has been widely used to determine the depth profile of the vector magnetization structure in magnetic heterostructures, especially at interfaces between dissimilar materials [2]. Interfaces can play a critical role in determining the properties of magnetic heterostructures, e.g. compositionally intermixed interfaces can enhance the energy product of ultra-strong exchange-spring permanent magnets, which consist of a high-magnetization soft phase and a high-anisotropy hard phase. Nanoscale variation of the micromagnetic properties at the interface is believed to be the underlying mechanism, but direct probing in a quantitative manner remains a challenge. We have determined spatially resolved profiles of micromagnetic properties via complementary studies of polarized neutron reflectometry and micromagnetic simulations [2], which we have coined the name "micromagnetic reflectometry" (Fig. 1). In comparison to the profiles estimated from the mixture model, the exchange stiffness is higher but the magnetic anisotropy is lower at the interface. Overall, the interfacial intermixing gives rise to new phases that efficiently couple the soft and hard layers but at the cost of the total magnetization. This result could not have been predicted from the nominal compositions. There are some important technical details in the data analysis. Particularly, significant spin-flip scattering was observed in large magnetic fields in the PNR experiments. The large applied magnetic field lifts the degeneracy of the vacuum energy states for spin-up and spin-down neutrons, i.e., the so-called Zeeman effect, which needs to be taken into account for PNR data analysis [3, 4]. Work at ORNL's Spallation Neutron Source was supported by the Scientific User Facilities Division, Office of Basic Energy Sciences, U.S. Department of Energy (DOE).

BA-04. Polarized Neutron Reflectometry of Epitaxial Fe[0.25 + x] Pt[0.75 – x] Layers.

Australian Nuclear Science and Technology Organisation, Lucas Heights, NSW, Australia; 4. Guangdong Technion-Israel Institute of Technology, Shantou, China

Abstract: Epitaxial Fe[0.25 + x]Pt[0.75 – x] layers can be either antiferromagnetic (AF) or ferromagnetic (FM) depending on the degree of chemical ordering controlled by the deposition temperature. Our neutron diffraction studies were the first to study AF phase transitions in these thin films [1] and we have also shown using PNR that a mixed AF-FM film is exchange biased with itself [2]. In AF-FM exchange-biased superlattices with a modulated chemical order parameter, PNR shows the magnetization can be modulated through the film thickness with no composition modulations [3]. Our recent results reveal that He+ ion bombardment and annealing can be applied toward controlling magnetic phases in epitaxial Fe[0.25]Pt[0.75] layers [4]. Introduction: The magnetic ordering of Fe[0.25 + x]Pt[0.75 – x] is a sensitive function of composition, crystal structure, and temperature. Chemically disordered epitaxial films with $-0.05 < x < 0.05$ are ferromagnetic with Curie temperatures of approximately 380 K. Epitaxial films in this range of composition prepared in the L12 crystal structure can exhibit two types of antiferromagnetism with ordering vectors along the (110) or (100) directions and Néel temperatures of approximately 160 K and 100 K, respectively. Nanostructured composite epitaxial films of ordered and disordered Fe[0.25 + x]Pt[0.75 – x] can be field-cooled through the Néel temperature resulting in chemically homogeneous material that exhibits a unidirectional anisotropy or exchange bias. In this talk, fabricating composite films by ion bombardment as well as characterizing their nanoscale magnetic structures will be discussed. Experimental: Epitaxial layers of chemically ordered single-crystalline material were deposited onto (001)-oriented MgO substrates by magnetron sputtering from a Fe[0.25]Pt[0.75] target. The film thickness was estimated from the sputtering rate and surface epitaxy was monitored by in-situ RHEED measurements. To determine the order parameter of the material, the intensity ratio between fundamental and superstructure x-ray diffraction peaks was measured. Magnetisation vs. field behaviours were measured using a Quantum Design PPMS vibrating sample magnetometer. Low temperature hysteresis curves were acquired after 10 kOe field-cooling from room temperature to establish a preferential exchange bias direction. Results and Discussion: Polarized neutron reflectometry (PNR) is used to aid in depth-profiling the magnetic modulation present in chemically continuous Fe[0.25]Pt[0.75] layers. By conducting a reflectivity measurement using two antiparallel neutron polarization states and taking the difference, the magnetization profile as a function of depth is determined. PNR data collection was performed on the PLATYPUS time-of-flight neutron reflectometer at ANSTO. All PNR measurements were performed in 10 kOe after field-cooling from 300 K in a 10 kOe external magnetic field. He+ ion irradiation was used to modify the chemical ordering in the film, and thus change the magnetic depth profile. Sample irradiation was performed on the SIRIUS tandem accelerator at ANSTO using 15 keV He+ ions, resulting in a FM (near-surface irradiated) / AFM (non-irradiated) FePt3 bilayer structure depicted in FIG. 1. Hysteresis loops of as grown and films irradiated with 15 keV He+ ions reveal changes in the magnetic properties of Fe[0.25]Pt[0.75] layers. The ion bombardment caused chemical disorder between Fe and Pt atoms and a subsequent increase in the 10 K magnetization is observed. Polarized neutron reflectivity was applied to probe the depth dependent magnetization and the data was analyzed to determine structures of films subjected to different ion bombardment and annealing conditions. PNR determines the depth of the disordered region of the irradiated films. These results were applied to further optimize the ion irradiation and annealing to produce tailored structures. A comprehensive model describing how the magnetic behavior is changed by varying degrees of local chemical disorder will be discussed. Acknowledgement: G.J. Mankey acknowledges funding from Bell South and shared equipment at the Center for Materials for Information Technology. BA-05. Characterization of Magnetic Nanostructures with Polarized Neutron and Resonant X-ray scattering.

S. Sinha[1]
1. Physics, University of California San Diego, La Jolla, CA, United States

The basic physics of many magnetic nanostructures used for applications in magnetic information storage, read heads, etc. relates to the behavior of the spins at the interfaces. Measurement of the spatial distribution of magnetization at buried interfaces is often conveniently carried out via techniques such as polarized neutron reflectivity or resonant x-ray magnetic reflectivity and off-specular scattering. One example of a system where interface spins play a key role is an exchange-biased bilayer film, where the hysteresis loop of a ferromagnetic film in juxtaposition to an antiferromagnet is shifted, and this was assumed to be due to "frozen spins" in the antiferromagnet at the interface [1]. Neutron and X-Ray reflectivity have enabled the identification of these frozen spins and of the role they play in exchange bias. Examples will be given of two such systems, namely a Co film deposited on a film of antiferromagnetic FeF2 grown epitaxially on a MgF2 substrate [2]; and a permalloy film grown on a CoO substrate, where the interface interactions and thus the mechanism for exchange bias, are somewhat different [3]. Another example of magnetic nanostructures studied in thin films which have been studied with resonant magnetic X-ray scattering at synchrotrons are the topological entities known as skyrmions. While neutron scattering has played a major role in the discovery of skyrmions and of skyrmion lattices in a variety of materials, some unusual aspects of skyrmions have been discovered using synchrotron radiation. This includes the discovery of bound pairs of opposite helicity skyrmions in Fe-Gd thin films or "skyrmion molecules" [4]. Normally skyrmions are believed to arise as a result of the Dzyaloshinskii-Moriya interaction (DMI) in non-centrosymmetric magnetic materials competing with the regular exchange interaction, although topologically similar spin structures can be stabilized by the competition of long-range dipolar energy in a thin film geometry and domain wall energy [4]. We have shown how in Fe-Gd films, under the right conditions of magnetic field and temperature, one can trace the development of various phases, namely : a stripe domain phase; stripe-to-skyrmion transitions, a skyrmion lattice phase and a uniform magnetization phase. Diffuse magnetic neutron or X-ray scattering from interfaces can play an important role in determining the magnetic domain structure at interfaces and its correlation with interface roughness. We will illustrate this with an example of diffuse magnetic scattering from a Ni film on a V2O3 substrate, which has been shown [5] to yield a large enhancement in the magnetic coercivity at the temperature of the metal-insulator transition (MIT) of the V2O3. An explanation of this effect postulates the creation of a nano-domain structure in the Ni film patterned by the domain structure on the surface of the V2O3 that results from the crystallographic transition accompanying the MIT. Diffuse magnetic scattering utilizing polarized neutrons has enabled the determination of the sizes of these domains. Similarly diffuse magnetic resonant scattering from the interfaces of the Co/FeF2 exchange bias system has shown how the interface domain structure determines the exchange bias as a function of applied magnetic field and temperature. Finally, we shall show how resonant magnetic X-ray scattering using *coherent* X-rays have been used to study the dynamics of some of the spin systems discussed above. This is done using the technique of X-ray Photon Correlation Spectroscopy (XPCS) where the intensity pattern due to magnetic speckle on a two-dimensional detector is autocorrelated with the same pattern at a certain time delay later, yielding the so-called normalized intermediate scattering function f(q,t), which is related to the Fourier transform of the magnetic scattering function from the spins, namely S_{mag}(q, w). This provides an alternative to inelastic neutron scattering (INS) which is useful for looking at longer time-scales than those probed by INS, which are typically a fraction of a nanosecond or less. Thus, one may look at time scales from milliseconds to thousands of seconds using conventional synchrotron sources (used for studying slow fluctuations of magnetic domain walls or frustrated spin systems such as spin glasses), or use the novel double-pulse method with fixed, tunable delays developed at X-ray sources such as the Linear Coherent Light Source (LCLS) at the Stanford Linear Accelerator Center. BA-06. Imaging the statics and dynamics of sub-10nm skyrmions using x-ray holography and scanning transmission x-ray microscopy.

F. Buettner[1]
1. Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, MA, United States

Skyrmions are topologically non-trivial spin textures with enormous potential for applications in computing and data storage technologies. Most of the present interest in these special types of magnetic domains derives from the possibly extraordinary small size of these features. For instance, at cryogenic temperatures, skyrmions down to 1 nm in size were observed already a few years ago [1]. More recently, room temperature skyrmions were observed in ferromagnetic multilayers [2–5]. The fact that all of these room-temperature skyrmions were observed by x-ray imaging illustrates how powerful and significant x-ray probes are for the skyrmion community. X-ray magnetic imaging is based on resonant photon aborption (x-ray magnetic circular dichroism), which provides element-specific magnetic contrast. The most established x-ray imaging techniques are Scanning Transmission X-ray Microscopy (STXM), TXM, and Photo-Emission Electron Microscopy (PEEM). All of these techniques were used to image skyrmions in the range of several tens of nanometers [3–5]. Key advantages of these established techniques are ease of use and rapid image acquisition. For instance, STXM has an unbeaten efficiency of time-resolved imaging. Full time-resolved videos can be acquired in less than 30 min. STXM is therefore a perfect tool for high throughput time-resolved magnetic imaging. The problem of STXM, TXM, and PEEM is that the resolution is limited to 15 nm and that this limit is not likely to be improved dramatically in the near future. In addition, all of these real space imaging techniques suffer from sample drift, which adds to the uncertainty. Therefore, real space imaging is most suitable to study skyrmions of several tens of nanometers in diameter. By contrast, most applications require skyrmions to be sub-10 nm in diameter at room temperature. We have recently derived by analytical modeling that sub-10 nm skyrmions can indeed be stabilized at room temperature [6]. The theory predicts that these sub-10 nm skyrmions exist in materials with close to zero stray field interactions, such as ferrimagnets and synthetic antiferromagnets. The unique capability of element-selective magnetic imaging offered by x-rays is crucial for imaging such antiferromagnetically ordered spin states. It is hence critical to advance x-ray imaging to detect the statics and dynamics of sub-10 nm skyrmions. The most promising route to achieve a breakthrough in high resolution x-ray imaging is to eliminate all lenses and optical elements. Instead, the diffraction pattern of the specimen is directly recorded on a CCD camera, see Fig. 1. The real space image is then reconstructed numerically. Fourier-Transform x-ray Holography (FTH) [7], coherent diffractive imaging (CDI) [8], and ptychography [9] are different strategies of performing this numerical task. The resolution of Fourier space imaging is fundamentally limited only by the wavelength of the incident light and the maximum recorded numerical aperture. An additional advantage of eliminating all lenses is that Fourier space imaging can be performed at next generation x-ray light sources with (sub)-femtosecond temporal resolution, such as free electron lasers [10] and high harmonic generation sources [11]. Furthermore, we have not observed any carbon deposition even after many days of imaging the same sample, which is most helpful when performing systematic studies on a particularly interesting sample. Finally, Fourier space imaging is intrinsically immune to sample drift, which we have recently exploited to track skyrmions with a precision of better than 3 nm in full time-resolved imaging [2]. Here, I will focus on the key advantages of STXM and FTH in the context of imaging small skyrmions. I will show how we applied STXM to measure the skyrmion Hall angle [12] and to systematically study the phase diagram of skyrmions and stripe domains in multilayers as a function of temperature, magnetic field, and applied current [13]. Using FTH, we have tracked the gyrotopic trajectory of a skyrmion with sub-3 nm precision and used this information to determine the skyrmion topology and its quasi-particle equation of motion [2]. Furthermore, we have found a deterministic and ultrafast way of creating skyrmions with spin-orbit torque current pulses [14]. Most recently, we have studied ferrimagnets in which we have observed skyrmions with ultrasmall diameters. Using a combination of apparent size and contrast of the observed features, we can conclude that they are indeed 10 nm in size. Finally, I will discuss strategies to advance Fourier space x-ray imaging to fully resolve sub-10 nm magnetic features in a reliable, robust, and fast way.

Nanocrystalline Fe-Co-Si-B-P-Cu alloys exhibit high saturation polarization J_s above 1.8 T combined with good soft magnetic properties and good glass forming ability [1,2]. In this work we investigated the influence of the annealing time on the structural and magnetic properties in Fe-Co-Si-B-P-Cu alloys. Amorphous ribbons of $Fe_{85.2-x}Co_xSi_{0.5}B_{9.5}P_4Cu_{0.8}$ (x=0, 4, 10, 15, 20, 25, 35, 40 and 57) have been produced by rapid solidification in 25 mm width and 22 μm thickness. The material was annealed at 470°C at various annealing times in the range from 10 s to 60 s [3]. As a result we obtained a nanocrystalline structure of bcc FeCo grains embedded in an amorphous matrix. The crystalline volume fraction (about 50% for all Co-contents), the saturation polarization and the saturation magnetostriction proved to be largely insensitive to the precise annealing time. However, the grain size D and, hence, the coercivity H_c increase significantly with increasing annealing times t_a. Figure 1 shows characteristic examples for the grain size dependence on annealing time, while Figure 2 depicts the corresponding grain size dependence of coercivity. For low Co contents H_c follows a D^6 law while a D^3 dependence is observed for intermediate Co concentrations. For the highest Co contents we observe a transition from a D^3 law for small, to a D^6 dependence for large grain sizes, respectively. These results can be understood from the corresponding contributions of magneto-elastic and magneto-crystalline anisotropy, respectively, which are both changing as a function of the Co-content [4, 5, 6].

Small sized, light weight and high efficiency electrical devices are very important for green and low carbon society. The only way to reduce the size and weight of electrical devices is to operate them at higher frequencies (f) and high power levels. Unfortunately, the operating frequency range of present high magnetic flux density (B) core materials is below few kHz. This is due to various factors related to fabrication as well as fundamental magnetic properties. For example, at high frequencies, energy loss due to hysteresis ($W_h \propto f$) and eddy current ($W_e \propto f^2$) become too large. Generally the material which can be operated at several hundreds of kHz to MHz exhibit low saturation magnetic flux density (B_s). At present magnetic materials used for core applications in high frequency range (10 kHz to MHz) are ferrites. Ferrite has low conductivity, so their eddy current loss is low. That's why ferrite is suitable for high frequency applications. Recent developments in semiconducting components allow circuits to operate at higher frequencies and higher power levels, which force soft magnetic cores to be heavier and larger in size. This is due to low $B_s \leqq 0.5$T of ferrite. Therefore, to miniaturize electrical components and improve their performance at higher frequencies, materials with high B_s and low core loss (W) must be developed. Metallic alloys, such as amorphous and nanocrystalline have excellent soft magnetic properties ie. high B_s and low coercivity (H_c). Best high B_s (~1.85 T) and low core loss material with the ability to mass-produce is based on FeSiBPCu alloy (trade name NANOMET®) [1, 2]. There are some issues for applying this alloy to high frequency applications. For example, eddy current loss is high due to its high electrical conductivity. Developing the alloy in powder form can help in reducing the eddy current loss. Alloy with lower content of Fe (~76 at.%) can be produced in amorphous powder form by gas atomization process. However, it is difficult to produce amorphous powders with higher contents of Fe (>79 at.%) in the alloy, and it is due to low amorphous forming ability. A special technique like spinning water atomization process (SWAP) which has high cooling rate is required. The SAWP can produce amorphous powders of FeSiBPCu alloy with Fe content up to ~83.3 at.%. The average powder particle size produced with gas atomization and SWAP is ≥ 30 μm [3]. Size of the powder particles is very important for suppressing the eddy current loss at high frequencies. Therefore it is necessary to produce small size powder particles of FeSiBPCu alloy. Based on skin depth, the average powder particle size should be below 10 microns for the core operating at frequencies up to few tens of MHz. There is hardly any report on fabrication and magnetic properties of such small sized soft magnetic powders. We have attempted to produce the soft magnetic powder particles of size below 10 μm by gas atomization. Here, we report on the fabrication and magnetic properties. Two alloys were selected for the fabrication of powders; one (FeSiBP) with lower content of Fe (~76 at.%), and the other FeSiBPCCu with higher contents (~81.5 at.%) of Fe. This selection was made after analyzing the properties of these alloys in ribbon form. The cooling rate in gas atomization process is influenced by the type of the gas and its pressure, therefore we used Ar, N_2, and He gases with pressure up to 9 MPa. Size distribution of powder particles was measured by laser based particle size analyzer. Powders were classified in to different size ranges for example under 10 μm, under 20 μm, between 20-38 μm etc. Powders were analyzed in terms of their shape, structure, thermal and magnetic properties. Toroidal cores were made by mixing with a polymer resin. Atomization with He and N_2 gas is effective for increasing the cooling rate, when compared with Ar gas. The $Fe_{76}Si_9B_{10}P_5$ alloy powders made with different gases were amorphous, and it is due to high amorphous forming ability of this alloy. However, the results were quite different for high Fe content $Fe_{81.5}Si_{0.5}B_{4.5}P_{11.0}Cu_{0.5}C_{2.0}$ alloy. Processing with Ar gas only produces amorphous powders with size below 10 μm. The He and N_2 gasses showed significant improvement in cooling rate, and we could obtain amorphous powders with size below 20 μm. Intestinally the yield of powder particles with size below 10 μm was highest for He gas. The classified powders were mixed with polymer resin and molded under a pressure of 1500 MPa to make toroidal shaped cores (inner diameters: 13 mm, outer diameters: 8 mm). Pressed cores were annealed to optimize the magnetic properties by releasing the process related stress. Magnetic permeability was measured using impedance analyzer. Total core loss, which is the sum of hysteresis loss and eddy current loss was measured by ac B-H analyzer. Figure 1 shows the core loss at different frequencies (up to 1 MHz) under the magnetic induction B_m of 50 mT for $Fe_{76}Si_9B_{10}P_5$ alloy powder cores made under similar conditions. A significant decrease in coreloss at higher frequencies is noticeable. The core loss at 1 MHz is almost more than 4 times lower for a core with smaller particle size (under 10 μm) when compared with a core made from large sized particles (20 - 38 μm). The obtained results are important for the development of future high frequency and high power electronics. The details of the results and their analysis will be presented during the conference.

Miniaturization of the RF passive devices and DC-DC converters is key to achieving lighter, faster and more efficient mobile devices, and high-conversion ratio DC micro-grids, as the 5th generation (5G) wireless network and Internet of Things (IoT) paradigms emerge. In order to realize this objective, however, the biggest challenge remains shrinking the size of the chip-integrated magnetic components (e.g. micro-inductors, micro-transformers). Due to their flux amplification properties and high operating frequencies, integrated thin film magnetic cores with high permeability based on amorphous and polycrystalline magnetic alloys promise further device miniaturization, lower energy loss and thus lower power operation [1,2]. Yet, integrating these magnetic films on the silicon complementary metal oxide semiconductors (Si-CMOS) platform is technologically very challenging, since for a significant inductance enhancement, several-micrometer-thick films with ultra-low losses need to be deposited. Moreover, leveraging this gain requires complex tailoring of the device architecture and magnetic thin film properties, since maximizing simultaneously the inductance, frequency bandwidth and peak quality factor is very difficult [3]. In this work, we present an economical method of manufacturing magnetic thin films, which allows combining soft magnetic materials with complementary properties, e.g. high saturation magnetization, low coercivity, high specific resistivity and low magnetostriction. Soft magnetic multilayered thin films based on the $Ni_{78.5}Fe_{21.5}$, $Co_{91.5}Ta_{4.5}Zr_4$, $Fe_{52}Co_{28}B_{20}$, $Fe_{65}Co_{35}$ alloy materials were deposited on 8" bare Si and Si/200nm-thermal-SiO_2 wafers in an industrial, high-throughput Evatec LLS EVO II magnetron sputtering system [4]. The sputtered multilayers consisted of stacks of alternating 80nm-thick ferromagnetic layers and 4nm-thick Al_2O_3 dielectric interlayers. Since the substrate cage rotates continuously, such that the substrates face different targets (e.g. NiFe, FeCoB, CoTaZr) alternatively (Fig. 1a), each ferromagnetic sublayer in the multilayer stack can exhibit a nano-layered structure with very sharp interfaces as revealed by X-ray reflectometry (XRR) and transmission electron microscopy (TEM) (Fig. 1b,c). We adjusted the thickness of these individual nanolayers by changing the cage rotation speed and the power of each cathode, which is an excellent mode to engineer new, composite ferromagnetic materials with tunable properties. The ferromagnetic layers were deposited by DC sputtering at a pressure of 1.7×10^{-3} mbar using Ni-21.5%Fe, Fe-28%Co-20%B (at.%) and Co-4.5%Ta-4%Zr long life (~250 kWh) targets, whereas the dielectric Al_2O_3 interlayers were deposited by RF sputtering from monoblock Al_2O_3 targets at a pressure of 5×10^{-3} mbar. We introduced the in-plane magnetic anisotropy in these multilayered thin films during sputtering by a linear magnetic field parallel to the wafer plane, which is designed such that the magnetic field of the magnetron located behind the opposite target is not perturbed. In-plane hysteresis loops (along the EA and HA directions) measured by means of magneto-opto Kerr effect (MOKE) and B-H looper revealed that the coercivity (H_c), anisotropy field (H_k) and magnetostriction of these thin films can be tuned with the thickness of the individual magnetic nanolayers (Fig. 2). The behavior of the coercive field for these nanolaminated films was explained by the random-anisotropy model based on grain size considerations (Fig. 2a). The nanolaminated structure exhibited a uniform magnetization throughout its structure with good microwave properties, as revealed by broadband (100 MHz - 10 GHz) RF spectra. The classical Landau-Lifschitz-Gilbert (LLG) model could describe well the experimental behavior of the magnetization dynamics of the multilayered structure (Fig. 2c,d). Since the nanolaminated multilayered structures exhibited no degradation upon post-annealing up to a temperature of 300°C, these materials are very promising for on-chip micro-magnetic devices.

Soft magnetic Fe-based Fe-Si-B amorphous alloys have been widely used as magnetic components in high frequency transformers, inductors, and sensors due to their magnetic behavior [1], [2]. These materials are typically produced by the "melt-spinning" technique, involving the rapid solidification process. It is important to remark that the amorphous ribbons obtained by the melt-spinning technique were widely introduced as soft magnetic materials in the 70s. One of the ways to advance in the research field of magnetic materials involves the exploration of new routes to fabricate them. Thus, a novel technique of rapid solidification that we have successfully used to produce soft magnetic amorphous alloys is gas atomization [3], which produces the material in powder form. In this technology, it is possible to reach average cooling rates of up to 10^6 K/s, depending on processing conditions and the atomizing gas. The soft magnetic character of gas atomized powders with composition $Fe_{70}Si_{18}B_{12}$ was reported by the authors in [3]. It was showed that particles <10 μm were amorphous and exhibited a low coercive field of around 7 Oe. Recently, the authors have produced a gas atomized powder of composition $Fe_{72.5}Si_{12.5}B_{15}$ that is fully amorphous for the whole particle size distribution, whose 90th percentile is 48.7 μm. Particles with a diameter <20 μm exhibit a coercivity of 3.26 Oe. It is well known that a thermal treatment below the crystallization temperature leads to structural relaxation with a significant improvement of the soft magnetic character [4]. In this work, we report the effect of the thermal treatment (at 250, 350, and 450 °C for 0 and 1 h) on the magnetic behavior of amorphous powder $Fe_{72.5}Si_{12.5}B_{15}$ with a particle size <20 μm. The annealing time of 0 h means that the sample was heated up to the annealing temperature and immediately cooled down without any holding. After such thermal treatments, the amorphous character of the annealed alloys was checked by X-ray diffraction technique. Fig. 1 shows the hysteresis loops of the annealed samples measured at room temperature, denoting the soft magnetic character associated with a very low value of coercive field. In fact, coercive field significantly decreases (see Fig. 2) from 3.26 Oe (as-atomized) to 0.44 Oe (annealed at 450 °C). There is an influence of the annealing time in this drop, with lower values of coercivity in the samples treated for 1 hour, except for the samples treated at 450 °C, whose coercivity is practically the same. The above mentioned behavior of the coercivity should be ascribed to the structural relaxation associated with thermal annealing without crystallization, decreasing the internal stresses and leading to a significant reduction of the magnetoelastic anisotropy.

BB-05. Novel making method of high resistive surface layer of Fe-based amorphous alloy powder by surface-modification using two-step acid solution process.

K. Sugimura[1], N. Yabu[1], M. Sonehara[1] and T. Sato[1]
1. Faculty of Engineering, Shinshu University, Nagano, Japan

Silicon carbide (SiC) and gallium nitride (GaN) based power devices are well known for the application for high frequency switching converters, and their low on-resistance property is beneficial for the replacement of silicon (Si) based power devices [1], [2]. Application of these power devices to MHz switching DC-DC converters is expected to realize a compact and light-weight converter with a high conversion efficiency. Although the magnetic core for inductors and transformers must have low core-loss at MHz band to be applied to SiC/GaN based MHz switching converter, currently there are only Ni-Zn ferrite core available[3]. The authors reported an iron(Fe)-based metal composite magnetic core with 2.6 μm-diameter amorphous alloy powder (AMO-powder)/epoxy-resin and its application to MHz switching LLC resonant converter[4]. In order to reduce the core-loss at MHz band or above, the AMO-powder (Fe-Si-B-Cr-C) should have high electrical resistivity surface layer to suppress the over-lapped eddy current between the adjacent AMO-powders within the composite core. Silica (SiO_2) coating and surface oxidization are effective to make a high-resistive thin layer on the surface of such the metal powder[4], [5]. In this study, the authors have proposed a novel making method of the high-resistive thin layer on the water-atomized AMO-powder (Fe-Si-B-Cr-C) using the acid solution treatment. The novel method was based on the two-step acid solution treatment, the first-step phosphoric acid (H_3PO_4) treatment and the second-step hydrochloric acid (HCl) treatment. FIG. 1 shows the cross-sectional SEM image of a typical example of the surface-modified AMO-powder through the first-step treatment using 5 %-H_3PO_4 for 6 hours and the second-step treatment using 5 %-HCl for 4 hours. As shown in FIG. 1, two layers on the surface of the AMO-powder were observed. The inner layer was formed through the first-step phosphoric acid treatment and the outer layer was formed through the second-step hydrochloric acid treatment. The surface-modified layer thickness could be changed by the process conditions such as concentration of the acid solution and treatment time. The surface-modified two layers of the AMO-powder were analyzed by using X-ray photoelectron spectroscopy (XPS), where the XPS analysis targeted Fe-2p and Si-2p spectrum, the main reason for selection of Fe-2p and Si-2p spectrum was based on an idea that Fe and Si element in the AMO-powder were considered to contribute in the formation of a high-resistive surface layer composed of the iron-oxide and silicon oxide. FIG. 2 shows the XPS spectrum of Fe-2p and Si-2p evaluated for as-atomized AMO-powder and the two-step surface-modified AMO-powder. In the as-atomized powder, the peaks of metal-iron Fe(0), iron-oxide and oxygen deficient silicon-oxide near Si_2O_3 were observed. After the first-step phosphoric acid treatment, the peak of the metal-iron Fe(0) disappeared and the silicon-oxide changed to stoichiometric silicon-dioxide SiO_2. After the second-step hydrochloric acid treatment, the spectrum derived from the iron-oxide disappeared, and the SiO_2 peak became sharp with increasing the treatment time. From the above-mentioned results, the most outer surface layer of the two-step processed AMO-powder was considered to be high-resistive stoichiometric silicon-dioxide SiO_2. It was also thought that we could make a single-phase SiO_2 thin layer on the AMO-powder by an appropriate condition of the two-step acid solution treatment. The novel method for making the single-phase SiO_2 thin layer on the AMO-powder will be effective to suppress the eddy current over-lapped between adjacent powders within the composite magnetic core. The more detailed results will be presented at the conference.

The physical properties of the amorphous metallic alloys are useful for different practical applications. For example, corrosion resistance of amorphous Fe-based alloys with reduced Cr content is higher than corrosion resistance of the crystalline stainless steel. An electric resistivity of amorphous phase is 2-4 times higher than of crystalline one usually, as a result, the lower eddy current losses can be detected. Ferromagnetic amorphous metallic alloys are extremely soft. More other, amorphous alloys have good mechanical properties and they can be manufactured in different forms: ribbons, wires, powder, microwires etc. As a result of these properties combination, ferromagnetic amorphous metallic alloys are widely used as high-frequency cores of transformers, high performed sensors etc. [1-3] There is the stress distribution through the characteristic size (diameter or thickness) because of rapid cooling manufacturing processes, whose influence on magnetic properties has drastic role. Depending on fabrication technique, the value of stresses and the distribution are various even for the same composition of the alloy. In our research we compared properties of amorphous ribbons (up to 2 cm width and 29 micron thickness), rapid quenching method – microwires (up to 180 micron in diameter), Ulitovski-Taylor technique – glass-coated microwires (up to 23 micron of metallic diameter and 29 micron of total diameter) with similar composition. Amorphous structure and chemical composition were examined by XRD and EDX analysis, correspondingly. Magnetostatic properties were studied by Vibrating Sample Magnetometer (VSM), high frequency magnetic properties – by spectrum analyser. For hysteresis loops measurements by VSM the 15 mm length of the samples and magnetic field amplitude up to 2kOe were used. For magnetoimpedace measurements the following characteristics were used: I_{AC} till 20 mA, f_{AC} = 0.5-20 MHz, H_{ext} = 0-40 Oe. The comparison was made after length normalization. Depending on the stress distribution through the characteristic size of sample, its magnetic properties are quite different, shape of the hysteresis loops are drastic changed (see Fig. 1). Magnetoimpedance measurements allowed us, solving the inverse problem, to find the field dependences of the magnetic permeability of microwires with different diameters (see Fig. 2). Based the comparison we estimated the distribution of the permeability in the samples. Acknowledgement. The work was supported by the Russian Foundation for Basic research (grant No 18-02-00137)

Cylindrical ferromagnetic glass-coated microwires are among the most studying types of the numerous family of wires consisted of objects with different dimensions and shapes [1-3]. A peculiar crystal state, and magnetic properties as a consequence, of the microwires are extremely sensitive to initial manufacturing conditions, which makes them convenient to tune required properties. The sensitivity of engineered magnetic properties to further external conditions makes microwires useful for a lot of practical applications. For instance, ferromagnetic glass-coated microwires show a number of outstanding effects depending on composition (Fe-, Co-, CoFe-based alloys, Heusler alloys etc.) and crystal state (amorphous, nanocrystalline or crystalline) of the ferromagnetic core [4, 5]. These effects include magnetic bistability [6] used in coding, logic, and memory systems (for example, [7, 8]), magnetoimpedance effect [9, 10] used in high-performance sensors [11, 12], shape memory and magnetocaloric effects [13, 14] for magneto-mechanical actuators [15]. The ability to produce partially crystalline microwires was demonstrated several years ago (for example, [3, 16, 17]) and is actively studied now (for example, [18, 19]). For obtaining nanocrystals in amorphous matrix different methods were used, for example, adding new components to initial alloy [16], or changing the manufacturing conditions [17, 19]. The possibility to switch magnetisation of different phases by varying magnetic field strength leads to a step-wise hysteresis loops. Magnetic properties of microwires which can be controlled and tuned in this way, are used for sensing and logical devices [20–22]. The purpose of this work is twofold: (i) to explore the effect of partial crystallisation in the metallic core on the magnetic properties of microwires and (ii) to find the manufacturing conditions for formation of single and multiphase metallic core of glass-coated microwires. We investigated glass-coated $Fe_{77.5}Si_{7.5}B_{15}$, $Fe_{45}Co_{30}Si_{10}B_{15}$ and $Co_{69}Fe_4Cr_4Si_{12}B_{11}$ microwires with metallic core diameter, d, from 8 mkm to 24 mkm, and total microwires diameter, D, from 12 mkm to 29 mkm. All samples were manufactured by quenching and drawing method. Changing technological parameters, such as a drawing velocity (1.3-9.1 m/sec) and cooling conditions (air and water cooling), leads to the variation of microwires diameters (both d and D) and enables production of microwires with tunable crystal structure of the magnetic metallic core: amorphous, nanostructured, the nanocrystals (can be with different crystal cells) inside the amorphous matrix [19]. The crystalline structure of the microwires was investigated by X-ray diffraction analysis and transmission electron microscopy. The Lake Shore vibrating sample magnetometer was used for evaluating magnetostatic properties. The length of the samples was 15 mm to exclude the influence of demagnetization factor. The rectangular hysteresis loops and amorphous structure – magnetic bistability – were found to be for all microwires prepared at high rate of cooling (water) independent of velocity of extraction and for $Fe_{77.5}Si_{7.5}B_{15}$ and $Co_{69}Fe_4Cr_4Si_{12}B_{11}$ microwires at low rate of cooling (air) and high velocity of extraction. The step-wise hysteresis loop in Figure ($Fe_{45}Co_{30}Si_{10}B_{15}$ microwire, air cooling) is typical for biphase microwires. The wide parts of the loop correspond to the crystal phase magnetisation reversal. By analyzing the step-wise hysteresis loop, we have estimated an amorphous phase volume (M_1/M_S) as well as coercive forces for each phase (Hc is estimated at half-height) depending on diameter of metallic core (see Figure). Our assumptions, based on the results of magnetic measurements, coincide with XRD and TEM analysis of the microwires. The same evaluation of properties can be trace for $Fe_{77.5}Si_{7.5}B_{15}$ wires. The magnetic response of different phases (amorphous, FCC and HCP Co modifications) of metallic core of $Co_{69}Fe_4Cr_4Si_{12}B_{11}$ wire is expressed as a change of the loop slope. The following tendency was found: if the volume of crystalline phase in the amorphous matrix is small (less than 20%) bistability is not suppressed: magnetisation reversal occurs mainly through the large Barkhausen jump, and a second phase arises, leading to a change in hysteresis loop shape to a step-wise one; formation of a larger volume of crystalline phase (more than 70%) in metallic core of microwire leads to a substantial change of magnetisation behavior: the multiphase behavior is expressed in the change of the hysteresis loop slope. In summary, we have found conditions to prepare single, bi- or multiphase glass-coated microwires (see table) and analyzed the role of structural properties on magnetic characteristics of glass-coated microwires [19]. Thin cylindrical wires attract considerable attention due to the interesting features of domain wall motion like absence of the Walker breakdown that makes possible to reach very high domain wall velocities [1]. While several experimental techniques allow for well controllable deposition of magnetic structures with complex geometries [2], a reliable determination of the surface magnetization usually meets several obstacles in case of samples with curved surface. Here, we provide a full analytical calculation of the Magneto-Optical Kerr Effect (MOKE) contrast for cylinders with reduced diameter. Understanding the underlying mechanisms allows devising a new approach for interpretation magneto-optical observations of amorphous glass-coated microwires. It is shown that the cylindrical shape of sample surface gives rise to a spatial distribution of the planes of incidence that are all tilted each to other [3]. Such mutual orientation of incident rays in combination with circumferential dependence of a local angle of incidence gives rise to apparent magneto-optical contrasts [3,4] that cannot be interpreted well without considering the curved surface of a cylinder. The magneto-optical contrast of magnetic cylinder is calculated for various angles of incidence, directions of surface magnetizations, directions of linear polarizations and as a function of an angle between polarizer and analyzer. Theoretical calculations [3] are tested experimentally on amorphous glass-coated microwires with well-defined cylindrical shape. Finally, our framework is used to study the shape of domain wall in FeSiB microwire characterized by very fast domain wall propagation that can reach up to several km/s. Our results show that a domain wall has tilted structure in these wires, which partially explains such high velocities.

1. Hebei University of Technology, Tianjin, China

I. INTRODUCTION In recent years, the application of nanocrystalline alloys in the field of electrical engineering is becoming more and more common. Nanocrystalline alloy materials have become one of the most important magnetic materials [1]. The nanocrystalline alloy has excellent electrical and magnetic properties and has been well developed in power, communications, medical, defense and civil products. At high frequencies, compared with the silicon steel sheet material for electrical workers, the nanocrystalline alloy not only has high permeability and low eddy current loss. The study of the magnetic properties of the nanocrystalline alloy, especially its properties in high-frequency rotating magnetic field, is of great significance for the use of this material. First of all, two-dimensional high-frequency rotating magnetic properties testing system is built. Secondly, two methods for measuring the magnetic flux density are compared, which are the probe method [2] and the capacitance method [3] Then, the magnetic properties of nanocrystalline alloys at high frequency were measured and compared respectively by the two methods of measuring the flux density. Finally, the advantages and disadvantages of the two methods were analyzed by the experimental results. II. TWO-DIMENSIONAL MAGNETIC PROPERTIES DETECTION SYSTEM The principle of the excitation is to pass the current signals 180 ° out of phase with each other in the orthogonal winding so as to generate a two-dimensional alternating magnetic field. Two-channel excitation signals are generated by LabVIEW programming software. As the excitation signal is weak enough to magnetize the excitation winding, the signal is amplified by two high-performance linear power amplifiers to drive the two axial excitation coils on the measurement device, For the excitation device to provide excitation current to ensure that the AMDA sample to be fully magnetized at a given frequency. The sample of the microcrystalline alloy is installed inside the BH composite sensor integrated module. After the sample is magnetized, the two sets of probes on the B sensor can measure two voltage signals corresponding to Bx and By, and the H coil can measure Hx and Hy corresponding to the two sets of voltage signal. Then, the collected four sets of voltage signals are amplified by a voltage preamplifier. Finally, through the four virtual input channels of the data acquisition card, the amplified voltage signal is collected and sent to the computer connected with it, and the data is processed and analyzed by LabVIEW software on the PC side. III. MAGNETIC FLUX DENSITY SENSOR AND H COIL During the experiment, the voltage signals corresponding to Bx and By, and Hx and Hy corresponding to Hx and Hy are measured by the sensor after the magnetization. Then, the signal is amplified by an amplifier. Finally, the voltage signal is collected by a data acquisition card and transmitted to Computer analysis and processing. A. probe method of measuring flux density NPT in the measurement process, the flux changes make the sample section eddy current, the sample has conductivity At the resistor), this creates a potential difference across the surface of the sample and the magnetic flux density B can be calculated from the induced voltage drop. The measurement principle shows that the method is suitable for monolithic measurement of magnetic materials. B. Capacitance flux density sensor In order to ensure good electrical contact, some force must be applied to the probe surface to the sample. The force is usually provided by a spring-connected probe that is pressed against the sample by a spring probe to maintain a constant force. The combination of force with the very sharp tip of the probe can lead to micro-damage on the surface of the material. The capacitance method is the probe for the conductive patch attached to the surface of the sample to be measured, the same use of eddy current pressure drop to derive the magnetic flux density. Its advantages are twofold: first, there is no need to insulate some samples; second, it does not introduce any micro-damage on the sample surface. C. H coil The principle of measuring the size of the magnetic field is the law of electromagnetic induction. There are two H coils for measuring the magnetic field strength, namely the Hx coil for measuring the magnetic field in the x direction. The structure of two H coils is exactly the same, the winding directions of the coils are perpendicular to each other, and used to measure the magnetic field strength in both directions of x and y. The coil is composed of a skeleton and enamelled fine copper wire. The skeleton is an insulating material and has a thickness of 0.5mm. The winding part is a square with a side length of 14mm. The diameter of the thin copper wire is 0.03mm, which is uniform and close Winding into a single layer, a total of winding 310 turns. In order to eliminate interline interference, H coil lead-out part also uses the form of twisted pair. IV. CONCLUTION It can be seen from the measurement results that the experimental data of the flux density measured by the capacitance method are very close to the data measured by the probe method. However, the capacitance method can obtain a sinusoidal waveform with better magnetic flux density, which is easy to control and reduces The complexity of the control method is a good way to obtain the nanocrystalline magnetic properties at higher magnetic flux densities.

BB-10. Thickness dependent high frequency properties of multistripe patterned FeCoBSi magnetic films.

L. Zhang[1], Y. Liu[1], H. Zheng[1], W. Zhu[1], M. Zhang[1], P. Zhou[1], H. Chen[1], X. Wang[1], H. Lu[1], J. Xie[1] and L. Deng[1]
1. School of Microelectronics and Solid-State Electronics, University of Electronic Science and Technology of China, Chengdu, China

With the rapid development of telecommunication technology, the problems of electromagnetic inference (EMI), which deteriorate the performance of such systems in high frequency, attract public attentions significantly. EMI suppression materials, especially for magnetic shielding materials with noise suppression at high frequencies, pave the way for material scientists and RF engineers to protect susceptible devices. In order to satisfy requirements of EMI shielding materials, broadband and controllable resonances of magnetic films are desired. Meanwhile, a high damping factor at designed frequency would make contribution to realize promising EMI devices. Due to in-plane uniaxial anisotropy of a film could lead to well soft magnetic properties at Gigahertz frequency, hence better absorption properties, several methods including induced magnetic field, induced stress during deposition, multi-layer design, post annealing under external magnetic field were investigated. Besides, patterned magnetic films with induced shape anisotropy designed by artificial structure, draw great public attention due to its controllable and robust properties. Therefore, in this paper, in order to expand the resonance band furthermore, we introduced a unique multi-striped patterned FeCoBSi thin films and analyzed the novel broadened band phenomenon due to multiple resonance peaks with the Landau-Lifshitz-Gilbert (LLG) processional motion formulism. A series of $Fe_{66}Co_{17}B_{16}Si_1$ thin films were deposited on silicon (111) substrates by DC magnetron sputtering at room temperature. An external magnetic field of 500 Oe was applied along the short axis of the substrate to induce in-plane uniaxial anisotropy. Traditional ultraviolet (UV) lithography technology and lift off method were used to fabricate the multistriped patterns. A combined stripe patterned FeCoBSi films containing various stripes with different width were processed depending on thickness. The stripes were arranged successively with width sequence as 5um, 10um, 15um, 20um and 25um respectively. A separation gap of distinctive stripes was fixed at 5μm. The thickness of the patterned films varied from 45 nm to 135 nm. VSM measurement was operated at room temperature in order to characterize the static properties of magnetic films. The films with different thickness all possess a significant in-plane uniaxial anisotropy as figure 1 showed. Such uniaxial anisotropy was contributed by induced magnetic field as well as the stripe shape induced anisotropy. Furthermore, the hysteresis loops in figure 1 revealed well soft magnetic properties with coercivity as low as 13 Oe. With increase of film thickness, coercivity would decrease from 32 Oe at 45nm to 13 Oe at 135 nm, which was in accordance with random anisotropy model proposed by Herzer[1]. When the films were composed of amorphous or granular structure, if the grain size exceeded the exchange length (for FeCo-based alloys, the exchange length is approximately 46 nm[2]), the coercivity was inversely proportional to the former factor, hence decreased with increase of film thickness[3]. The broad resonance band phenomenon was enhanced with full width half maximum (FWHM) of 3.85 GHz at thin thickness, i.e. 45 nm for our experiments as showed in figure 2. The broaden band phenomenon was due to the different shape anisotropic field induced by different width stripe as our assumption. Consider the fixed width of the gap as 5um, which is large enough to magnetically separate the two consecutive stripes without coupling effect. Thus, each stripe was actually independent to each other leading to separate magnetic response under microwave excitation. The total response to the high frequency electromagnetic field should be a mathematical addition of every stripe[4]. Meanwhile, the alteration of resonance frequency could be predicted by the mathematic formula related to demagnetization factors. The results could be further illustrated by the shape induced effective anisotropy filed due to distinguished stripe width, which made it possible to control by the traditional lithography process in the actual application. In conclusion, multistripe patterned FeCoBSi thin films with different thickness were fabricated by DC sputtering and UV lithography technology. Band broadened phenomenon and multiple resonance peaks were observed in the experiment. Compared to the former double-striped patterned films, multistriped pattern could extend the resonance band (FWHM) furthermore to 3.85 GHz. By calculating the theoretical resonance frequency of different stripe, one can conclude that the band broadened phenomenon is contributed to supposition effect of various resonance peaks. The broaden band phenomenon could be controlled by tuning width of different stripe as well as thickness of magnetic films in order to meet the requirement in the actual application, which may be useful in the future EMI devices.

BB-11. Microwave behaviour of metacomposites containing CNTs-coated ferromagnetic microwires.

Y. Luo[1], S. Wei[1], D. Estevez[1], F. Qin[1] and H. Peng[1]
1. Material Science and Engineering, Zhejiang University, Hangzhou, China

Metamaterials are featured with peculiar left-handed electromagnetic (EM) characteristics in favour of a wide range of interesting applications such as invisibility cloak, zero-loss imaging, perfect absorbers, etc.1,2 Nevertheless, conventional metamaterials are restricted to designs of periodical structures without considering the intrinsic materials' properties of building blocks. Fabrication technologies allow realising metamaterial properties from microwave to optical frequencies yet they are not cost-effective for mass production. We have proposed the term of 'metacomposites' to remedy these issues: (i)Metacomposites are 'true' piece of material possessing single/double negative left-handed features rather than a structure. (II) The eventual left-handed EM properties are manipulated by both dielectric/magnetic properties and geometrical arrangement of building blocks. (III) Metacomposites can be manufactured by an engineering technique. Microwires with ferromagnetic elements have been proved as desirable metamaterial building blocks due to their excellent soft magnetic properties and limited scattering effects to incident waves.3 It has been demonstrated that glass fibres reinforced composites containing ferromagnetic microwires display a double negative (DNG) feature evidenced by their transmission behaviour.4 However, such a metacomposite has rather limited response to external stimuli,5 e.g., magnetic fields, current, etc., which is crucial for practical applications. In the work, as a continuous effort, we design and manufacture rubber-based composites embedded with multiwall carbon nanotubes (MWCNTs) coated microwires. The magnetic properties of microwires can be optimised by a proper annealing dc current of 25 mA indicated by their giant magnetoimpedance (GMI) signature. The microwave properties of their composites show a remarkable on/off modes of left-handed behaviours tuned by external current bias. Experimentally, melt extracted amorphous $Co_{68.15}Fe_{4.35}Si_{12.25}B_{15.25}$ microwires with diameter of 70μm were used in the present work. MWCNTs (Cheaptube, purity 95%) were coated on the wires by electrophoretic deposition (EPD) technique in the following process.6 CNTs were chemically oxidised in a mixed solution of H_2SO_4, $KMNO_4$, $NaNO_3$, and H_2O_2 to generate carboxyl acid groups on the CNT surface in order to create negative surface charges. The deposition process was carried out at 10V bias for 120 seconds to ensure a homogeneous layer of CNTs on wire surface. Post current annealing was conducted by clamping microwires on a dc power supply with electrical current of 5mA, 10mA, 15mA, 20mA, 25mA, 30mA, respectively for 10 min. The impedance spectra Z(f, H) of microwires were extracted using a ZNB 20 vector network analyzer (VNA) (Rohde & Schwarz) with the probe current frequency within the range 1MHz $\leq$ f $\leq$ 200MHz.7 Testing frequencies are assigned as 1MHz, 10MHz, 100MHz and 200MHz, respectively with external fields swept in -40 $\leq$ H $\leq$ +40Oe. For the manufacture of composites, CNT-coated microwires were arranged into rubber matrix in a parallel manner with identical spacing of 2 mm, followed by an oven curing process at 125 oC for 30 min. Microwave measurement was conducted in WR-90 waveguide in the range of 8.2-12.4GHz. The complex permittivity was computed using the Reflection/Transmission Epsilon Fast Model.8 The low-frequency MI profiles (1 MHz) of CNT-coated wires (inset of Fig. 1) showcase a typical single peak feature, indicating that domain wall displacement dominates the magnetization process in the wires. Also, such mechanism is insensitive to CNTs-coating and annealing currents. Further, a double-peak transition appears (Fig. 1) as the measuring frequencies increases due to the stronger spin rotating therein. It is found that applying a dc bias up to 25 mA is beneficial in enhancing the GMI ratios arising from the increased volume of circular anisotropy of the used Co-based wires due to the relaxed surface stresses between CNT/wire interfaces. However, further increasing current to 30 mA is detrimental to GMI properties due to the possible crystallization on the wire surface that is unfavourable of magnetization rotation. Remarkably, the real part of permittivity of wire-composites shows a non-plasmonic signature as the annealing current is below 25 mA, suggesting a non-metamaterial medium. This is attributed to the discontinuous CNT islands that prevent the wires being as perfect electric conductor, which is a prerequisite for using Pendry's model.9 Further increasing annealing current to 30 mA induces dipole-dipole polarisation among CNTs and enhances the conductivity of CNT-coated wires and excited dielectric responses from the surface impedance (Fig. 1). Subsequently, plasmonic behaviour appears as evidenced in Fig. 2. The key features in the present study provides insights to design and fabricate tunable left-handed composites that are of potential engineering interest for cloaking and sensing applications.

The need for more efficient energy conversion and/or distribution systems is a challenging and strong demand nowadays. Among other materials, amorphous and/or nanocrystalline soft magnetic alloys are a viable alternative for both storage and transportation of the energy. In the recent years, they turned out to become competitive with silicon electrical steels and various ferrites for niche applications, mainly the ones involving working at high frequencies and temperatures [1]. The literature reports many attempts to improve the soft magnetic properties of Fe-based amorphous and/or nanocrystalline rapidly solidified materials, by modifying either the composition or annealing conditions. For example, it was shown that by replacing 22 at.% of Fe with Co, the Co-substituted FINEMET alloy can be used at 500^{0}C, the relatively low coercivity being preserved even at such high temperatures [2]. In order to study further these correlations and to understand why an amorphous and/or nanocrystalline material with nearly-zero magnetostriction has a large output response when subjected to a mechanical stress or vibration, in this work we will present comparatively our latest results on the collective behavior of nanograins in Co-substituted FINEMET and VITROPERM 800 rapidly quenched alloys, having nominal compositions $(Fe_{1-x}Co_x)_{73.5}Cu_1Nb_3Si_{13.5}B_9$ and $(Fe_{1-x}Co_x)_{73.5}Cu_1Nb_3Si_{15.5}B_7$, respectively (x = 0, 0.25, 0.5, 0.75 and 1), in the as-quenched state and after annealing at temperatures between 500 and 600°C. Our study mainly focusses on how Co influences the precipitation and anisotropies of the nanograins, as well as the temperature variation of magnetic and magnetoelastic properties of the 2 systems. In addition, we were interested to understand why the small compositional variations of Si and B in FINEMET and VITROPERM 800 alloys are inducing a strongly different magnetoelastic behavior in the as-quenched amorphous samples, with small positive magnetostriction values for FINEMET samples and zero magnetostriction for VITROPERM 800 ones. The as-quenched samples are fully amorphous as one can see from the TEM images shown in Fig. 1, while the ones subjected to annealing are nanocrystalline, with grains of 15-30 nm, randomly dispersed within the amorphous matrix, depending on the annealing temperature and Co content. The optimum magnetic properties are obtained at different annealing temperatures (between 510 and 550^{0}C), depending on Co content, as shown in Fig. 1; the larger the Co content, the lower is the optimum annealing temperature. The total substitution of Fe with Co is strongly influencing the microstructure and is hardening the material (Fig. 2). The substitution of Fe with Co followed by optimum annealing reduces drastically the saturation magnetostriction due to the more random distribution of internal micro-stresses in Co-substituted samples compared with the ones containing Fe only, but also due to the different orientation of the anisotropies of Fe(Co) grains relative to the matrix. The optimum magnetic properties are obtained for samples with Co contents ranging from 25 to 50 at.%, annealed at temperatures in the range of 530-540^{0}C, when the nanograins reach their optimum sizes (between 15 and 25 nm) and the percolation limit increases to 60-70%. In this case the collective behavior of the nanograins reaches the maximum strength, this being also influenced by the presence of Co in the DO_3 nanograins, which slightly shifts the nanograins structure from bcc towards fcc or even hcp. Such a specific behavior is also strongly dependent on the Si to B contents, a larger content of Si in VITROPERM 800 playing a more significant role in the exchange interactions between the grains through the amorphous residual matrix. *Financial support from the ITN-FP7 Marie Sklodowska-Curie program "VitriMetTech" N. 607080 and 3MAP NUCLEU Program (2018) is thankfully acknowledged.*

We present a magnetically actuated paper based microfluidic two-way valve that includes a neutral position — the first of its kind. The presented valves are highly robust, customizable, contact-free and fabricated using facile and cost effective methods suitable for microfluidic paper analytical devices (µPad) applications. The advent of a neutral position and ability to precisely control switching frequencies unlocks a new platform for highly controlled fluid flow in paper based microfluidic test assays. We demonstrate the feasibility of the two-way valves performing a fully automatized colorimetric assay on a Magnetic µPad (M-µPad). Portable and disposable diagnostic devices for Point-of-Care usage should be robust, lightweight, inexpensive, and easy to use. Microfluidic paper analytical devices (µPads) have emerged as an alternative to expensive glass or polymer based chips [1]. µPads offers numerous advantages compared to classical microfluidic approaches. Indeed, their capillary action eliminates the need for external pumps. Furthermore, µPads are bio-compatible for various applications including clinical diagnosis, food quality control, and environmental monitoring [2]. However, a downside to this promising technology is that many active elements used in microfluidic applications assuring robust fluid control such as valves and switches are hardly reproducible in disposable paper-based devices. Magnetism is widely used in microfluidics as it provides contactless and long-range forces that can be either repulsive or attractive. Li et al. reported on the fabrication of a paper-based magnetic valve by attaching an iron loaded PDMS film on one side of a paper cantilever [3]. By applying an external magnetic field, the cantilever deforms and closes a gap with an underlying paper, allowing fluid to flow downstream. However, this method presents numerous limitations. The preparation and deposition of the magnetic PDMS film adds a complexity to the µPad fabrication. The use of soft magnetic nanoparticles as magnetic structure implies that only attractive magnetic forces can be used to close the valve. While these two limitations could be solved by replacing the loaded PDMS with industrially produced permanent magnetic adhesive tape, the third is more problematic: as the magnetic film covers one side of the paper cantilever, fluid flow can only be assured through the opposite paper side. Recently, we have developed techniques to micro-pattern high-performance hard-magnet / polymer composites based on magnetic powders [4] or pillars [5], producing field gradient values as high as 10^6 T/m. We further managed to embed conducting polymer within paper thus making an active paper/polymer composite [6]. We are now integrating hard magnetic powders such as NdFeB and SmFeN directly into paper [Figure 1 a/b], so that both paper surfaces remain available for capillary fluid transport. To obtain a functional paper magnetic valve, both surfaces of the paper must remain accessible for capillary fluid transport. We present two different techniques to achieve paper magnetic valves: in the Deposit, Composite and Magnetize (DCM) technique, the magneto-active regions were directly integrated during the paper fabrication process. After fabricating a sheet of paper through an ISO 5269/1 TAPPI process, the outline of the valve was traced using a pen on the still-wet sheet. Hard-magnetic powders were deposited to form the magneto-active zone. A second sheet of paper with identical properties was fabricated and placed on the first one. The composite structure was subsequently dried in a sheet dryer at 60 °C, resulting in a stable valve without additional chemical binding substances (Figure 1 a). The second approach, the Emboss, Impregnate and Magnetize (EIM) technique consists of coating parts of one valve surface with hard magnetic powders without blocking capillary fluid transport through this surface. After cutting the valve out of the sheet we embossed the magneto-active region using a 3D printed mask prior to powder deposition. Hard magnetic powders dispersed in PDMS are spread on the embossed paper and due to the porosity of the paper, the PDMS eventually penetrated the embossed areas. After curing the PDMS at 80°C for 30 min, the magnetic powders were permanently fixed to the paper surface (Figure 1 b). We built an ELISA-compatible colorimetric assay M-µPad demonstrator compatible with both magnetic valve techniques. In our prototype, 2 reagent pads (red/blue fluids) were used, which are connected to a microfluidic syringe pumping fluid at a constant flow. In Figure 1 d, the valve was first opened towards reagent 1, filling up the strip zone with blue dye. After 120 s, the valve was switched towards reagent 2, which allows red dye to enter the test strip. Finally, the valve was closed towards position 0, stopping the fluid flow. Note that a microchip controlled the magnetic fields that were operating the entire sequence. We demonstrate the fabrication of a programmable 2-way paper based microfluidic valve - a missing element in the microfluidic circle. The highly customizable system remains robust, low cost and operates without external contact. We also demonstrated its applicability in an ELISA-compatible colorimetric assay.

Cell counting has shown great impact across several areas of biological sciences: from clinical applications to environmental monitoring[1]. These devices are continuously being miniaturized[1,2], i.e. microcytometers, for automated cell couting[2,3]. Aligned with this goal, we present a magnetoresistive cytometer[4,5] that integrates spin-valves sensors(SVs), a new permanent magnet(PM) design for magnetization of magnetic beads(MBs), and, a new microfluidic feature to increase the system sensitivity. Magnetic sensing microcytometers, using SVs[4,5,6,7] or μHall sensors[8], present several advantages when compared to optical systems[8] or electrical impedance techniques[9]. Firstly that these devices rely on a more stable labelling by using magnetic beads (MBs), instead of fluorophores, to label the cells and secondly that specificity is attributed through magnetic labeling. The magnetic field of MBs in flow is quantified by the sensor, providing local signal detection from the MBs on the surface of the cells, even in the presence of other cells[10]. The sensors used are solid-state technology and are easily integrated with microfluidic channels to present the cells one-by-one in close proximity to the sensors. The magnetic detection is performed directly through a digital-to-analog electronic acquisition board without the need of integrating complex components such as microlenses in optical microcytometers[3]. Here we show an optimization for magnetic cytometers by developing an adaptable 3D flow focusing method into microfluidic channels that present the cells closer to the SVs. We demonstrate the two and three-dimensional confining capabilities of the fluid by hydrodynamic focusing on a microfluidic channel with 300μm in width and height of 50μm. This was achieved by observing the performance of a fluorescent focused sheath under a fluorescent and confocal microscopy and compared to simulation model(Fig.1(a)). The SVs, with 200μm in length, are located on the bottom of the microchannel. First, lateral focusing was set, using a combination of flow rates for the sample (Q_S) and lateral sheath (Q_L), to have a width of 100um (Q_L=2Q_S). The vertical flow rate (Q_V) can be adjusted accordingly to the cells size to be detected, from submicron up to 50μm diameter cells. The cells employed here have an average diameter of 20μm, thus a combination of vertical sheath flow Q_V=3Q_S=1.5Q_L was chosen to limit the sample height to 25um above the sensor. The microchip presented here(Fig.1(b)) incorporates 12 SVs located on a 2x6.5mm^2 area and are distributed in 6 microfluidic channels, with 2 sensors each. Typically, commercial permanent magnets(PM) are used for the magnetization of the superparamagnetic MBs. They are difficult to align and may reduce the SVs sensitivity due to the in-plane component of the magnetic field which drastically varies over the length-scale of the PM. We show the design of an innovative PM that presents a homogeneous, high out-of-plane magnetic field over the SVs (>1000 Oe out-of-plane and in-plane below 10 Oe). The SVs without a PM present average MR values of 8.07%±0.11 and sensitivity of 1.38±0.04 Ω/Oe. Using a commercial PM(N42 grade disc of 3cm and 3mm thick) below the chip, MR and sensitivity lowered significantly over all SVs to 6.45%±1.24 and 0.32±0.24 Ω/Oe and when subjected to the new custom-made magnet, MR ratios and sensitivity was increased, 7.55%±0.29 and 0.58±0.09Ω/Oe. The new magnet confers a high magnetization and can be used without careful alignment to ensure optimal operation on all SVs for the 6 microchannels. Afterwards, the effect of the 3D focusing in the detection biochip was verified with 1μm MBs flowing over the SVs. Signal bipolar peaks[4,5] were recorded and can be decomposed by two recognizable characteristics values: the amplitude of the peak(PA) and time-of-flight(TOF). Then, two SVs spaced by 300μm were used to measure the time between the signal peaks, on separate signal acquired channels, to obtain the linear velocity of the MBs. The system can be operated at high-speed flow conditions, reaching up to 7cm/s, and velocities with increasing vertical flow rates agrees with numerical microfluidic simulations. Finally, we demonstrated the system capability to increase a three-fold sensitivity of the device when cancer cells labelled with MBs are injected with vertical focusing over the sensors. The labelling of cancer cells were performed with 0.5um diameter MBs. Previous work with smaller cell sizes of myeloid leukemia cell line (5μm in diameter) [4] and *streptococcus agalactiae* cells (1μm in diameter) [5] using 50nm MBs for their detection. However, as cancer cells present higher sizes (around 20μm), larger MBs were required for the signal detection. Biotinylated anti-EpCAM antibodies against specific membrane receptors for the target cells were immobilized on the surface of the streptavidin -MBs and incubated with cells. The samples were analyzed in the same microchannel with and without vertical focusing and same output flow rate. Figure 2(a) and (b) shows the PA and TOF values for each detected signal with and without vertical focusing and compared to a sample composed only of MBs.

BC-03. Magnetic Micro/Nano Structures for Biological Detection and Manipulations. ***(Invited)***

C. Li[1], B. Chen[1], Y. He[1], C. Hou[1], H. Huang[1] and *Z. Wei*[1]
1. National Tsing Hua University, Hsinchu, Taiwan

Magnetic micro-/nano-structures were designed and fabricated for bio-detection and bio-manipulation. First, some three dimensional micro-/nano-structures were proposed as biosensors. These three dimensional magnetic sensors can actively attract the magnetically labeled cells to the sensor position and fix the cells to be detected, which is advantageous over traditional two dimensional thin film biosensors.[1] Besides, by the integration of the spintronics and microfluidics, a Wheatstone bridge giant magnetoresistance (GMR) biosensor was also demonstrated for the detection and counting of magnetic cells.[2] Second, manipulating cells in specific positions is a very important issue for cell scaffold applications. In our study, by controlling magnetic domain walls in patterned magnetic thin films or by controlling the aligned direction of electrospun PVA-gelatin nano-fibers [3] with magnetic nanoparticles, the patterning of magnetic cells can be achieved. We also demonstrated that self-assembling of magnetic fluid or microdroplets can be used to form periodic lattice structures which can be employed for cell culture scaffolds. These research results can be applied to tissue engineering. Finally, the microstructured cone arrays made from ferrofluid molding technique as shown in Figure 1 were employed to systematically understand how the inclination of the trichome structures on leaf surface influences the wettability of leaves. By this engineering approach, it can also reveal how the inclination angle is optimized through natural selection. [4]

BC-04. Magnetic sensing of Antimony bioactivity through Antimony bearing Ferrihydrite bioreduction.

A. Zegeye[1], C. Chang[2], m. Abdelmoula[3] and *T. Hauet*[2]
1. LIEC, Université de Lorraine, Nancy, France; 2. Institut Jean Lamour, Université de Lorraine, Nancy, France; 3. LCPME, Université de Lorraine, Nancy, France

Industrialization and related anthropogenic activities in the twentieth century have contributed to an unprecedented concentration of large quantities of heavy metals in the natural environment. Anthropogenic metal pollution poses significant risks to humans and ecosystems, in the form of contaminated soil and ground water, as well as reduction in food quality and land arability. The need to protect and restore ecosystems contaminated by anthropogenic metal pollution is at the forefront of environmental and public health advocates and policymakers. However, the current assessment methods are complex and hard to implement and fall short in fulfilling their intended purpose. As other groups [1,2], we are working on magnetic characterization methods to sense the metal mobility and the bioavailability, beyond the basic characterization of soil metallic pollution [3,4]. Indeed Fe(III) oxide such as ferrihydrite are ubiquitous in sediments and soils and due to their large surface area and reactive surface properties, they can be important sorbents of metal and metalloid such as antimony (Sb) [5]. Sorption and co-precipitation are considered to be the predominant processes by which most of the metals are scavenged by iron oxides, although co-precipitation appears to be more efficient for the removal of metals from solution. However, co-precipitated metals can be released to the surrounding environment as a direct or indirect consequence of dissimilatory iron reduction (DIR), which is a microbial reduction process of geochemical importance in natural systems. The aim of the present study was to investigate Sb behavior during DIR. Sb-bearing ferrihydrites, with variable Sb/(Fe+Sb) molar ratios, were synthezised by coprecipitation and incubated with an iron reducing bacteria, *Shewanella oneidensis* MR1 [4]. First, chemical and Transmission electron microscope analysis were undertaken to monitor the rate and the extent of the bioreduction and the mobilisation of Sb. Then Mössbauer and SQUID analysis were carried out to characterize the magnetite nanoparticles produced during the bioreduction. On the one hand, Mossbauer spectra at different temperature were fitted to obtain the isomer shift, quadrupole splitting and magnetic hyperfine field. On the other hand, field cooling (FC) and zero field cooling (ZFC) measurements, as well as hysteresis loop measurements were performed. The results revealed that the presence of Sb impacted the extent of reduction but no significant difference was measured in the rate of Fe(III) reduction. Sb is incorporated in the structure of the biogenic magnetite. The magnetite crystal structure is not modified but we were not able to distinguish if Sb cation occupies mainly octahedral or tetrahedral sites. The size of the biogenic magnetite decreases from 10 to 15nm with absence of Sb down to 2nm as the initial Sb concencentration in the ferrihydrite increases. As a consequence of both Sb incorporation and nanoparticle size decrease, magnetic features drastically changed at room and low temperature from ferromagnetic arrangement for zero Sb to superparamagnetic in the case of an initial concentration of few percent of Sb (see Fig. 1). Therefore, when a pollution in Sb is expected, macroscopic magnetometry measurements should be able to reveal the bioactivity of Sb in natural environment where bacteries can activate the bioreduction of ferrihydrite.

BC-05. Novel Electromagnet for MRI Applications.

J. Alonso-Valdesueiro[1], B. Sisniega[1] and J. Collantes[1]
1. Electricity and Electronics, University of the Basque Country (UPV/EHU), Leioa, Spain

Introduction: Magnetic Resonance Imaging is one of the most useful tools for medical diagnosis around the world. It is applied in diagnosis and treatment of many types of cancer, soft tissue injuries, *in-vivo* brain experiments and studies with drugs. Despite its development since the 70s [1], MRI still has to deal with problems that affect directly the sensitivity of the signal and the spatial resolution of the image. Some of these problems are related to the Nuclear Magnetic Resonance phenomenon in solid-state samples [2], and others come from the MRI technique itself [3]. Our work is focused on the development of a novel design of MRI magnet able to mitigate the spatial resolution problems in MRI experiments. RF-MAFS: Resolution problems in MRI are related to different inter and intramolecular phenomena [4] and experimental imperfections. In NMR, they are usually mitigated by applying the Magic Angle Spinning technique where the sample is tilted with respect to the main static magnetic field and spun around its principal axis, averaging to zero the effect of nuclear interactions on the NMR spectrum [5]. In MRI, the spatial resolution is also affected by changes in magnetic susceptibility along the sample, movements of the patient during the experiment and magnetic field inhomogeneities [3]. Applying MAS techniques in MRI experiments is not straightforward. Although some experiments have been performed on rats spun at very low spinning rate [6], the mechanical spinning of a human patient during MRI experiments looks extremely risky. A solution was proposed early in the 60s [7], thought for low-field NMR applications [8], [9] and implemented with permanent magnets for MRI purposes [10], where the main magnetic field is tilted with respect to the main axis of the sample and spun around it at very low spinning rates. The resultant field rotates around the sample at an angle of 54.74^{o} with respect to the sample main axis. Our approach follows the work developed in [9], where RF signals will produce a rotating magnetic field in the transverse plane with respect to the main axis of the sample and an optimized solenoid will produce a static field aligned with that axis. This is what we call RF-MAFS and it is able to achieve, in theory, ultra-high field spinning rates. To do so, we propose a magnet consisting of two Double-Helix Dipole coils [11] and an optimized solenoid [12] (see Fig. 1). RF-MAFS Magnet Development: Fig. 1 plots the concept for the RF-MAFS magnet. The magnet includes two Double-Helix Dipole coils of 81 turns, 10^{o} tilting angle and 1.5 mm effective conductor diameter with radii as specified. Theoretically (Biot-Savart integration) they produce two linearly polarized magnetic density fluxes of 2.4 mT/A 1.7 mT/A respectively. If the coils are placed in spatial "quadrature", the RF signals feeding the coils are compensated in amplitude and they are also phase shifted 90^{o} with respect to each other, the total magnetic flux density corresponds to a rotating magnetic field of B_{rot} = 1.7 mT/A over a large volume inside the coils. In practice, we have built two DHD coils with 5 mm spaced grooves (2x2 mm section) where we have placed 1.2 mm diameter copper wire. The grooves are carved on 4 G10 material tubes 3 mm thick resulting in two ~900 mm assemblies. Their impedances have been measured with a VNA in the 1 kHz-1.5 MHz band (see Fig. 1) for better tune and match. The optimized solenoid will be placed concentric to this assembly producing the static field component, B_z, needed to obtain the RF-MAFS field. Fig. 2 shows the measurement system developed to obtain the magnetic flux density generated by the DHD coils assemblies along their axis. The system consists of two pick-up coils of 5x5 mm section oriented in spatial "quadrature". The voltage induced by the time-varying magnetic flux is amplified by two instrumentation amplifiers working up to 15 kHz with G_v = 500 and filtered by a low-pass filter before going to an AGILENT-Infiniium oscilloscope. Fig. 2 also shows the normalized magnetic flux density, B_{rot}, produced by the two DHD coils when a 2 V_{pp} signal is amplified by an AR3501AH amplifier delivering ~1 A_{rms} (~10 W) when its gain is set to 50%. The measurement was taken every 2 mm along the *z*-axis with an almost constant SNR of 25 dB. The frequencies were kept in a range where the value of $|Z_L|$ reach a minimum keeping a considerable Signal to Noise Ratio ($|Z_L|_{int}$ @9 kHz = 6.72 Ωand $|Z_L|_{ext}$ @4 kHz = 10.35 Ω). B_{rot} was normalized to the value at the geometric center of the coil (*z* = 0 in Fig. 2). Fig. 2 demonstrates that the assembly produces a flat region of ~40 mm along the axis. In order to better evaluate the volume of homogeneity, a measurement system with 5 pairs of 2x2 mm pick-up coils placed on the surface of a 15 mm radius cylinder is being implemented at the moment. The coils will be moved 20 mm around the geometrical center of the assembly and a Cylindrical Harmonics Decomposition will be performed. The system will also include a hall detector per pair of coils in order to analyze in the same way the longitudinal magnetic field generated by the optimized solenoid, B_z. At the end, we will be able to deploy the RF-MAFS magnet optimized to provide a magnetic flux density ~2 mT/A with enough homogeneity to perform MRI experiments inside a cylindrical volume of 2.9x10^{-5} m^3.

Single-cell characterization techniques, such as mRNA-seq, have been applied to a diverse range of applications in cancer biology, yielding great insight into mechanisms leading to therapy resistance and tumor clonality. While single-cell techniques can yield a wealth of information, a common bottleneck is the lack of throughput, with many current processing methods being limited to the analysis of small volumes of single cell suspensions with cell densities on the order of 10^7 per mL. In this work [1], we present a high-throughput full-length mRNA-seq protocol incorporating a magnetic sifter and magnetic nanoparticle (MNP)-antibody conjugates for rare cell enrichment, and Smart-seq2 chemistry for sequencing. We evaluate the efficiency and quality of this protocol with a simulated circulating tumor cell system, whereby non-small-cell lung cancer (NSCLC) cell lines (NCI-H1650 and NCI-H1975) are spiked into whole blood, before being enriched for single-cell mRNA-seq by EpCAM-functionalized magnetic nanoparticles and the magnetic sifter. We obtain high efficiency (> 90%) capture and release of these simulated rare cells via the magnetic sifter, with reproducible transcriptome data, enabling highly predictive cancer diagnostics and treatment. We demonstrate the first integration of a high-throughput immunomagnetic cell separation platform (magnetic sifter), with a 96-well microplate-based single-cell full-length mRNA-seq technique (Smart-seq2 [2]), enabling rapid enrichment and sequencing of rare cells. This speed allows Smart-seq2 sequencing of a rare subset of cells ($\approx 10^2$) from a background of $\approx 10^9$ cells to start in under 4 hours. In contrast, recent notable papers reporting single-cell sequencing of circulating tumor cells (a notable rare cell of biological and clinical interest) have required longer overall processing times, separately due to incubation times [3], slower volumetric processing [4], or manual cell picking [5]. Our validation studies also demonstrate that our mRNA-seq data is of comparable quality to previous single-cell studies [6]. Additionally, we describe variant analysis on mRNA-seq data, capitalizing on the full-length reads from Smart-seq2, and illustrate how a combination of expression and variant analysis on single cells can help differentiate heterogeneous cells, in contrast to the current paradigm of thinking solely in terms of either variant (DNA-based) or expression (RNA-based) analysis. This is of interest to the single-cell sequencing community as it illustrates the strength of full-length mRNA-seq methods relative to 3'-biased methods, and might be a key consideration for future single-cell mRNA-seq studies. In summary, we present a unique MNP-based method of broad interest to the multidisciplinary research communities of cell separation and single-cell sequencing. We demonstrate a cell separation platform (magnetic sifter) that enables rapid single-cell sequencing of rare cells in complex biological systems, and envision this method would facilitate time-sensitive studies in areas such as immune or cancer biology, and liquid biopsies in diagnostics and immuno-therapy. This work was supported by US NIH through the Center for Cancer Nanotechnology Excellence (U54CA151459) and the Innovative Molecular Analysis Technologies (R33CA138330). CCO was supported by an A*STAR fellowship (Singapore).

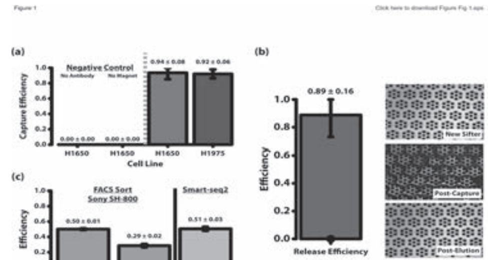

Fig. 1. Efficiencies of different steps in this method. (a) The sifter shows high capture efficiencies (> 90%) for 2 NSCLC cell lines tested (H1650 and H1975). (b) The sifter also exhibits good release properties of captured cells and magnetic nanoparticles (89%). Optical images illustrate the effectiveness of elution from the magnetic sifter. The sifter surface post-elution appears as pristine as the surface of a brand new sifter. (c) FACS sort efficiencies vary with sort purity settings. 2 sort settings on the Sony SH-800 cell sorter are tested. Efficiencies of 50% and 29% are observed for the semi-purity and ultra-purity modes respectively. A reduced purity setting is required for higher yields. By following the Smart-seq2 protocol exactly, we observed successful cDNA synthesis in 51% of the wells.

BC-07. Development of Peak to Peak Voltage Detector Type MI Gradiometer for Magnetocardiography.

J. Ma[1] and T. Uchiyama[1]
1. Graduate School of Engineering, Nagoya University, Nagoya, Japan

1. Introduction Since the magnetic field generated by the human heart was detected for the first time, the magnetocardiography (MCG) has attracted considerable attentions in research and medical diagnostics. The ionic currents not only create the electric potential differences measured as the electrocardiogram (ECG), but generate a magnetic field (MCG signal) as well. According to the previous studies and clinical data, MCG has some advantages over ECG for the diagnosis of right atrial hypertrophy and right ventricular hypertrophy. It suffers from less limitations than ECG, because magnetic sensors can detect the signals directly related to undistorted cardiac electric current. The MCG has been gradually developed into a non-invasive technology for heart health screening [1], [2]. Up to now, the magnetometers based on SQUID are the main choices for detecting extremely week bio-magnetic signals. It has been developed as a medical instrument for diagnosing the ischemic cardiac disease and arrhythmias. Meanwhile, the SQUIDs are still limited by the need of cryogenic cooling liquids and a shielding room. Therefore, there are some miniature, low-cost, and highly sensitive magnetic sensor systems have been developed. As reported recently, a laser-pumped magnetometer and a pico-tesla resolution flux gate sensor are studied for MCG measurement. [3] In this study, we have proposed a peak to peak voltage detector type MI gradiometer (shortened: Pk-pk VD-type MI gradiometer), which is aimed to measure an extremely weak magnetic field. Meanwhile, we have demonstrated Pk-pk VD-type MI gradiometer for detecting magnetic cardiogram signals, with simultaneous measurement of cardiac electric activity. 2. Pk-pk VD-type MI gradiometer In the previous study, we had reported a high-performance MI magnetometer [5]. However, for detecting extremely weak magnetic field such as a bio-magnetic field, we have to cancel the background uniform noises such as geomagnetic field. For further improvement, in this study, we have developed the Pk-pk VD-type MI gradiometer for detecting the bio-magnetic signals in unshielded environment, based on the pk-pk VD-type MI magnetometer reported recently. The new MI gradiometer is composed of a pair of MI elements: a sensing element and a reference element. The pick-up coils are equipped in combination with the 30 um diameter CoFeSiB amorphous wire to realize a highly linear magnetic sensor by off-diagonal MI effect [6]. The distance between the coils is set to be 3cm. The figure 1 illustrates the block diagram of new MI gradiometer. The pulse generator produces a rectangular voltage wave to differential circuit. Then, the rectangular waves are transferred into three different positive pulses. As illustrated in Figure 1, we detect both the positive peak and negative peak of induced waves in each pick-up coil excited by rising edge and drop edge of the excitation pulse, by using the staggered pulses and analog switches. Finally, the Pk-pk VD-type MI gradiometer outputs the difference between the sensing element and reference element for canceling out uniform magnetic field noise. Therefore, we can achieve a highly sensitive, low noise level, and stable MI sensor system for bio-magnetic field measurement in unshielded environment, at room temperature. The field detection characteristics of two MI element are shown in Fig 1(b). Both of sensing and reference MI elements illustrate good linearity. The difference in the sensitivity of sensing and reference elements is within 1%. As illustrated in Fig 2(a), we investigate the magnetic noise spectral density of Pk-pk VD-type MI gradiometer, comparing with the environment magnetic noise spectral density measured by a commercial flux gate sensor, in an unshielded environment. The noise floor of the Pk-pk VD-type MI gradiometer is lower than 2 $pT/Hz^{1/2}$ in the frequency range from 1 Hz to 100 Hz. It is 1/5 of noise level of previous MI gradiometer in a 1-100 Hz frequency range [7]. Meanwhile, the Pk-pk VD-type MI gradiometer can cancel the environment magnetic noise by 34 dB. 3. MCG measurement MCG measurement by using the Pk-pk VD-type MI gradiometer is carried out on a male subject (aged 26) in siting position, without any magnetic shielding equipment. We set up the MI gradiometer on a wooden table, and the sensor head is perpendicularly placed to the chest surface, with a distance of 10 mm between the chest surface and sensor head. The measurement point is set at the chest surface, 25 mm to the left of the pit of stomach. The output superposing noise of new MI gradiometer is lower than previous MI gradiometer. Meanwhile, we have successfully measured the MCG signals in averaging over only 6 cycles. Comparing with the previous MCG measurements [8], we have markedly reduced the cycles for arithmetic average processing. The Fig.2(b) illustrates the simultaneously measured ECG and MCG signals in averaging over only 6 cycles. As illustrated in Fig.2(b), we can obviously identify a sharp magnetic peak, corresponding to the QRS complex of ECG. The amplitude of this magnetic peak related to the R peak is approximately 100 pT, which coincides well with the reported MCG value [3].

BC-08. Eddy Current-TMR Sensor for micro-motion detection of orthopaedic implants.

R.P. Khokle[1], S. Cardoso de Freitas[2], K. Esselle[1], M. Heimlich[1], F. Franco[2] and D. Bokor[3]
1. Engineering, Macquarie University, Sydney, NSW, Australia; 2. INESC-MN - Microsistemas e Nanotecnologias, Lisbon, Portugal; 3. Faculty of Medicine, Macquarie University, Sydney, NSW, Australia

Introduction Every year millions of people around the world undergo orthopaedic surgeries with partial or complete joint replacements. However, according to the various arthroplasty registers around the world, about 10 % of the implants require re-surgery at some point in their lifetime [1]. About 80-90% of implant failures occur due to mechanical reasons [1-2]. It is proposed in [2], that micromotion of the orthopaedic implants during the limb movement can provide insights on the possible implant failure in the future. For this purpose, it is necessary to monitor the motion of metallic orthopaedic implants with the resolution of the order of tens of microns when the person moves a limb. In this paper, it is proposed to use a small sensor embedded inside the bone at a distance from the orthopaedic implant. The space available for such a sensor is limited to the cylindrical hole of dimensions 3 mm x 10 mm. *Sensor Design and Experiment* A two-turn rectangular eddy current (EC) loop with trace width 0.2 mm is designed on Rogers RT Duroid 6010 substrate (e_r=10.2, tand = 0.0023) having dimensions 2.5 mm x 10 mm x 0.254 mm. For simulations, human male body model from Ansys HFSS is used. The electromagnetic tissue properties are used from IT'IS database [3]. A tibial metallic implant is assigned the properties of titanium which is one of the widely used materials for orthopaedic implants. The EC loop has a self-resonant frequency at 925 MHz. This high SRF ensures a stable performance of the sensor at low frequency. The simulation inside the human body showed that with increasing frequency the power absorption by the human tissue increases. Around 500 MHz, the power lost in tissue becomes equal to that dissipated in the current loop [2]. The operating frequency also depends upon the skin depth of the titanium implant which depends upon frequency. It is advantageous to keep the eddy currents on the surface of the implant which requires the frequency of operation to be high. A similar setup was also simulated without human body structure. It is observed that at 10 MHz, the difference of sensitivity between both the scenarios is negligible. Considering all these factors, therefore, operating frequency is decided to be kept in the range of 1 MHz – 10 MHz. The magnetic tunnel junction resistor offers very high sensitivity and low SNR. The MTJ stack is fabricated and characterised at INESC-MN by optical lithography and ion beam milling. The optimized stack is TJ937-940 – Si / 1000 SiO2/ 5 Ta / 15 Ru / 5 Ta / 15 Ru / 5 Ta / 5 Ru / 20 IrMn / 2 CoFe30 / 0.85 Ru / 2.6 CoFe40B20 / 1 MgO / 2 CoFe40B20 / 0.21 Ta / 4 NiFe / 0.20 Ru / 6 IrMn / 2 Ru /5 Ta/ 10 Ru/ 15 TiWN2 (Thickness in mm). The material resistance area product was set at RxA = 40kΩm^2. The linearity of the sensor is achieved by proper annealing steps that set the pinned layer perpendicular to the free layer. An array of 4x8 sensors per chip is fabricated. The chips were diced and wire bonded to a polyimide flexible PCB. Then the sensor is characterized to measure the TMR by using the same methods as in [4]. The TMR sensor IC is wire-bonded to the signal pads printed on a polyimide flexible substrate. Wire bonding is protected by a silicone-based glob top encapsulant. Since out of plane field detection is needed, the TMR sensor is mounted vertically on the horizontal EC loop by using a superglue. In the proposed range of frequency operation, the inductive coupling of EC-MR sensor assembly could produce higher voltage than the MR sensor response. Hence, to decouple this with the TMR response, heterodyne detection of the signal is proposed. The EC sensor is fed with a signal and TMR sensor is fed with a signal at using Agilent 33210 waveform generator. The TMR sensor response can, therefore, be obtained at 10 KHz difference signal using DSP 7265 signal recovery Lock-in amplifier. To ensure the synchronization of signals the internal clock reference was share between signal generators and a lock-in amplifier. Three signal generators and lock-in amplifier are controlled using LabView. The micromotion stage from Newport Corp. is actuated by using Conex CC controller. It is programmed for motion in 10 mm range using a MATLAB program. The entire measurement assembly is shown in figure 1. Figure 2a shows the shows the output response of the TMR sensor as measured by lock-in amplifier for the target moved from 1.65mm to 3.5mm. The output of the sensor is normalized and expressed at percent change with respect to the output at 1.65 mm standoff distance. Due to the chip size and vertical mount, it is not possible to have standoff distance shorter than 1.65 mm. As the stand-off increases, the change in output decreases. The output signal changes by 1.65% for 3 mm of total displacement. Figure 2b shows the MR percent change as the function of the applied field when the sensor is biased by 100 mA current. It shows 168.4 % TMR sensitivity. The resistance varies from 3.69KΩ to 9.9KΩ. These measurements verify the idea that TMR sensors in conjunction with eddy current loops can sense motion with high resolution at large standoff distances.

BC-09. On-chip magnetophoretic concentration of Malaria-infected red blood cells and hemozoin nanocrystals.

M. Giacometti[2], L.B. Callegari[1], A. Collovini[2], M. Monticelli[1], C. Rinaldi[1], D. Petti[1], G. Ferrari[2], M. Sampietro[2], A. Dimasi[2], M. Piola[2], G.B. Fiore[2] and *R. Bertacco*[1]
1. Department of Physics, Politecnico di Milano, Milano, Italy; 2. DEIB, Politecnico di Milano, Milano, Italy

According to World Health Organization(WHO), 3.2 billion people are at risk for malaria. In 2015, 212 million new cases and 429000 deaths were estimated [1,2]. Despite treatment in the early stage of the disease is usually very effective, conventional diagnostic tests via optical microscopy examination of thick and thin blood smears are unsuitable for an effective screening of the population. On the other hand, the over-treatment of the disease due to the large percentage of false positives in currently available rapid diagnostic tests (RDTs) may increase the risk of drug resistance. In this scenario, there is a strong need of novel RTDs with (i) the same sensitivity of the gold standard (optical microscopy examination) and (ii) a reduced number of false positives. To fulfill the last requirement, a real improvement would be to move from the detection of antigens or antibodies, which can be hardly washed out in a patient living in an endemic zone even after many weeks from the last malaria episode, to the quantification of infected red blood cells in a blood smear (i-RBC). This essentially means to go back to the concept of gold standard tests, with the additional requirement of integrating i-RBC counting in lab-on-chip platforms suitable for low-cost, rapid and on-site wide screening of the population in endemic zones. It is well known that i-RBCs display a paramagnetic behavior with respect to blood plasma, so that they can be separated from healthy ones and other corpuscles in a high magnetic field gradient. [3] This is due to the fact that, during the intra-erythrocytic development, the parasite degrades hemoglobin into free heme. This molecule, highly toxic to the parasite, is converted in an insoluble form, known as hemozoin or malaria pigment, which crystallizes into paramagnetic nanocrystals found both within the i-RBCs and free in the blood, after RBCs lysis. Of course, both the concentration of free hemozoin crystals and i-RBCs can be used for the determination of the parasitemia. In this paper we present an on-chip magnetophoretic platform for the separation and concentration of i-RBC and hemozoin nanocrystals on pre-defined areas of a chip. This is a pre-requisite for the quantification of the relative percentage of i-RBC with respect to healthy ones (parasitemia) with high sensitivity. The blood drop is placed on a glass substrate, which is then put in close contact to the surface of a chip with Nickel micropillars, at a distance defined by an outer ring which defines also the volume of the cell where magnetophoretic separation takes place. The chip is placed face-down, so that magnetic attraction towards the nickel pillars, in the macroscopic field gradient produced by an external system of permanent magnets, opposes the gravity. In this configuration, i-RBCs and hemozoin crystals are attracted upwards, towards the micropillars, while non-infected erythrocytes and the other blood cells (i.e. white blood cells and platelets) sediment towards the glass substrate. Our design allows to obtain a macroscopic field gradient as high as 1×10^{15} A^2/m^3 up to a distance of 500 micron from the chip surface, strong enough to overcome gravity and attract i-RBCs and hemozoin crystals towards the chip surface. The chip consists of an array of Ni pillars, with 20-30 micron diameter and 20 micron height, fabricated by electroplating and arranged on a hexagonal closed packed lattice. In close proximity to the chip surface, Ni pillars produce a much stronger field gradient, up to 3×10^{16} A^2/m^3 at a few microns from their surface, which concentrate the i-RBCs and hemozoin crystals. We have tested this system using RBCs from bovine blood, treated with $NaNO_2$ in order to induce the transformation of hemoglobin into paramagnetic meta-hemoglobin.[4] In this way, we obtained suspensions in PBS of RBCs mimicking i-RBCs, suitable for experiments of capture. In figure 1 we report optical images from experiments performed in a direct configuration, where gravity and magnetic forces act in the same direction. Untreated RBCs (ut-RBCs) and treated ones with NaNO2 (t-RBCs) were stained with a red fluorophore to improve the quality of optical images. As evident from Figure 1, in case of t-RBCs we observed a capture efficiency of 100% by magnetic pillars in a lattice with center to center spacing of 80 microns. For hemozoin crystals the capture is even easier, because of their much larger volume susceptibility, 3.4×10^{-4} to be compared with 3.9×10^{-6} in case of i-RBCs. These results pave the way to the use of our magnetic chips as active slides for the magnetophoretic separation and concentration of malaria markers, both i-RBCs and hemozoin crystals, in well-defined areas of the chips where quantification can be performed with high sensitivity.

The most researches are devoted to integrated response of GMR sensor to the significant amount of particles contributing to the detected magnetic field. Single magnetic nanoparticles and their ensembles cause locally inhomogeneous magnetization of the ferromagnetic CoFeB layer. This circumstance changes the magnetization dynamics of the films and domain walls propagation as well as integrated output of GMR sensor. Local impact of the nanoparticles ensemble can oversaturated microsized area of the FeCoB films resulting in nonlinear output of the scheme, not proportional to the particles amount. In this paper, we would like to propose monitoring of the GMR sensor surface during different stages of accumulation of protein–magnetic tag complexes binding to the antigen Anti-LGR5 fixed on the sensor surface. The LGR5 complex plays role of R-spondin receptor providing the modulation of Wnt/β-catenin signaling in normal and neoplastic stem cells. The LGR5-positive cells contribute to the nucleation and spreading of cancer in stomach, kidney, small intestine, colon, hair follicle being highly specific marker of stem cells. Scanning of the sensor surface by magnetic force microscope will allow us to distinguish the role of nucleation events, statistical distribution of the particles and effects on integrated GMR output. This work is aimed to analysis of magnetic response of CoFeB/Ta/CoFeB trilayer GMR platform to deposition of ferromagnetically labeled LGR5 cells on its surface. Two types of GMR platforms possessing perpendicular anisotropy were used in our experiments: MgO(2.5nm)/CoFeB(1.1nm)/Ta(0.75nm)/CoFeB(0.8nm)/MgO(2.5nm) bilayer and MgO(2.5nm) Ta(t)/CoFeB(0.8nm)/MgO(2.5nm) sinle layer (Figure 1). These systems were grown on a GaAs substrate by magnetron sputtering. The MFM method provides recording of the surface profile in the first scanning pass, while distribution of the second derivative of the normal component of magnetic field was mapped during second backward pass. Obtained images correspond to phase shift of cantilever vibrations caused by magnetic interaction of cantilever with the sample surface. Since CoFeB films possess comparatively low coercivity (~ 100 Oe), low magnetized high resolution CoCr magnetic tips, two times thinner compare to standard MFM tips were used. Low moment of the cantilever tip with reduced magnetic stray fields prevents magnetization of the surface by cantilever. Same surface of the sensor platform was measured three times: initial ultrasound cleaned surface, surface with deposited nanoparticles (with no biology cells), surface with cells labeled by the same nanoparticles. Surface with nanoparticles allowed one to distinguish separated a-Fe_2O_3 nanoparticles in AFM as well as in MFM mode (Figure 2). AFM profile of single nanoparticles was approximated by method proposed in. Frequency shift of the MFM canilever, *Df*, is known to be proportional to the magnetic moment of the individual nanoparticle *m* placed on nonmagnetic surface. Magnetic hysteresis loops of the reference trilayer and monolayer system at T = 300 K is presented on the Figure 1, 2. Four states M_1, M_2, M_3, M_4 sketched in the inserts corresponding to different combinations of layers magnetizations. The M_1 and M_4 states correspond to parallel orientation of top and bottom layers magnetizations M_U and M_D along and against positive direction of the field H, respectively; the M_2 and M_3 states correspond to antiparallel mutual orientations of M_U and M_D. Magnetic hysteresis loops of the trilayer and monolayer system with RA MicroBeads have been changed (Figure 2). Hysteresis appeared in contrast with absence of the hysteresis in the Si sample covered by same a-Fe_2O_3 nanoparticles. Following conclusions were proposed: Effects of cell microbead's labelled with commercial a-Fe_2O_3 nanoparticles on magnetic properties of MgO/CoFeB/Ta/CoFeB/MgO/GaAs spin valves and monolayer system MgO/CoFeB/MgO/GaAs wereobserved. Magnetic scattering fields of the ferromagnetic nanoparticles captured in cells shift critical switching magnetic controlled by competition magnetic anisotropy, interlayer exchange coupling and Zeeman energy in the synthetic ferrimagnet with strong perpendicular anisotropy. Local magnetic field of the nanoparticle and its effect on ferromagnetic film included in the spin valve were estimated accordingly with results of magnetic force microscopy. Scattering magnetic fields of NP's increases switching magnetic field of GMR sensor up to 240 Oe due to increase of free layer magnetization. Sensitivity of the switching field to the NP's is ~ 5 10^4 labeled cells per 1 Oe is well enough for reliable measurements of cells concentration. Recently, STT-MRAM has been commercialized. MRAM with voltage controlled magnetic tunnel junction (VC-MTJ) has been expected as a post-STT-MRAM memory with faster speed and lower power [1-5]. Since read operation for VC-MTJ uses TMR as other MRAMs, conventional read can be used. On the other hand, VC-MTJ has specific write feature where write error rate (WER) is oscillatory dependent on pulse width. Hence, WER reduction for VC-MTJ is crucial. Previous studies have shown VC-MTJ applications for cache and main memory [6, 7]. Recently, storage class memory (SCM) has been introduced to mitigate memory gap between storage and main memory [8]. SCM is also a candidate for VC-MTJ utilization, since VC-MTJ has unipolar write suitable for 3D-crosspoint (3DX) configuration. This is the first paper to describe feasibility of VC-MTJ for SCM applications from the viewpoint of designs for memory cells and circuits. Typical SCM is characterized by 3DX structure with two-terminal selector device(SD) (Fig. 1(a)). SD has longer switching time than VC-MTJ[9-11]. Here, switching time variations of SD changes write pulse width of VC-MTJ that causes WER degradation. This is a major issue. To solve this, we propose a novel two-step pulse write method as described later. We evaluate WER improvement with this method by advanced circuit simulation. We further analyze WER reduction by interconnect and write driver. Major requirement for SD in 3DX memory is high on-off ratio to suppress sneak leakage current. Various SD have been intensively developed [9]. Among them, threshold type selector is considered to be promising due to large on-off ratio [10, 11] and several ten ns switching time. Figure 1(b) schematically shows conventional write pulse voltage (V_W), voltage across SD (V_{SEL}) and voltage across MTJ (V_{MTJ}). Initially, write voltage is applied to only SD, since off-state SD has much higher resistance than MTJ. After SD switches into on-state, write voltage is applied to only MTJ, since on-state SD has much lower resistance than MTJ. As SD has switching time variation, pulse width of V_{MTJ} (T_{MTJ}) varies and WER degrades severely. To suppress WER degradation, we propose two-step write pulse method (Fig. 1(c)), where write pulse has two voltage steps. First voltage is only for switching of SD and smaller than switch voltage of MTJ. Second voltage is for switching of MTJ. In this method, switch time variation of SD affects only the first voltage time, and not affects the second voltage time, T_{MTJ}. To evaluate WER with a proposed method, we firstly obtained V_{MTJ} shape in 3DX arrays by circuit simulation based on 2X nm 3DX memory[8]. WER was then calculated using the V_{MTJ} shape by Monte-Carlo simulation [3]. Figure 2 (a) shows WER of VC-MTJ in 3DX when 1024 bit cells are connected to a word line (WL). We calculated WER for various WL interconnect thickness, assuming interconnect material is tungsten[8]. The interconnect thickness was selected between 40 nm and 80 nm, since that of 3DX memory products is about 40 nm to 65 nm[8]. We also assumed damping constant, a = 0.025 and, diameter, f = 20 nm for MTJ, and external magnetic field to in-plane direction, H_{ext}= 152.6 Oe, so that switching time is about 1ns. Fig. 2(a) also shows WER when an idealistic trapezoidal pulse having no interconnect delay is directly applied to VC-MTJ for reference. These results indicate that as interconnect becomes thicker, WER of VC-MTJ is improved, and it becomes closer to a target WER for SCM (~1x10^{-4}). This reason is that the decrease in pulse rise and fall time by resistance reduction of interconnects. However, increasing interconnect thickness might make etching process difficult and obstacles further memory cell scaling. In case that interconnect thickness cannot be increased, we propose dual wordline (WL) driver circuit (DWD) shown in Fig. 2(b). When conventional single driver circuit is used for each WL, pulse distortion is largest at the other end. By driving WL from both ends using DWD, pulse rise and fall time become smaller than conventional ones. In this case, difference in activation time (t_{delay}) between the two WL drivers degrades WER (Fig. 2(c)), as shown in Fig. 2 (d). When t_{delay} is larger than 200 ps, WER becomes larger than single driver case. Therefore, we have to design interconnects and drivers so as t_{delay} to be ~0s. WER is, then, almost the same as that of direct pulse application, as shown in Fig. 2(d). As a result, DWD circuit can reduce WER considerably close to a target WER for SCM(~1x10^{-4}). These results thus indicate that WER of VC-MTJ for 3DX memory can be improved by proposed circuit designs. Figure 2 (e) compares write performance of various nonvolatile memories, which indicates VC-MTJ is superior to others, since it has higher-speed and lower-power write with higher-endurance compared with others. This work was partly supported by the ImPACT Program of the Council for Science, Technology and Innovation (Cabinet Office, Government of Japan). The authors would like to thank Yoichi Shiota for his contributions to VC-MTJ.

BD-02. Nanoscale spin-orbit torque devices with Co/Pt multilayers for wide-temperature range applications.

B. Jinnai[1], S. Fukami[1], H. Sato[1] and H. Ohno[1]
1. Tohoku University, Sendai, Japan

Spintronics memory devices utilizing spin-orbit torques (SOTs) to manipulate a magnetization direction as write operation [1-3] are promising for ultralow-power and high-performance integrated circuits owing to their non-volatility, fast operation capabilities, and design flexibility. Being integrated in leading-edge integrated circuits, SOT devices are required to have high thermal stability to secure enough data retention and large SOT efficiency generated by unit current to achieve low switching current in nanoscale dimensions. Especially considering those applications used in harsh conditions, such as automobile and aerospace, those requirements need to be met over a wide range of operation temperature, for example, –40 to 125°C according to one of automobile industry standards, i.e. AEC-Q100 Grade 1. To explore a material system meeting these requirements, we have been investigating Co/Pt multilayers for SOT devices [4], as they possess high magnetic anisotropy [5] and generate SOT despite of their symmetric structure [6]. The Co/Pt multilayers have high damping constant a [7,8], which is detrimental to device performances when they are used in a free layer of widely-studied spin-transfer torque (STT) switching devices. On the other hand, theoretical work predicts that a has little impact on threshold switching current of SOT devices with a perpendicular easy axis due to a different symmetry of the torques from that of STTs [9]. This allows to take advantage of Co/Pt multilayers in SOT devices. We have previously shown SOT-induced magnetization switching in micrometer-scale Hall-bar devices with Co/Pt multilayers and enhancements of switching efficiency and effective fields with increasing the number of Co/Pt stacking [4]. In this work, we study the SOT-induced magnetization switching in nanoscale SOT devices with Co/Pt multilayers down to 20 nm together with evaluation of their thermal stability over a wide range of operation temperature. Magnetization switching by current is observed in all the studied range of the width. A thermal stability factor Δ ($\equiv E/k_BT$, where E is an energy barrier against thermal fluctuation, k_B the Boltzmann constant, and T an absolute temperature) of more than 200 is obtained at 125°C in the device with 30-nm width. The feasibility of SOT devices with Co/Pt multilayers for those applications used in harsh conditions is discussed. The stacks of Ta(3)/Pt(3)/[Co(0.4)/Pt(0.4)]$_4$/Co(0.4)/Ta(0.2)/$(Co_{25}Fe_{75})_{75}B_{25}$(1)/MgO(1.2)/capping layers are prepared on Si substrates by dc/rf magnetron sputtering. The numbers in parentheses are nominal thicknesses in nanometer. The films are processed into nanowire devices with pairs of Ta/Pt channels and probes using EB-/photo-lithography, reactive ion etching, and Ar ion milling. Figures 1(a) and 1(b) show the schematic and top-down SEM image of a nanowire device. Nanowire widths are ranging from 20 to 400 nm with nanowire length of 300 nm. After the process, the device is annealed at 300°C under an application of perpendicular magnetic field of 0.4 T for an hour. To evaluate SOT-induced magnetization switching, dc current is applied to the channels under an in-plane field application in the collinear direction to the current while monitoring a Hall resistance R_{Hall}. Δ is determined by switching probability when repeating a sweep of perpendicular magnetic field. During the electrical measurements, stage temperature is controlled in order to examine the temperature dependence of the device properties. Width dependences of switching current I_{sw} and switching current density J_{sw} under an external in-plane field $|\mu_0H_{ext,in}|$ of 200 mT and Δ at room temperature are plotted in Figs. 1(c) and 1(d), respectively. While I_{sw} is scaled with the width, J_{sw} starts to increase below the width of 200 nm. The behavior is also observed in the previous report [10] and suggests that a magnetization reversal mode changes at the width of around 200 nm; as the width increases, a magnetization reversal mode involves incoherent magnetization dynamics, which may decrease J_{sw}. Δ exceeds 200 in the range of the width from 20 to 400 nm and has no clear trend with the width. Figures 2(a) and 2(b) show temperature dependences of I_{sw} under $|\mu_0H_{ext,in}|$ of 200 mT and Δ, respectively, in devices with the width of 30 nm. I_{sw} slightly decreases with increasing temperature due to thermal fluctuation. Δ also decreases with increasing temperature but Δ of more than 200 is obtained at 125°C. This means that the use of Co/Pt multilayers in nanoscale SOT devices can provide long enough data retention time at high temperature. Therefore, Co/Pt multilayers are promising to achieve reliable operations of nanoscale SOT devices over a wide range of temperature and consequently suitable for those applications that require high reliability even in harsh conditions. This work was partially supported by R&D Project for ICT Key Technology of MEXT, ImPACT Program of CSTI, and JST-OPERA.

BD-03. Novel approach for nano-patterning magnetic tunnel junctions stacks: A route towards high density STT-RAM application.

I.L. Prejbeanu[1,2], V. Nguyen[1,2], P. Sabon[1,3], J. Chatterjee[1,2], N. Perrissin[1,2], S. Lequeux[1,2], L. Tillie[1,4], S. Auffret[1,2], R.C. Sousa[1,2], E. Gautier[1,3], L. Vila[1,2] and B. Dieny[1,2]
1. Université Grenoble Alpes, Grenoble, France; 2. INAC-SPINTEC, CEA, Grenoble, France; 3. SPINTEC, CNRS, Grenoble, France; 4. CEA-LETI, Grenoble, France

Spin-Transfer-Torque Magnetic Random Access Memories (STT-RAM) based on out-of-plane magnetized MTJ (pMTJ) are one of the most promising emerging non-volatile memory technologies as they combine a unique set of assets: quasi-infinite write endurance, high speed, low power consumption and scalability. Embedded STT-MRAM are about to enter in volume production for e-FLASH replacement. For this type of applications not requiring very high memory density, the preferred etching technique is still Ion Beam etching (IBE) [1]. However this technique is not appropriate for high density memory as it requires to etch the MTJ stack at specific angles to minimize the re-deposition on the sidewalls of the tunnel junctions. Etching at some angle leads to shadowing effects which give to the pillars a conical shape. This effect worsens as the memory pitch shrinks below typically 5F resulting in a poor control of the critical dimension at very dense pitch. Besides it is difficult to implement on large wafer with good uniformity [2]. Reactive ion etching (RIE) was also tried for MTJs with various gas but was found to be very complex due to the heterogeneous nature of the MTJ stacks and to cause corrosion of the magnetic materials [3]. Therefore, to be able to use STT-RAM as a dense working memory requires a new method for nanopatterning MTJ elements at small feature size (<20nm) and high pitch (~2F). In the approach we propose, the MTJ material is directly deposited on pre-patterned pillars (e.g Ta pillars prepared by RIE or Cu or W vias prepared by damascene process). The MTJ stack is then naturally patterned while being deposited thus not requiring any post-deposition etching. For the pre-patterned non-magnetic posts, we chose Ta as post-material since its reactive ion etching is very well controlled. In order to avoid the risk of electrical shorts between pillars due to the material deposited in the trenches between posts, the latter are given an undercut shape. Thanks to this shape, during the MTJ deposition, no metal gets deposited on the pillar sidewalls nor at the foot of the metallic posts. The process for fabricating the conducting non-magnetic Ta posts with undercut is depicted in Fig. 1. Ta is coated by Pt to form the top part of the post and protect the top Ta surface from oxidation. Then, following the formation of cylindrical Ta/Pt posts by an anisotropic RIE process, an isotropic RIE process is subsequently used in order to laterally trim the Ta part of the posts. Perpendicular MTJ stacks with MgO barrier were then deposited on these pre-patterned substrates. By depositing the MgO tunnel barrier at oblique incidence while rotating the substrate, it is possible to completely coat the MTJ bottom electrode with MgO and even to get thicker MgO deposit on the sidewall of the bottom electrode than on the horizontal part of the MTJ. This can help to concentrate the current away from the edge of the nano-patterned MTJ thus reducing the influence of possible edge defects. Similarly, lateral gradient of chemical composition can be induced in the storage or reference layers. Such gradient can be used to induce different properties at the edges and center of each dot in order for instance to reduce demagnetizing or nucleation effects at edges and improve STT switching efficiency. The magnetic properties of pMTJ stacks deposited on the pre-patterned substrate were evaluated by focused Kerr microscopy. Half-MTJ stacks were first deposited with bottom and top electrodes only to characterize the interfacial perpendicular anisotropy of the deposits on top of the posts CoFeB/MgO. The contribution of individual pillars and of the continuous deposit in the trenches could be distinguished. After optimizing the structural and magnetic properties, electrically characterization of these patterned MTJs were performed in terms of TMR and STT switching characteristics. The field-voltage switching phase diagram at room temperature was measured and is shown in Fig.2. At a constant applied field and even at zero field, the junctions can be switched from AP to P and from P to AP by STT. A switching voltage of 0.34 V for 100ns pulse was measured which is quite comparable or even slightly lower than similar MTJs patterned by IBE [4]. These electrical results demonstrate that functional patterned perpendicular MTJs can be obtained by this novel patterning process consisting in depositing the MTJ material on pre-patterned conducting posts. In conclusion, we have demonstrated a novel approach for nanopatterning MTJ down to sub-30nm dimensions at very narrow pitch by depositing the MTJ material on pre-patterned metallic posts. Remarkably, our approach allows to fabricate extremely dense arrays of very small size MTJs which is still impossible to achieve by IBE. This opens a possible route toward high density STT-MRAM application.

BD-04. Voltage-control spintronics memory (VoCSM) with potential cell-size of 4F^2 using in-plane magnetic tunnel junction.

S. Shirotori[1], H. Yoda[1], Y. Ohsawa[1], M. Shimizu[1], A. Buyandalai[1], K. Koi[1], T. Inokuchi[1], N. Shimomura[1], H. Sugiyama[1], Y. Kato[1], S. Oikawa[1], M. Ishikawa[1], A. Tiwari[1] and A. Kurobe[1]
1. Toshiba corporation, Kawasaki, Japan

Magnetic random access memory (MRAM) is a candidate for memory applications because it offers advantages such as high density in the Gbit class and low energy consumption. Recently, voltage-control spintronics memory (VoCSM), which uses the voltage-control magnetic anisotropy (VCMA) effect as a selection method and the spin Hall effect (SHE) as a write method, has emerged as a promising candidate for high-speed and high-density applications, offering advantages such as ultra-low energy consumption, high-speed writing, read-disturb robustness, and unlimited endurance over conventional STT-MRAM [1]-[5]. VoCSM consists of a three-terminal configuration with a string-cell structure as shown in Fig. 1 (a), such that the ideal cell size is 4F^2 in the case of magnetic tunnel junction (MTJ) cells with perpendicular magnetic anisotropy (P-MTJ) as shown in Fig. 1 (b). The write mode is deterministic without application of magnetic field for precessional switching as shown in Fig. 1 (c). MTJ cells with in-plane anisotropy (I-MTJ) are normally used because the easy axis is perpendicular to the write-current direction [6], [7]. However, the conventional I-MTJ has the disadvantage of larger MTJ size than that of P-MTJ because of the shape anisotropy. In this study, MTJs with strain-induced in-plane magnetic anisotropy (SI-MTJ) were examined for use in memory cells. Figure 1 (d) shows a schematic diagram of our concept of the strain-induced VoCSM structure. An SI-MTJ can be produced by using an anisotropy control (AC) layer under the SHE electrode. We developed an AC layer that has the function of expanding the lattice of the storage layer using an SHE electrode. That is, the magnetic anisotropy of the storage layer is controllable by the strain and patterning of the AC layer and SHE electrode. Figure 2 (a) shows the measured resistance versus magnetic field (RH) hysteresis loops of MTJ in the VoCSM where the MTJ configuration consist of Ta (5.0 nm)/CoFeB (1.25 nm)/MgO (1.6 nm)/CoFeB (1.2 nm)/Co (0.6 nm)/Ru (0.84 nm)/CoFe (1.8 nm)/IrMn (8.0 nm) grown on a thermal oxide Si substrate with and without an AC layer, and patterned by using a two-step self-alignment (TSSA) process to form the 80 × 80 nm MTJ nanopillars on a 80-nm-wide Ta SHE electrode [4]. Even though the aspect ratio (AR) = 1, a clear switching behavior is observed. Moreover, a change in the coercive force (H_C) of over 300 Oe was observed due to the strain induced in the MTJ by using an AC layer. The stress (σ) along the magnetic easy-axis direction in the free layer in the MTJ was estimated to be 630 MPa by using the magnetostriction constant (λ) of the free layer of 17 ppm. This can also be controlled from 630 to 450 MPa, which is 0.2% to 0.3% of lattice expansion, by changing the configuration of the AC layer. The thermal stability factor has been measured to become around 2 times larger by controlling σ as shown in Fig. 2 (b). In summary, we successfully demonstrated that MTJs with strain-induced in-plane magnetic anisotropy had large unidirectional anisotropy even with an in-plane aspect ratio of 1. This work was partly supported by the ImPACT Program of the Council for Science, Technology and Innovation (Cabinet Office, Government of Japan).

BD-05. Ultra Low Power Composite Free Layer Spin-Orbit Torque MRAM.

W. Hsu[1], R. Bell[1] and R.H. Victora[1]
1. Electrical and Computer Engineering, University of Minnesota, Minneapolis, MN, United States

I. INTRODUCTION AND METHODS Spin-transfer torque MRAM (STT-MRAM) serves as a promising candidate for next generation memory. However, STT-MRAM suffers from tunnel barrier degradation under rapid operations and a poor spin polarization. In contrast, spin-orbit torque MRAM (SOT-MRAM) utilizes spin-orbit interaction at the interface of heavy metal (HM) and ferromagnetic (FM) layers via mechanisms such as the Rashba effect and spin Hall effect (SHE)[1,2]. Since current only flows through the heavy metal in SOT-MRAM, device performance is no longer limited by insulator breakdown. Because no charge current through the FM layer is needed in SOT devices, the other unrecognized benefit of SOT is its compatibility with low-damping magnetic insulators (MI). SOT experiments with YIG/Pt, YIG/Ta, and YIG/W have demonstrated the potential for ultra-low damped switching of YIG in SOT systems[3,4]. SOT switching has also been demonstrated in TmIG based system[5]. Here, we propose a composite free layer SOT-MRAM (Fig. 1a). The MTJ is a cylinder structure with a diameter D. The free layer consists of an easily switched YIG layer and a thermally stable high anisotropy (K_u~10^7 ergs/cc) $L1_0$-FePt or $L1_0$-FePd layer. These two layers are ferromagnetically coupled through the RKKY exchange provided by the Pd layer. It has been shown that exchange coupling between magnetic soft and hard layers can reduce the critical current[6]. Current CoFeB based devices necessitate larger diameters due to the low anisotropy. By adopting FePt or FePd, we can reduce the device area, which is favorable for high density applications. We optimized our device by running micromagnetic simulations in the macrospin approximation. A device of small diameter (D < 30nm) with low write energy (E_w < 1 fJ) can be achieved for 1 ns switching while maintaining thermal stability $\Delta = 60k_BT$ at room temperature. II. RESULTS When the charge current passes through the HM layer, a spin current transverses the HM/YIG interface due to spin-orbit interaction via the SHE. This spin current generates a torque to reverse the magnetization of the easily-switched YIG and eventually switches the hard layer (HL) through exchange coupling (Fig. 1b). An optimal design can be found under a fixed volume ($V=60k_BT/K_u$) and a fixed thickness of hard layer (t_{HL}) by varying the exchange coupling strength (J_{ex}) and the thickness of YIG layer (t_{YIG}). We found that the optimal $(t_{YIG}M_{s,YIG})/(t_{HL}M_{s,HL})$ and $J_{ex}/(2t_{HL}K_{u,HL})$ are fixed, where M_s is the saturation magnetization. For different hard layer thickness, we also found that the optimal write energy is proportional to the thickness of hard layer, i.e., inversely proportional to the device area at fixed hard layer volume. A write energy of ~17 aJ is achieved for 1 ns writing for a FePd/YIG composite free layer with diameter of 26.5 nm (t_{FePd} = 0.25 nm). The write energy as a function of the device size is shown in Fig. 2. The write energy of 17 aJ is within a factor 80 of the theoretical limit of $60k_BT$. When thermal fluctuations are included in the simulations, the write energy is only four times larger than the write energy obtained without thermal fluctuations even at a required bit error rate of 10^{-9}. Zhao et al.[7] found CoFeB based STT-MRAM to have E_w about 0.5 pJ with Δ = $50k_BT$. A CoFeB based SOT-MRAM proposed by Manipatruni et al.[8] has E_w about 100 aJ with $\Delta = 40k_BT$. These points are also plotted in Fig. 2 and suggest advantages for our proposed structure. In addition, the write energy of 17 aJ in our proposed structure represents 500× improvement relative to state-of-the-art DDR4 DRAM cells and 5×10^4× improvement when DRAM refresh energies are included.

With their very rich static and dynamical properties, magnetic vortex dynamics excited by a spin polarized current represent not only a model system to study the physical mechanisms of spin transfer phenomena but could also give birth to a new generation of multi-functional micro-wave spintronic devices [1]. The key property of spin-torque nano-oscillators (STNOs) is their high nonlinearity [2] which gives rise to manifold phenomena such as injection locking to an external rf signal [3-4] or synchronization of multiple STNOs [5-7]. On the other hand, their large nonlinearity causes the oscillator's very poor spectral coherence and leads to a coupling between amplitude and phase noise [8]. While the noise distribution for offset frequencies far from the carrier frequency is reasonably well understood [8] and described by the general nonlinear autooscillator theory [2], low frequency noise remains under investigation as it limits the frequency stability of the oscillator. Extensively studied in GMR and TMR sensors [9-12], this work addresses the low frequency noise of a TMR-based spin-torque vortex oscillator in the regime of large amplitude steady oscillations. In detail, we present a precise experimental study of the TMR-based spin-torque vortex oscillator's low frequency noise, which remains poorly investigated for STNOs in the regime of large amplitude steady oscillations, as we propose here. The measured STNO's magnetic tunnel junction layer stack of PtMn/CoFe/Ru/ CoFeB/CoFe/MgO/FeB/MgO/Ta/Ru was realized by sputter deposition and nanopillar devices of 100-600nm were nanofabricated. The devices have a free running frequency from 100 MHz to 1 GHz depending on the diameter and the applied field value, with an integrated power of up to a few μW and a linewidth of typically ~100 kHz. In complement to the experimental measurements, we have also developed a phenomenological theory aiming to investigate the low frequency flicker noise in these vortex-STNOs. Starting from the corresponding nonlinear Langevin equations and a colored noise distribution, we find additional noise contributions to the white noise power spectral densities. This also gives an additional coupling term between amplitude and phase noise. Noteworthy, we find that this prediction agrees well to our experimental results of the gyrotropic mode's low frequency noise (fig. (a)). Furthermore, we analyze the noise dependence on the control parameter (the operating dc current) and the oscillator's active magnetic volume, reflected by the Hooge-formula for TMR sensors [12] and the oscillator's nonlinearity itself (fig. (b)). S.W. acknowledges financial support from Labex FIRST-TF. EU FP7 grant (MOSAIC No. ICT-FP7-8.317950) is also acknowledged for support.

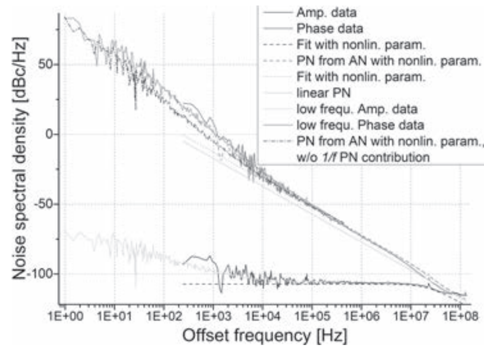

Fig. 1. Noise power spectral density of a spin torque vortex oscillator. The experimental data are shown together with the theoretical curves governed by the preliminarily determined nonlinear parameters [13] as well as the noise curve for a linear oscillator. Theoretical and experimental curves exhibit a good agreement. Here, the theoretical low frequency phase noise curve underestimates the experimental data because the low frequency pure phase noise contribution was neglected due to an experimentally hardly determinable parameter (the corresponding Hooge-factor). AN: Amplitude Noise, PN: Phase Noise.

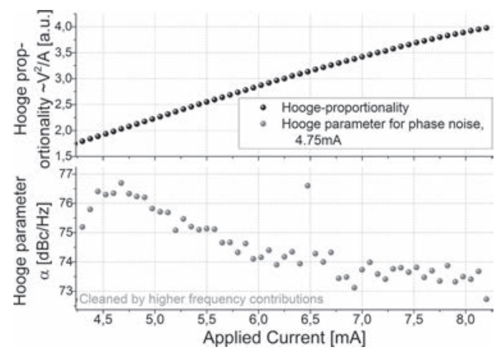

Fig. 2. Although the Hooge-proportionality, which mainly determines the 1/f noise in magnetic sensors, increases, the experimental Hooge-parameter decreases with higher applied current due to the dominant nonlinear effects. V: Voltage, A: Active magnetic surface.

2. Material Science Lab, Data Storage Institute, Singapore, Singapore

Perpendicular magnetic tunnel junctions (*p*-MTJs), based on CoFeB-MgO systems, are widely accepted as the key component for realizing high-density magnetoresistance random access memories (MRAMs).[1] Several experimental and theoretical research have been focused towards investigation of suitable "boron-sink" materials as a CoFeB underlayer to achieve high thermal stability, and low critical current in *p*-MTJs. [2–4] While Ta is the archetypal "boron-sink" underlayer for CoFeB-MgO systems, Hf has emerged as an alternative to Ta with the recent demonstration of 35% increase in interfacial perpendicular magnetic anisotropy (PMA) on replacing Ta.[2] However, important questions with regards to its spin properties such as interfacial magnetoelastic effects, role of orbitals in enhancing PMA, gilbert damping, spin-pumping, etc. remain which need to be addressed. Particularly, in the context of MRAM development, it is essential to investigate these properties in the ultra-thin limit of ferromagnetic thickness, t_F <1.3 nm. In this work, we report a comprehensive study on Hf/$Co_{20}Fe_{60}B_{20}$/MgO for t_F <1.3 nm, by investigating the crystallinity, PMA, and gilbert damping parameter supported by first principles calculations. First, high-resolution transmission electron microscopy (HRTEM), of the stack deposited by sputtering, reveals the crystallinity of the Hf underlayer as well as the MgO layer [Fig. 1 (a)]. Next, we observe a strong non-linear dependence of effective magnetic anisotropy on CoFeB thickness, which can be modelled by incorporating the contribution from magnetoelastic coupling in the standard Néel model [Fig. 1(b)].[5] The magnetic anisotropy energy reaches value as high as ~0.07 erg/cm^2, and PMA is observed for t_F <1.24 nm, significantly wider thickness range compared to Ta underlayer. First principles density-functional calculations (DFT) support the enhancement of PMA in Hf underlayer. Also, to understand the magnetization dynamics as a function of t_F, we use broadband ferromagnetic resonance spectroscopy. Within the PMA range of t_F, the damping is as low as ~0.012 [Fig. 2(a)]. By systematically comparing with MgO/CoFeB/MgO system, we account for non-local effects which contributes to enhancement of effective damping, and also follows a reciprocal relationship with t_F [Fig. 2(b)]. We model this enhanced non-local effect as originating from large spin-mixing conductance. Finally, with the help of DFT, and looking at the density of states, we discuss the true intrinsic damping in this system [Fig. 2(c)]. Our study opens up opportunities for niche applications in MRAM, where broad t_F range for PMA, and tunability in damping are desired.

BD-08. A thermally robust perpendicular magnetic tunnel junction with the FeTa decoupling layer.

J. Yu[1], X. Wang[1] and H. Fukuzawa[1]
*1. Emerging Memories, Institute of Microelectronics, A*STAR, Singapore, Singapore*

Spin-Transfer-Torque Magnetoresistive Random Access Memory (STT-MRAM) has attracted great attentions as an emerging non-volatile memory. For embedded application, its memory cell i.e. perpendicular magnetic tunnel junction (p-MTJ) needs to withstand the 400 °C thermal process which is involved in the semiconductor back-end-of-line (BEOL) process. Although several groups have reported 400 °C thermal robustness [1, 2], the key required atomic-level structure for p-MTJs has not yet been clarified. In this work, we have achieved 400 °C p-MTJ thermal robustness with an untrathin FeTa decoupling layer in the pinned layer, and analysed the atomic-level structure of the film. By comparing the crystal structures of thermally robust and thermally degraded p-MTJs, we have identified that decoupling the body-centered cubic (bcc) CoFeB reference layer and the face-centered cubic (fcc) Co/Pt superlattices is essential in achieving good thermal stability. Firstly, we have confirmed the thermal robustness of a thick p-MTJ against 400 °C as reported in Ref. [3]. The p-MTJ structure is Sub/Ta (1.2)/Pt (2.0)/[Co (0.3)/Pt (0.5)]$_6$/Co (0.5)/ Ru (0.85)/Co (0.5)/Pt (0.5)/[Co (0.3)/Pt (0.5)]$_4$/Ta (0.3)/$Co_{20}Fe_{60}B_{20}$ (1.2)/MgO(1.0)/$Co_{20}Fe_{60}B_{20}$ (1.2)/Mo(2.0)/Cap [thickness in nm]. However, for a thinner pinned layer p-MTJ by reducing the Co/Pt repetitions from 4 to 2 labelled as the conventional p-MTJ in Fig. 1(a), thermal stability degradation was observed from the major *M-H* loops [Fig. 1(b)]. Since the free layer exhibited sufficient thermal stability as shown in the inset of the figure, we speculated that thermal degradation could be initiated from the crystal interference in a thin region of Ta insertion layer where the bcc and fcc crystals meet each other. In order to solve this issue, we proposed a FeTa insertion layer to replace the Ta layer. The improved p-MTJ structure is shown in Fig. 1(a). FeTa was selected due to its amorphous structure as deposited. Under 400°C thermal annealing, it could nucleate and grow in an epitaxial manner along both bcc and fcc crystal boundaries of the neighbouring layers. This unique crystallization behaviour enables FeTa to act as a buffer to effectively decouple the bcc and fcc crystal structures. Regarding the magnetic function, the required ferromagnetic exchange coupling between the CoFeB reference layer and the Co/Pt superlattices was obtained thanks to the intrinsic magnetic property of FeTa alloy. As a result, the thermal robustness against 400 °C has been successfully achieved for the improved p-MTJ. Fig. 1(c) shows the decent major and minor *M-H* loops with little thermal degradation for the improved p-MTJ. To clarify the mechanism for achieving thermal robustness of the improved p-MTJ, we adopted the spherical aberration corrected Scanning Transmission Electron Microscope (Cs-corrected STEM) to visualize the atomic-scale structural difference at the Ta and FeTa interfaces (Fig. 2). Images show that a flat interface is present with the improved FeTa sample, and its CoFeB reference layer is more crystalline structured. In contrast, the conventional Ta sample shows a rougher crystal interface and the CoFeB reference layer tends to be amorphous. The structural difference suggests that the FeTa layer is more effective in decoupling the bcc and fcc crystal structures. This result could also account for the observation by another group that a thicker CoFeB reference layer resulted in thermal stability degradation [2]. Theoretically, a thicker film layer leads to a better thermal tolerance owing to its more robust crystal structure. However, when comes to a complex p-MTJ system consisting of both bcc and fcc lattices in an ultrathin region, a thicker CoFeB layer enhances the structural integrity of bcc lattice against the fcc Co/Pt superlattices. This subtle thickness change may break the thermodynamic equilibrium status between these two lattices during 400 °C thermal process, thus causing the degradation of perpendicular magnetic anisotropy originated from the Co/Pt superlattices. This also explained the slightly thermal degradation of the improved p-MTJ when thickening the CoFeB reference layer from 0.8 nm to 1.2 nm even though the FeTa insertion layer can realize more effective crystal decoupling between the bcc CoFeB and fcc Co/Pt superlattices. In summary, maintaining the crystal integrity of both the CoFeB bcc and Co/Pt fcc crystal structures and well control of their interface are essential in achieving good p-MTJ thermal tolerance for embedded STT-MRAM application.

BD-09. Effect of MgO interface in double barrier CoFeB MTJ structures.

S. Srivastava[1], A.P. Chen[1], T. Dutta[1], R. Ramaswamy[1], M. Saifullah[2], K. Yamane[3], J. Son[1,3], K. Lee[3], P. Yang[1] and H. Yang[1]
1. National University of Singapore, Singapore; 2. Agency for Science, Technology, and Research, Institute of Materials Research and Engineering, Singapore, Singapore; 3. GLOBALFOUNDARIES Singapore Pte. Ltd., Singapore, Singapore

The double barrier perpendicular MTJ system with CoFeB as the magnetic free layer and MgO as the barrier is the most preferred structure, due to its high thermal stability, for MRAM applications. In order to improve the MTJ free layer performance, it is essential to optimize magnetic properties of CoFeB. In literature, few works have studied the CoFeB composition dependence of the magnetic properties, however these studies are limited to either the bulk systems or a very few compositions. On the other hand, state of the art MTJs use ultrathin magnetic layers with the MgO interface, which show very different properties compared to the bulk systems. Thus, it is necessary to develop a comprehensive understanding of the effect of CoFeB composition with the MgO interface to identify the factors influencing the magnetic anisotropy and damping of the free layer, which are crucial factors for MRAM development. In this work, we have carried out a comprehensive study of various magnetic properties for different CoFeB compositions. We find that the saturation magnetization shows an anomalous trend with respect to CoFeB composition in contrast to conventional Slater-Pauling curve. Further, we also find a minimum in composition dependence of the damping parameter, which could not be explained using the theories and concepts established in previous studies. To explain these new observations, we theoretically calculated the density of states (DOS) and magnetic moments for different compositions. Figure 1 shows the composition transition of the nature of anisotropy from uniaxial to cubic anisotropy. Using this anisotropy information and the theoretical magnetic moments, we propose that this change in anisotropy is the predominant underlying mechanism for the observed anomalous magnetization behaviors. Furthermore, the theoretical calculations of DOS are also used to explain the minimum in the Gilbert damping parameter, which is shown in figure 2. Our results suggest that it is necessary to consider the structure of CoFeB ultra-thin films with MgO interface to understand the underlying physics of the magnetic properties in CoFeB/MgO based MTJs, which is important for scientific development. Our study also identifies the best CoFeB composition for the lowest spin transfer torque switching current, highest thermal stability and other characteristics which are important for applications.

BD-11. Effect of stray field from adjacent bits of high-density STT-MRAM on switching current.

S. Itai[1], T. Kai[1], M. Nakayama[1], T. Daibou[1] and J. Ito[1]
1. Institute of Memory Technology Research & Development, Toshiba Memory Corporation, Kawaksaki, Japan

Magnetoresistive random access memory (MRAM) has the potential to become the ultimate random access memory due to its non-volatility, high-speed operation, and unlimited read/write endurance. The experimental observation of spin-transfer torque (STT) switching [1-2] has stimulated considerable interest in high-density MRAM due to its simple cell structure. Last year, Toshiba and SKhynix reported [3] for the first time the realization of 4 Gbit high-density MRAM by employing perpendicular magnetic tunnel junctions (MTJs) with a 90 nm pitch between bits. However, enhancement of stray field between adjacent MTJ bits is expected to become a serious problem as the distance between MTJ bits decreases at higher densities. This effect causes degradation of various MTJ properties including thermal stability and the STT switching current. In this study, we investigate the effect of MTJ properties on the stray field from adjacent MTJ bits by using micro-magnetic calculations based on the Landau–Lifshitz–Gilbert equation [4]. We also investigate the dependence of STT switching current on the distance between bits. The micro-magnetic simulation that we used examines 9 to 25 bits that are modeled. Electric current is applied to only the center MTJ bit, which allows us to calculate the STT switching behavior for various configurations of the magnetization direction of the storage layer. We assume that the magnetization direction of the reference layer is fixed in the upward direction. The parallel configuration (P) has the magnetization direction of the storage layer pointing upward, and the anti-parallel configuration (AP) has the magnetization direction of the storage layer pointing downward. The storage layer parameters that we used are *Ms* (saturation magnetization) = 1400 emu/cc or 1700 emu/cc, *Ku* (magnetic anisotropy) = 17 Merg/cc or 14 Merg/cc, *D* (MTJ diameter) =14 nm or 20 nm, and *L* (distances between bits) = 2D nm or 3D nm. In general, the thermal stability factor, ΔE, is dependent on the external field and is given by $\Delta E_{eff} = \Delta E_{int} (1-H_{ext}/H_k)^2$ (1), where H_{ext} is the external field and H_k is the anisotropy field of the storage layer. Here, H_{ext} means the stray field from adjacent bits, the magnitude of which depends on the magnetization pattern of the adjacent storage layer. The switching current, *Ic*, of an MTJ with perpendicular magnetization is proportional to ΔE. Therefore, the value of *Ic* in the presence of stray field from adjacent MTJ bits is given by $Ic/Ic_{\_iso} = (1-H_{ext}/H_k)^2$ (2), where $Ic_{\_iso}$ is the calculated *Ic* of an isolated pattern without the adjacent MTJ bits. Figure 1 and 2 show $Ic/Ic_{\_iso}$ as a function of H_{ext}/H_k for various bit patterns. In this case, *Ic* is the P-AP switching current of the center bit, and H_{ext} is the average field over the z-direction estimated from a simple analytic model. In this report, we present calculations for two patterns. In one pattern, all the bits are in the AP configuration except the center bit as shown in Fig. 1, and the center bit is in the P configuration, which means that the storage layer magnetization direction of only the center bit shows a different direction. In this case, the direction of the stray field from the adjacent bits points upward, therefore the switching current *Ic* from P to AP increases for the disturbance of the STT switching with its stray field as compared to the switching current of the isolated pattern, *Ic_iso*. However, the quantitative dependence is different from Eq. (2), which may be due to the complex spatial distribution of the stray field from the adjacent bits. In another pattern, all the bits are in the P configuration as shown in Fig. 2, which means that all the bits show the same upward direction in the storage layer. In this case, the switching current exhibits very little change depending on the external field. We conclude that the effect of stray field from adjacent bits on the switching current is much larger than expected from a simple theoretical model. Importantly, these results suggest that it is necessary to carefully investigate the influence of adjacent bits when designing high-density MRAM devices.

BE-01. Effects of spin-orbit torque on the magnon gas.

V.E. Demidov[1], S. Urazhdin[2], B. Divinskiy[1] and S.O. Demokritov[1]
1. Institute for Applied Physics, University of Muenster, Muenster, Germany; 2. Emory University, Atlanta, GA, United States

Spin orbit torque (SOT) provides the possibility to control the magnetization state of conducting and insulating magnetic materials. Recently, it was shown that the influence of SOT on the spin system of ferromagnets results in either enhancement or suppression of magnetic fluctuations, depending on the polarization, which can be equivalently described as generation or annihilation of incoherent magnons. This mechanism is not specific to certain magnon states, and is expected to change magnon populations throughout the entire spectrum, thus avoiding the non-thermalized transient states inherent to other mechanisms used to drive magnon gases, such as the parametric pumping. Recent theoretical studies suggest that SOT can drive the magnon gas into a quasi-equilibrium state described by the Bose-Einstein statistics with non-zero chemical potential, suggesting the possibility of electrically-driven Bose-Einstein condensation (BEC) of magnons. These theories have been supported by the successful application of the developed theoretical framework to incoherent magnon transport. Variations of the chemical potential of the magnon gas were recently detected in measurements of spin relaxation rates of a nitrogen-vacancy center in diamond coupled to spin waves in a magnetic insulator. However, there was no direct experimental evidence that the magnon gas driven by SOT forms a quasi-equilibrium distribution, and the dependence of the effective thermodynamic characteristics has not been established. We studied the effects of SOT on the magnon distribution over a broad spectral range, by utilizing the micro-focus Brillouin light scattering (BLS) spectroscopy. The studied system comprises a 2 micrometers wide and 5 nm thick Pt strip overlaid by a 1 micrometer wide and 10 nm thick ferromagnetic Permalloy (Py) strip (Fig. 1a). The system is magnetized by the static magnetic field applied along the Py strip. The electric current I flowing in Pt is converted by the spin-Hall effect (SHE) into a spin current injected into Py through the Py/Pt interface. The magnetic moment carried by the spin current is either parallel or antiparallel to the Py magnetization M, depending on the direction of current, resulting in a decrease or an increase of the magnon population, respectively. The BLS spectra reflecting the current-dependent spectral density of magnons (Fig. 1b) allowed us to analyze the spectral magnon population function and determine the thermodynamic characteristics of the magnon gas. Our analysis clearly indicated that the magnon distribution can be described by the Bose-Einstein statistics expected for the quasi-equilibrium state. We determined the current-dependent chemical potential and effective temperature of the magnon gas (Fig. 2), and showed that, for one polarization of the spin current, the effective temperature of the magnon gas becomes significantly reduced, while the chemical potential stays almost constant (Fig. 2a). In contrast, for the opposite polarization, the effective temperature remains nearly unaffected, while the chemical potential linearly increases with current, until it closely approaches the lowest-energy magnon state (Fig. 2b), indicating the possibility of spin current-driven Bose-Einstein condensation. Our experimental results provide direct spectroscopic evidence that the magnon gas is driven by the SOT into a quasi-equilibrium state, which can be described by the Bose-Einstein distribution with current-dependent values of chemical potential and effective temperature. These findings support the theoretically proposed mechanism for the formation of current-induced magnetization auto-oscillations via the Bose-Einstein condensation of magnons. Our results should stimulate further experimental and theoretical exploration of the relationship between the thermodynamics of magnon gases driven by spin currents, and coherent magnetization dynamics.

BE-02. Current-Induced Superparamagnetism in CoFeB Nanodots.

A.M. Abdelgawad[1], B. Parks[2] and *S. Majetich*[2]
1. Materials Science and Engineering, Carnegie Mellon University, Pittsburgh, PA, United States; 2. Physics, Carnegie Mellon University, Pittsburgh, PA, United States

Superparamagnetic tunnel junctions with perpendicular anisotropy have a fluctuation frequency that can be controlled by a voltage through voltage controlled magnetic anisotropy [1], but statistical mechanics limits the range of the time-averaged magnetoresistance. Here we describe how a much larger range can be achieved using nanostructures with in-plane magnetization. Such devices could be important for low power logic gates and probabilistic computing. [2,3]. The sample stack consists of an in-plane magnetic tunnel junction (MTJ) with a pinned synthetic antiferromagnet fixed layer: Pt(5)/Ta(10)/CoFeB(2.5) /MgO(1.0)/ CoFe(3)/Ru(0.8)CoFe(2)/PtMn(20)/Ta(50)/Si, where the numbers are in nanometers. In-plane hysteresis loops measured by alternating gradient magnetometry showed a 4 kOe switching field for the fixed layer. Out-of-plane loops indicated a free layer anisotropy field of ~ 600 Oe. The stack was patterned by electron beam lithography and etched down to the MgO tunnel barrier via ion milling, leaving arrays of circular 20 – 80 nm diameter CoFeB dots. After patterning the CoFeB layer, the sample was initialized with a permanent magnet along the pinning axis to orient the fixed layer. Conductive atomic force microscopy (CAFM) was then used to measure the magnetoresistance R as a function of in-plane magnetic field H, bias voltage V, and time t. Here positive bias corresponds to electrons flowing from tip to sample. At low voltage bias (50 mV) with no external magnetic field, the CoFeB dots were magnetically stable, for all sizes. Resistance as a function of magnetic field indicated coercivities on the order of 7 Oe, independent of size. In addition, there were small loop shifts due to orange peel coupling associated with interface roughness that varied with location and favored the parallel (P) state. Figure 1a shows resistance as a function of voltage bias measurements for a 40 nm tunnel junction, with H applied = 0. Figure 1b shows the result after an external field was used to cancel the local orange peel. There a high negative bias the device is stable in the P state, and at high positive bias it is stable in the antiparallel (AP) state. Between –50 mV and +250 mV the fluctuations indicate current-induced superparamagnetim of the 40 nm CoFeB dot. The threshold for fluctuating behavior is higher to stabilize the AP state than the P state. Similar asymmetric thresholds are also seen with stable MTJs and giant magnetoresistance spin valves. This, together with the current densities (here 3.4×10^6 A/cm^2 at –50 mV) suggest that spin transfer torque is the dominant cause of the superparamagnetic fluctuations. Interpretation of the superparamagnetism is complicated by the time-varying voltage bias (1.5 V/s) in Figure 1, and so the resistance as a function of time was measured at a series of fixed bias voltages within the fluctuating region (Figure 2). The data are consistent with those of Figure 1, but provide additional details. The change in *R(t)* as function of the applied bias reflects a gradual change in the direction of the normalized time-averaged magnetization of the free layer over the full range from 1 to -1, corresponding to P and AP states, respectively. Unlike with perpendicular MTJs, which have random telegraph noise between two levels [1], these in-plane MTJs have variable resistance between the P and AP limits, indicating incomplete reversal. For analysis of superparamagnetism in terms of a Neel-Brown model, the nanomagnet must spends most of its time in one of the ground states, and this is not necessarily true here. As an alternative approach, the fast Fourier transform (FFT) of the time trace was fit to a Lorentzian function to determine the average fluctuation time (t = 20 ms for the 40 nm device at +50 mV). This method avoids artifacts associated with thresholding that could obscure the underlying physics of current-driven superparamagnetism. The amplitude and frequency of these fluctuations are characterized as a function of the bias voltage and current density, for the different CoFeB dot diameters. The 20 nm diameter dots show more significant thermal effects, as expected. The statistical randomness of the signal and its use in probabilistic computing are discussed.

BE-03. Out-of-plane auto-oscillation in spin Hall oscillator with additional polarizer.

T. Taniguchi[1]
1. Spintronics Research Center, National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan

This theoretical work proposes an experimental scheme to excite an auto-oscillation in a perpendicular ferromagnet by the spin Hall effect. The spin-Hall effect [1] in nonmagnetic heavy metals has attracted much attention from the prospective of both fundamental physics and practical applications. The spin Hall effect in a nonmagnetic/ferromagnetic bilayer injects spin current from the nonmagnet to the ferromagnet, and excites spin torque acting on the magnetization. The spin torque induces magnetization dynamics such as switching and oscillation [2], which are applicable to practical applications such as magnetic memory, high sensitivity sensor, and brain-inspired computing [3]. A critical problem for further development of spintronics devices based on the spin Hall effect is the geometrical restriction on the direction of the spin torque. Let us assume that electric currents flow in the nonmagnet along the *x* direction, while the ferromagnet is set in the *z* direction. The spin polarization in spin current by the spin Hall effect is then fixed to the *y* direction. The designs and performances of the devices are subject to limitation due to this restriction of spin polarization. For example, the magnetization switching of a perpendicular ferromagnet solely by the spin Hall effect is impossible because the spin torque does not break the planar symmetry with respect to the film plane. Using external magnetic field, tilted anisotropy, or exchange bias has been proposed to overcome this issue [4]. It was also shown that an auto-oscillation in a perpendicular ferromagnet solely by the spin Hall effect is impossible due to the symmetry of the spin torque [5]. However, the auto-oscillation in a perpendicular ferromagnet is attractive because the large amplitude oscillation leads to a large emission power. In this work, we investigate the possibility to excite the auto-oscillation in a perpendicular ferromagnet by the spin Hall effect [6]. We focus on recent theoretical works on the spin Hall effect in the presence of an additional ferromagnet to the free layer [7]. It is predicted that the additional ferromagnet provides an additional spin torque excited in the free layer. In this study, we consider adding another ferromagnet, referred to as the pinned layer, on the top of the free layer, as shown in Fig. 1(a). The spin Hall effect in the bottom nonmagnet injects spin current into the free layer, and excites the conventional spin torque as a result of the absorption of the transverse spin current. On the other hand, the spin current survived during the transport from the bottom nonmagnet to the free layer moves to the pinned layer. Reflecting the spin current at the interface and inside the bulk, the pinned layer injects the reflected spin current into the free layer, and provides an additional spin torque. We evaluate the additional spin torque from the diffusive spin transport theory. The magnitude, direction, and angular dependence of the additional spin torque are found to depend on the magnetization direction in the pinned layer. By choosing an appropriate direction of the magnetization in the pinned layer, an auto-oscillation in the perpendicularly magnetized free layer can be excited. Figure 1(b) shows an example of the auto-oscillation obtained from the numerical simulation of the Landau-Lifshitz-Gilbert equation, where the magnetization in the free layer oscillates around the perpendicular axis within a frequency on the order of gigahertz. We notice that the direction of the magnetization in the pinned layer is an important parameter to stabilize the auto-oscillation. Figure 2 shows the dependences of the oscillation frequency of the magnetization in the free layer on the current in the bottom nonmagnet. Several values of the tilted angle of the magnetization in the pinned layer from the perpendicular axis are presented. In the low current region, the oscillation of the magnetization at the ferromagnetic resonance (FMR) frequency is excited by random torque originated from thermal fluctuation. The FMR frequency depends on the direction of the magnetization in the pinned layer through the stray field from the pinned layer. Above critical values of the current, two kinds of magnetization dynamics are excited in the free layer. When the tilted angle of the magnetization in the pinned layer is relatively large, the magnetization switching to an in-plane direction is achieved. In this case, the oscillation frequency discontinuously drops from the FMR frequency to a certain constant value. On the other hand, when the tilted angle of the magnetization in the pinned layer is relatively small, a stable auto-oscillation is excited, where the oscillation frequency changes continuously. The results provide a guideline to design an auto-oscillator based on the spin Hall effect.

BE-04. Engineering lateral nanostructures for the study of spin accumulation phenomena, giant magnetoresistance, spin Hall effect, and sensors.

J. Attané[1], L. Vila[1], A. Marty[1], G. Zahnd[1], T. Van Pham[1], P. Noel[1] and W. Savero-Torres[1]
1. Univ. Grenoble Alpes, CEA, CNRS, Grenoble INP, INAC, SPINTEC, Grenoble, France*

Spintronics is mainly based on the phenomenon of spin accumulation, which is inherent to the circulation of an electric current at the interfaces between ferromagnetic and non-magnetic materials. These accumulations are conventionally obtained in multilayers for which the thicknesses of the layers are smaller than the characteristic lengths of the spin-dependent transport. It is thus possible to generate in these multilayers magnetoresistances or spin transfer effects. The development of nanofabrication processes makes it nowadays possible to create nanodevices whose lateral dimensions are less than the characteristic lengths of the spin-dependent transport, and thus to bring into play similar phenomena. In this contribution, we show results obtained in different ferromagnetic/non-ferromagnetic lateral nanostructures, demonstrating that it is possible to take advantage of the three-dimensional geometry of the structures, and of the different possible orientations of the injected spins. In particular, transport studies have been carried out in collinear and non-collinear regimes, in order to study the consequences of the non-collinearity on the spin accumulations and magnetoresistances. The effect of non-collinearity is examined using spin absorption measurements and Hanle measurements. We also show that the flexibility offered by the lateral geometry allows designing the ferromagnetic and non-magnetic materials, to tailor the spin accumulation and magnetoresistance signals as well as the magnetic states[1]. After presenting some of our recent spin to charge inter-conversion experiments by spin Hall effects[2], Rashba interfaces[3] and topological surface states[4], we then show that lateral spin valves offer various experiments for accessing the spin polarization and spin diffusion length of ferromagnetic materials, the properties of interfaces or of spin conductors. Thus, lateral nanodevices are very interesting tools for studying materials, interfaces and surface states, and for harnessing the spin orbit coupling[5]. Finally, we show that by combining lateral and vertical geometries, it is possible to evidence a magnetoresistance due to the spin accumulation. This new magnetoresistance is based on the modulation of the additionnal spin resistance generated by the presence of a spin accumulation at the vicinity of an interface.

BE-05. Robust electrical mutual synchronization of spin torque oscillators.

S. Tsunegi[1], T. Taniguchi[1], R. Lebrun[2], K. Yakushiji[1], A. Fukushima[1], J. Grollier[2], V. Cros[2], S. Yuasa[1] and H. Kubota[1]

Synchronization of spin torque oscillators (STOs) attracts much attention from fundamental and applied physics because it has a possibility to be used in practical devices such as the neuromorphic computing [1,2] and the phased array wave generator [3]. Recent studies have clarified that there are three key quantities determining the applicability of the synchronized STOs to the practical devices. First, it is necessary to synchronize a large number of STOs as the number of synchronized STOs determines the number of associative patterns in the associative memory [4]. Second, a fast transition from a given synchronous state to another is required because the transient time determines the operation speed of the devices. The third one is the robustness of the synchronization against the thermal fluctuations because the stability of the synchronization determines the output power. Very recently, we have successfully addressed these issues. First, we succeed to increase the number of the synchronized STOs up to eight [5]. This result guarantees the scalability of STOs. Moreover, we observe a fast transition time of STOs on the order of nanoseconds from asynchronous to synchronous states [6]. As for the robustness of the synchronization between STOs, a first approach has been to study the phase locking regime using a STO being synchronized to an external rf signal. The stability of the phase difference between the STO and the external signal is found to be of the order of milliseconds together with a phase noise level as low as -90 dBc/Hz at 1 MHz offset [7]. However, the stability of mutually synchronized STOs is expected to be relatively weaker as the phase noise of each STOs that are mutually synchronized shall affect the other ones. In fact, the robustness of the mutual synchronization has not been investigated yet and this is one of the main objectives of this study. Here, we aim at investigating the stability of the phase between the mutually synchronized STOs experimentally. To this purpose, we have measured the phase-slip time, during which the phase difference between the STOs is kept constant against the phase slip due to the thermal fluctuation. The circuit is composed of two vortex based STOs, each of them having a large emission power over 1 mW and a narrow linewidth being less than 300 kHz at the free running frequency around 330 MHz [8]. The STOs are electrically connected through directional couplers and attenuators. The coupling mechanism leading to the mutual synchronization originates from the emitted rf current from each STO which allows the efficient interaction between them [9] The directional couplers are used to characterize the individual signal of each STOs. The measured voltage signal is converted into the phase signal by the Hilbert transform. The attenuators are introduced to tune the coupling strength resulting in the synchronization force. Note that the individual magnets for each STO has been used in order to control separately the frequency of each STOs and make that the free running frequencies of the STOs are the same. In Figure 1(a), we show the time evolution of the phase difference Ψ between the synchronized STOs for several values of the attenuation A. The phase-slip time is determined by the shift of the phase difference with the factor of 2 π [9]. We confirm that the phase-slip time increases when the attenuation A is increased. In case of a strong coupling (A = 0 dB), it results in an extremely long stability of the phase difference. The stability is kept over one millisecond, corresponding to 10^5 oscillation periods. Unfortunately, we could not evaluate the phase-slip time for A = 0 dB because it is kept longer than the limit of the measurable time in our system. Therefore, we estimated the time between phase slips theoretically. The phase slip can be regarded as an escape of a Brownian particle from one stable state to the others in a periodic potential with the period of 2 π. We thus calculate the escape time as the phase-slip time by using the mean first passage time [10]. For a large coupling limit, the phase-slip time is given by $T_{slip}=\pi/\sqrt{AF_0}*\exp(\sqrt{AF_0}/D)$. Here, F_0 and D are related to the locking range at A=0 dB and the diffusion constant corresponding to the strength of the thermal noise. In Figure 1(b), we show the comparison of the phase-slip time evaluated from the experiments with the formula, where (F_0, D) =(3.73×10^7, 2.4×10^6) rad/s were determined by the fitting. These values correspond to a locking range of 6 MHz and a spectral linewidth of 630 kHz, which are consistent with our experimental results. According to the qualitative agreement between the experiments and theory, we predict that the phase slip time for A = 0 dB is 0.48 second corresponding to 10^8 oscillation periods. These results describe the first report highlighting a considerable long-time stability of the phase difference between the mutually synchronized STOs. We believe that it represents a crucial advances toward the development of the practical devices based on the STO arrays. Acknowledgments : the MIC/SCOPE # 162103105

INTRODUCTION The spin torque oscillators (STOs) are considered as the important devices, because the STOs are expected to be applied in many fields, such as a microwave generator or a magnetic field sensor. Therefore, the development of the STOs with the high emission power and the high Q-factor is in high demand. Considering a situation where a current density is constant, we can assume that a simple way to increase the emission power is to enlarge the STO device. Wang *et al.* have, however, reported that the emission power of a nano-pillar STO reaches to maximum around 300nm in the diameter [1]. They have speculated that the frequency of each magnetization oscillation of the free layer is same but the phase of that is different above 300nm in the diameter, which decreases the emission power of the STOs. To elucidate this phenomenon by simulations, it is essential to consider the size effect of the STOs. The micromagnetic simulation is key-tool because it can treat the geometry of the STOs and spatial magnetization dynamics. In this study, we simulate the STOs by using the micromagnetic simulations, analyze the emission power in various diameters and address a factor which enhances the emission power. METHOD The schematic picture of the model of the STO is shown in Fig. 1A. We prepared the STO models, the diameters of which are 200nm (D200), 250nm (D250), 300nm (D300), 350nm (D350) and 400nm (D400), respectively. The models are divided into unstructured hexagonal meshes, the size of which is about 3nm. The STO consists of five layers: FeB, MgO, FeCoB, Ru and FeCo. Hereafter, for simplicity, we call FeB, FeCoB and FeCo layers for the free layer (FL), reference layer (RL) and pinned layer (PL), respectively. To consider the current induced spin transfer torque effect, the magnetization dynamics of each layer is described by the Landau-Lifshitz-Gilbert equation including a spin transfer torque term[2].We consider that the spin transfer torque only acts between the FL and the RL through the MgO layer via a tunnel effect. In the FL, we use following physical properties: the saturation magnetization M_s is 1.82 T, the anisotropic constant K_U is 1.20 MJ/m^3, the exchange constant A_{ex} is 12.5 pJ/m, the damping constant α is 0.005 and the polarization p_0 is 0.54. As for the RL, M_s = 1.25 T, K_U = 0 MJ/m^3, A_{ex} = 10.0 pJ/m, α = 0.01 and p_0 = 0.54. As for the PL, M_s = 2.1 T, K_U = 0 MJ/m^3, A_{ex} = 10.0 pJ/m and α = 0.01. The external field, 300 mT, is applied onto the out-of-plane direction. The interlayer coupling constant, -0.1 mJ/m^2, is set between the RL and the PL. The exchange bias field, 100 mT, is applied to the PL. The current density is 200 GA/m^2 and flows through the STO from the PL to the FL. RESULTS Figure 1B shows the relation between the diameter of the STOs and the emission power obtained by the simulations. This result indicates that the peak of the emission power exists around D300. This is consistent with the reported experimental results [1]. Figure 1C shows the snapshot of magnetization states in D200 and D400, respectively. In the case of D200, although magnetization state is different between the center region and the edge region, the magnetization dynamics is relatively coherent. In contrast, the snapshot of D400 shows that the magnetization state is inhomogeneous. This indicates that oscillation phases at each area are non-uniform. Since the spatial phase difference reduces amplitudes of STO's oscillation, the emission power decreases at D400 and D350 (Fig.1 B). Figure 1D shows the time trajectories of the variance of an in-plane component of the FL's magnetization. This also indicates that the FL's magnetization of D400 is less coherent than of D200. Hence our simulations suggest that the degradation of the emission power is caused by the incoherent rotation of FL's magnetization. Figure 2 shows the emission powers of D200, D300 and D400 at various interlayer exchange coupling constants. In every diameter, the emission power is related to the strength of the interlayer coupling constant. We speculate that strengthening the interlayer coupling induces the coherent rotation of magnetization. This result suggests that increasing the interlayer exchange coupling by adjusting the Ru layer thickness can enhance the emission power of STOs.

The Spin Hall Effect (SHE) can be used to generate pure spin currents, capable of exerting a spin transfer torque (STT) that induces oscillations in a ferromagnetic layer[1–3]. Until now, reported publications concern the STT effect induced from a spin Hall current on a fixed MgO barrier[1,4]. However, the influence of R×A on a performance of spin Hall current induced STT oscillations not been studied yet. To this end, we study the effect of spin Hall current induced STT on variable (wedge) MgO thickness. In this work, a 3-terminal MTJ stack incorporating MgO-wedge was deposited on a 200 mm, Si/100 nm Al_2O_3 wafer in a Timaris Singulus PVD deposition system, leading to a variable $R{\times}A$ over the wafer from 1 Ωμm^2 up to 70 Ωμm^2. The deposited stack was consisted of the following materials: 15 Ta/1.4 $Co_{0.4}Fe_{0.4}B_{0.2}$/[Wedged] MgO /2.2 $Co_{0.4}Fe_{0.4}B_{0.2}$/0.85 Ru/2.0 $Co_{0.7}Fe_{0.3}$/20 $Ir_{0.2}Mn_{0.8}$/5 Ru (thickness in nanometer). The stack was subsequently patterned into 30 different circular and ellipse-shaped nanopillars. The nanopillars patterning were done using electron beam lithography followed by etching in ion beam milling. The Hall bar (Ta layer (24 μm long and 1 μm wide)) geometry was engineered targeting a small DC current through the Ta line (I_{Ta}) should stimulate a magnetization dynamic effects caused by the SHE. Subsequent of nanofabrication, the nanopillars were measured in an automated 4-point geometry for statistical measurement. The devices were then measured in high-frequency setup (3-terminal device geometry) for pure spin Hall nano-oscillator measurement. Fig. 1(a) shows the measured TMR (%) distribution as a function of $R{\times}A$ in the final devices. The $R{\times}A$ ranging from 20 Ωμm^2 to 100 Ωμm^2, the change of TMR (%) is relatively small (160 % to 200 %) and exponentially decreases as the $R{\times}A$ decreases below 20 Ωμm^2. The exponential decrease in TMR (%) in low $R{\times}A$ region can be explained by the barrier imperfection (pin holes) due to thin MgO barrier. The 10% devices TMR (%) found to be below 40%, this is due to the incomplete planarization process of the sample. However, the TMR ratio of 90% devices was TMR (%) of above 80% clearly indicates that the nanofabrication process was successful. The Fig. 1(b) represents four TC for $R{\times}A$ values of 55, 11, 5 and 1.8 Ωμm^2 of nanopillar size: 200 nm. The plotted curves clearly show that for a high R×A value (55 μm^2) the characteristic carve (TC) is in the centre with high TMR ratio of 195% while decreasing the R×A values causes a certain decrease in TMR (%) and there are significantly shifted towards negative field values, which indicates ferromagnetic coupling (H_F) between the free and reference layer of the multilayer stack[5]. This shift in H_F in low $R{\times}A$ can be a result from either lateral magnetic flux arising from the synthetic antiferromagnet (SAF) that leads to stray fields and couple with the free layer or Néel coupling induced by the roughness of the MgO/CoFeB interface. In contrast, The H_F decreases with higher $R{\times}A$ as the thickness of the barrier increases and is due to reduced Néel coupling in the thicker barriers. To get the deeper insight role of the H_F dependence as a function of $R{\times}A$ values, for two nanopillar diameter 100 nm and 200 nm are plotted as shown in Fig. 1(c). Where 200 nm diameter nanopillars show the transition from positive to negative H_F as the $R{\times}A$ decreases. While for the 100 nm nanopillars, H_F dependence is not quite visible except the low $R{\times}A$ region. The reason behind this behavior is not completely understood. Although the possible explanation would be that the roughness on the nanopillars edges contributed to having multi-domain behavior which leads to this behavior. After the statistical and magnetic analysis of the devices, a set of 100 nm nanopillar diameter with different $R{\times}A$ was measured in a high-frequency measurement setup. The magnetic field H_{app} = -150 Oe is applied to set the MTJ nanopillar in the anti-parallel state while keeping the tunneling current ($I^{tunneling}$) at a low fixed bias of -50 μA during the measurement to transduce the magnetic oscillations. The power spectral density (PSD) measurements were done as a function of the spin Hall current ($I^{spin\ Hall}$) with an alternative sign of ± 5 mA in the step of 0.5 mA. The fact that only one polarity $I^{spin\ Hall}$ of was shown oscillations excludes the possibility of having thermal STT on the device. Fig. 2 (a) shows the $P_{matched}$ and TMR (%) distribution as a function of $R{\times}A$ (each dots and square represents a single device). All the $P_{matched}$ values were acquired from the highest (negative) values of $I^{spin\ Hall}$. From the acquired results, it can be confirmed that the increasing the thickness of the MgO barrier (increasing $R{\times}A$) leads to increases the TMR (%) and in turn increases the $P_{matched}$ of the device. To quantify the obtained results, $P_{matched}$ and f were extracted and plotted as a function of spin Hall current density ($J^{spin\ Hall}$) as shown in Fig. 2(b-c) for a particular device. The total $P_{matched}$ of 12 nW is obtained. The observed f indicates Red-shift behavior as increases which is a signature sign of steady state oscillations.

Recent advances in the spintronic design and fabrication techniques have led to the development of spin torque diodes having a *perpendicular magnetic anisotropy* (STD-PMA) in their free layer. Such STD-PMAs can act as energy harvesters of ambient microwave radiation [1], and when driven with a dc bias current, can operate as microwave generators [2]. The analytical formalism [3] has shown that STD-PMAs have a number of interesting properties. In particular: (i) in the presence of an external microwave current they can produce a rectified dc voltage that is linearly proportional to the external microwave frequency, and independent of the input power; (ii) the STD-PMA can perform a signal rectification without an independent power supply, drawing power entirely from the input signal; (iii) in contrast with the traditional spin torque diodes, the STD-PMA do not require an external bias magnetic field, and therefore can be easily integrated with CMOS and other microelectronic systems; (iv) the power threshold of operation of STD-PMA is rather low (several nanowatts), and thus, they can be used in applications where non-spintronic (e.g. Schottky-diode-based) devices fail; (v) above a particular threshold frequency, the STD-PMA does not produce a dc voltage, thus acting as a natural lowpass filter. Here, we propose a novel application for an STD-PMA: this device can perform *passive demodulation* for low-power frequency-modulated (FM) signals. To demonstrate this effect we performed a numerical simulation for an STD-PMA under the action of an external FM signal. The magnetization dynamics of the STD-PMA free layer, which performs the signal demodulation, was modeled using the Landau-Lifshift-Gilbert-Slonczewski equation in a macrospin approximation. We chose the following typical parameters of the system. We used a 1.65 nm-thick circular free layer having a radius of 50 nm, and made of $Co_{20}Fe_{60}B_{20}$. With this configuration, the effective field of the 1st order PMA was 1162 mT, and the field of the 2nd order PMA was 63 mT. The Gilbert damping parameter was 0.02, the spin-polarization efficiency was chosen to be 0.6, and the pinned layer of the STD-PMA was assumed to have the in-plane magnetization. With these parameters, the static magnetization of the free layer had an equilibrium out-of-plane angle of 45 degrees, a resistance of ≈ 800 Ω, and a tunneling magneto-resistance (TMR) of 112.5%. The two figures below demonstrate the numerically modeled STD-PMA performing both digital and analog FM demodulation. Fig. 1 shows the passive demodulation of a signal encoded with frequency shift keying (FSK). A short digital data sequence with a data rate of 2.5 MB is shown in Fig. 1(a), with voltages varying between a high and low state, and Fig. 1(b) shows this data encoded in the frequency of a signal, where f_{in} = 40 MHz is representing the "low" state and f_{in} = 60 MHz is representing the "high" state. The FSK signal has two powers, starting initially at 14 nW (-48dBm), increasing to 25 nW (-45 dBm), then again decreasing to 14 nW. When the FSK signal is incident on the simulated STD-PMA, it produces a dc voltage as shown in Fig 1(c). For the "low" state, the STD-PMA produces V_{out} = 400 μV, and in the "high" state the STD-PMA produces V_{out} = 600 μV. Note, that the voltage V_{out} is only dependent on the input frequency, and is independent of the input power. It is also important to emphasize, that despite the low power levels of this signal, the STD-PMA is powered entirely by the external signal, and that the magnetic anisotropy allows its operation in the absence of a bias magnetic field. The FM demodulation of an analog signal using an STD-PMA is demonstrated in Fig. 2. An analog signal with frequencies scanning a 5 MHz bandwidth (Fig. 2(a)) is FM modulated by a 50 MHz carrier signal. The power spectral density (PSD) of the signal after a single-sideband FM modulation is shown in Fig. 2(b), with a bandwidth in the 50-60 MHz frequency range. The curve presented in Fig. 2(c) shows that the STD-PMA output dc voltage faithfully reproduces the shape of the input analog signal. In summary, a spin torque diode with perpendicular magnetic anisotropy can act as a reliable FM demodulator that does not require any power and/or any bias magnetic field. The basis of its operation is the linear relationship between the input frequency and the STD dc voltage output. Our numerical simulation has shown that an STD-PMA can demodulate both a digital signal encoded by FSK, and an analog signal with a single-sideband FM modulation. We believe, that STD-PMAs will be useful in power-critical applications, which has growing relevance for autonomous devices and internet of things (IOT) applications.

Spin-orbit coupling effects in materials with broken inversion symmetry are responsible for peculiar spin textures. Moreover, ferroelectrics could enable the non-volatile control of the spin degree of freedom through the electrical switching of the spin texture, achievable by acting on the spontaneous polarization [1]. Such functionality holds potential for technological applications exploiting spin effects controlled by voltage pulses. Within this framework, Germanium Telluride may represent a ground-breaking multifunctional material belonging to FErroelectric Rashba SemiConductors [1]. Its *ferroelectricity* provides the non-volatile state variable able to generate and drive a giant *bulk Rashba-type spin-splitting* of the electronic bands, while its *semiconductivity* and CMOS-compatibility allow for the realization of spin-based transistors. In this paper we present the idea of using GeTe has a switchable and tunable source of pure spin currents. Indeed, in a Rashba system, a charge current can generate a perpendicular pure spin current by intrinsic spin Hall effect (SHE) [2]. The ferroelectric control of the Rashba effect would then allow to tune the generation of the spin currents by intrinsic SHE. The ferroelectric control of the spin texture in GeTe has been experimentally proved by combined use of Piezoresponse Force Microscopy and Spin and Angular Resolved Photoemission Spectroscopy [3, 4]. Separately, spin-to-charge conversion was previously investigated by spin-pumping experiments on GeTe/Fe bilayers, providing the first evidence of sizable interconversion from spin to charge currents [5]. Here we investigate the efficiency of the *charge-to-spin interconversion process* due to spin Hall effect. To this aim, we used the concept of unidirectional spin Hall magnetoresistance (USMR), introduced by Gambardella *et al.* [6] and sketched in Figure 1a for Fe/GeTe heterostructures. A charge current flowing in the plane of a non-magnetic (NM) thin film generates a spin current perpendicular to the film itself. A ferromagnetic layer (FM) grown on top serves as spin "detector". Spin accumulation and spin scattering at the NM/FM interface will depend on the relative orientation between magnetization and spins direction, resulting in a variation of the conductivity upon magnetization reversal. As shown in Ref. [6], the second harmonic resistance ($R_{2\omega}$) accounts for current-induced resistive terms, including both SHE and "spurious" thermoelectric effects [7]. Preliminary experiments on Fe/GeTe bilayers reveal the presence of sizable spin Hall effect in GeTe. We detected a non-negligible variation of the longitudinal resistance upon inversion of the in-plane iron magnetization at relatively low temperatures (120 K). The relative variation of the longitudinal resistance increases linearly with the current density J (Figure 1b), as expected for spin Hall effect in GeTe and ruling out the role of "spurious" thermal effects [7]. Moreover, the slope of the effect versus J is reduced when the GeTe layer thickness increases from 5 to 15 nm, pointing out the interfacial origin of the resistance variation. A detailed investigation of USMR in GeTe versus temperature and ferroelectric polarization is ongoing to eventually demonstrate the ferroelectric control of spin transport with the non-volatile inversion of spin Hall effect in ferroelectric Rashba semiconductors. The research looks towards the realization of non-volatile, electrically-controlled sources of pure spin currents. This element would open unprecedented perspectives for spintronic applications, such as the electric control of magnetization in nanostructures, the realization of spin-based neuromorphic devices and reconfigurable logic elements, as well as the excitation of spin waves in magnonic devices.

BF-01. Anisotropy and coercivity analysis in tetragonal (Cu,Co)Fe_2O_4 particles.

H. Latiff[1,2], T. Devillers[1], H. Yanagihara[2], N. Dempsey[1] and D. Givord[1]
1. Université Grenoble Alpes, CNRS, Grenoble INP, Institut Néel, 38000 Grenoble, France; 2. Institute of Applied Physics, University of Tsukuba, 305-8573 Tsukuba, Japan

$CoFe_2O_4$ exhibits large magnetoelastic effects and a large magnetic anisotropy (MA) can be induced in the presence of strain, as demonstrated in epitaxially strained thin films [1-2]. The existence of MA in nanoparticle materials is desirable for many applications. The introduction of lattice distortion in nanomaterials was demonstrated by exploiting the Jahn-Teller (JT) effect of Cu^{2+} ions in (Cu,Co)Fe_2O_4 [3]. The considered samples are made of micron-sized particles, but the quadratic deformation due to the local strain occurs at the nanoscale. From the electronic configuration viewpoint, the high magnetic anisotropy is triggered by the activation of the spin-orbit interaction of the Co^{2+} ions on the B-site, in the presence of the Cu^{2+} with JT distortion. For the quantitative analysis of magnetic anisotropy in assemblies of (Cu,Co)Fe_2O_4 nanograins having various Co content, we have developed a software to model the applied field B_{app} dependence of the magnetization M. Coherent rotation of M is assumed in the model, and the two main physical parameters used to fit experimental data are the spontaneous magnetization M_s and the 2nd order anisotropy constant, K. By measuring $M(B_{app})$ for different applied field orientations, it was found that the grain orientation is fully isotropic. Under such circumstances, one expects that the ratio of the remanent magnetization M_r to M_s is equal to 0.5. In contrast, M_r/M_s>0.5 was systematically found and this suggests that some positive exchange interactions exist between individual nanograins. Adding a phenomenological exchange field between nanograins permitted excellent description of the experimental data (see Fig. 1). At 10 K, an anisotropy field $H_A \approx$ 2.8 MA/m is derived from M_s= 0.145×10^6 A/m and K= 0.25×10^6 J/m^3. While M_s is almost temperature independent, K shows a tendency to decrease with increasing temperature. This agrees with expected behavior. At 300K, $H_A \approx$ 1.9 MA/m, in fair agreement with the value estimated from rotational hysteresis measurements, where $H_A \approx$ 1.6 MA/m. From 10K to 300K, the exchange field decreases from 1.2 MA/m to 1.1 MA/m. Assuming that the exchange coupling is restricted to the first atomic layer of each nanograin, at low T, the exchange field value is renormalized to 40 MA/m, this is still 1-2 orders of magnitude less than the exchange field in the bulk of the grains, which is of the order of 10^3 MA/m. One of the main physical properties which is expected to be associated with magnetocrystalline anisotropy is coercivity, H_c. Tetragonally distorted $Cu_{1-x}Co_xFe_2O_4$ particles with x=0.1 showed an enhanced H_c value of up to 220 mT compared to non-distorted particles with x=0.2, for which H_c= 90 mT. It is well known that magnetic coercivity is not directly related to magnetic anisotropy but depends also in some poorly known manner on the sample's nanostructure. Under such circumstances, it is usual to relate the coercive field to the anisotropy field and demagnetizing field, assumed proportional to the spontaneous magnetization, $H_c = \alpha H_A - N_{eff} M_s$, within the so-called micromagnetic model [4], or to the domain wall energy, g, activation volume, v_a, and demagnetizing field (as above), $H_c = \alpha\ \gamma/(\mu_0 v_a^{1/3} M_s) - N_{eff} M_s$, within the so-called global model [5] (more rigorously, is replaced by, the coercive field in the absence of thermal activation effects, see below). In these expressions, α and N_{eff} are essentially phenomenological parameters. For the analysis, H_A was taken from the $M(B_{app})$ analysis described above. The domain wall energy may be expressed as $\gamma = 4\sqrt{AK}$, where A is the exchange constant related to the Curie temperature, taken as 6.57×10^{-12} J/m at low temperature and proportional to M_s^2. The activation volume, v_a, is related to the experimental viscosity coefficient S_v through $v_a = \mu_0 k_B T / S_v M_s$, where $S_v = S/\chi_{tot} - \chi_{rev}$, S being the logarithm dependence of the magnetization, χ_{tot} the total susceptibility and χ_{rev}, the reversible susceptibility [5]. The temperature dependence of the activation volume $v_a(T)$ derived from the magnetic viscosity measurements is shown in Fig. 2 (a) for two representative samples having the lowest (x=0.2) and highest (x=0.1) coercive field values considered in the present study; v_a increases from a value of around 2000 nm^3 at 10K for the two samples, up to around 175000 nm^3 for the low coercivity (almost cubic) sample and 5400 nm^3 for the strained tetragonal sample, at 300K. H_c was corrected for thermal activation to get $H_0 = H_c + 25S_v$ and H_0/M_s was plotted versus $\gamma/v_a^{1/3}\mu_0 M_s^2$ to extract α and N (Fig. 2 (b)). The dashed lines represent the linear fits for T=100–300K, giving the values for N and α: (α= 0.39; N= -0.24) for the tetragonal high H_c sample and (α= 0.29; N= -0.01) for the cubic low H_c sample. The parameter α has similar values in both samples, and the differences in finite temperature coercive field values between both samples is essentially due to the difference in the size of the activation volume. A simple physical argument explains this behavior. The activation volume is related to the cube of the domain wall thickness and it is obviously larger in the low anisotropy unstrained sample than in the tetragonally distorted one.

BF-02. The effect of surface spin disorder on magnetic properties of Fe/Fe_xO_y core-shell nanoparticles.

M. Lostun[1], D. Herea[1], M. Grigoras[1], G. Ababei[1], I. Ghemes[1] and *N. Lupu*[1]
1. National Institute of Research and Development for Technical Physics, Iasi, Romania

Fe-oxide nanoparticles are of considerable interest nowadays because of their unique characteristics, such as superparamagnetism, high saturation fields, and extra anisotropy contributions, which arise from the effects of finite size and large surface area. Usually they are obtained by chemical methods, but more recently some groups reported on their successful preparation by wet high-energy ball-milling. It is also well known that as the size of the nanoparticles decreases, surface effects would become more significant due to the increasing surface relative to their volume. We report here our recent results on the effect of ligands on the induced surface anisotropies and magnetic properties of Fe/Fe_2O_3 and Fe/Fe_3O_4 core-shell nanoparticles functionalized with 3-aminopropyltriethoxysilane (APTS) for biomedical applications (image contrast agents in magnetic resonance imaging (MRI) and magnetic carriers for drug delivery). Core-shell nanoparticles have been prepared by high-energy ball milling. In the presence of air or Ar, the Fe core was progressively covered with a Fe_2O_3 shell, and the obtained Fe/Fe_2O_3 nanoparticles have diameters of 200-300 nm after 68 h of milling. Fe/Fe_3O_4 nanoparticles of 20-60 nm were obtained by wet milling of Fe microparticles for 42 h. For milling times larger than 42 h the whole amount of Fe is transformed into Fe_3O_4, and the resulting magnetite nanoparticles have diameters ranging from 15 to 50 nm (Fig. 1). The magnetic properties of Fe/Fe_xO_y core-shell nanoparticles can be tailored from ferromagnetic Fe/Fe_2O_3 to weak ferromagnetic Fe/Fe_3O_4 and superparamagnetic Fe_3O_4 (Fig. 2). By choosing the appropriate milling conditions and starting materials is possible to tune the magnetic properties and make the Fe/FeO_x core-shell NPs suitable for different biomedical applications. The main advantage of such core-shell nanoparticles in biomedical applications, compared with simple Fe-oxides nanoparticles, resides in their easier use and manipulation for specific applications. To understand the surface spin disorder and its influence on the magnetic properties of Fe/Fe-oxide core-shell nanoparticles, their surface was systematically modified with APTS, by increasing progressively the concentration of the ligand. APTS was chosen as ligand because the bonding with the magnetic NPs is made through Si-O, NH_2 remaining free for bonding with different types of biomolecules. Low temperature magnetization measurements and ZFC/FC curves indicate a strong influence of the ligand on the magnetic properties. The change of the magnetic properties of nanoparticles also correlates with the specific coordinating functional group bound on the nanoparticles surface. The correlation suggests the decrease in spin-orbital coupling and surface anisotropy of magnetic nanoparticles due to the surface coordination. Because of the high saturation magnetization, these Fe/FeO_x core-shell NPs have a higher Specific Absorption Rate (SAR), making them suitable for hyperthermia applications. They can be also visualized by Magnetic Resonance Imaging because of the Fe-oxides shell. *This work was financially suported by the 3MAP NUCLEU Programme (2018).*

I. INTRODUCTION Ever increasing technological necessities have enthused researchers to discover potential compounds (bulk/nano forms). Towards this, multiferroic materials have attracted various applications in the interdisciplinary fields of biomedical engineering and electronics [1-2]. These are useful in a wide range of applications starting with thin film devices such as magnetoelectric (ME) actuators, sensors, *etc.*, to the memory devices as well as carrier materials for drug delivery. Nanoparticles with core-shell structure have been reported to enhance the magnetoelectric properties depending on their size and nature of compounds chosen for core and shell. $NiFe_2O_4$ (NFO) core @ $BaTiO_3$ (BTO) shell structure is reported to have oxygen vacancies in BTO which enhance the magnetic permeability of the composites, one of the essential requirements for large magnetoelectric (ME) coupling [2]. The ME effect is a product property and it is mainly a strain mediated mechanism. When an electric field is applied, the piezoelectric phase changes its volume according to the piezoelectric coefficient, which exerts a force against the ferromagnetic counterpart. The latter being magnetostrictive, magnetization develops as a result of the mechanical strain. A similar effect is anticipated in case of NFO@BTO nanocomposite system with a better ME effect due to high surface to volume ratio. This system is then compared with NFO@$Ba_{0.66}Sr_{0.33}TiO_3$ (BSTO) system, with a view to exploring the possibility of a higher ME effect. The studies on BSTO materials have shown high permittivity, low dielectric loss, and high tunability coefficient [3]. Other than these, the foremost advantage is the fact that the BSTO family is lead-free and hence, compliance with the present requirements for environmentally benign materials can be met. The magnetic properties of the NFO@BTO nanocomposite system have been studied and the effect of Sr^{2+} doping on the magnetic properties is presented in this paper. II. EXPERIMENTAL DETAILS Synthesis of NFO@BTO core-shell structure was carried out using a two-step process. In the first step, NFO was prepared through the sol-gel process in which, $Ni(NO_3)_2.4H_2O$ and $Fe(NO_3)_3.9H_2O$ precursors were used as the starting materials in the ratio of 1:2. A 0.05M solution was prepared using ethanol as solvent. Subsequently, in the second step, the NFO particles were coated with the BTO shell. In order to prepare the BTO shell, 5 millimoles of $BaCO_3$ solution were mixed with 5 millimoles of Titanium isopropoxide. 7 millimoles of NFO solution were then mixed with the above BTO solution and the mixture was sonicated for 2 h and then was kept at 60°C in a magnetic stirrer for 12 h followed by a heat treatment at 750°C for 5 h. The composite system of NFO@BTO was confirmed by powder X-ray diffraction (XRD) studies. The core-shell structure was confirmed by Transmission electron microscopy (TEM). A similar procedure was carried out for the synthesis of NFO@BSTO nanocomposite system. The structure and morphology of the NFO@BSTO nanocomposites were investigated by XRD, TEM and magnetization measurements employing a vibrating sample magnetometer (VSM). III. RESULTS AND DISCUSSIONS From the powder XRD patterns, BTO phase was found to have formed in perovskite structure with the space group P4mm. The (001), (011), (111), (002), (012), (112), (022), (003) and (013) peaks were observed. The formation of NFO phase in spinel structure with Fd-3m is confirmed with (022), (311), (400) and (440) peaks. The crystallite size of NFO@BTO and NFO@BSTO nanocomposite is around 13-14 nm. There is clear peak shift of 0.3°-1.6° to higher angle on doping Sr^{2+} in A-site of ABO_3 phase indicating the reduction in lattice parameter. TEM studies revealed the core-shell structure with an average particle size of about 15 nm. The magnetization of as prepared NFO nanoparticles is found not to saturate and is 37 emu/g at 40 kOe. The existence of magnetic dead layer at the surface can cause a reduction in magnetization compared to crystalline particles. On addition of a non–magnetic shell of $BaTiO_3$, the magnetization has decreased further to 14.8 emu/g; can be attributed to the isolated $NiFe_2O_4$ particles with shell coated around them. Further, upon substitution of one-third of Ba^{2+} by Sr^{2+}, it is observed that the magnetization has increased to 18 emu/g. Substitution of Sr^{2+} doping leads to the development of coarser grains, as confirmed from the sharper XRD peaks. This leads to a reduction of the surface to volume ratio, taking the particle towards crystallinity that can cause the magnetization to increase. IV. CONCLUSION The XRD and TEM studies confirmed the formation of NFO@BTO core-shell nanoparticles. The magnetization of core-shell nanoparticles with Sr^{2+} substituted partially for Ba^{2+} increased.

Track-etched polymer membranes with crossed nanochannels have been revealed suitable as template for the synthesis of 3D interconnected magnetic nanofiber networks that present interesting magnetic and magneto-transport properties [1-4]. Successive track-etch process allows the control of the template geometry, including the angles between the nanochannels and the template normal, the volumetric porosity and the mean diameter that can be tuned between few tens of nm to few hundreds of nm. The host porous template is later filled from a previously sputtered metallic cathode by an electrodeposition process allowing the control of the material composition and nano-structuration. 3D networks of interconnected nanowires (Fig. 1a.), core-shell nanocables, nanotubes (Fig. 1b.) and multilayered nanowires have been successfully fabricated. As shown in the inset of Fig. 1a., the interconnected structure provides a reasonable mechanical stability to the 3D nano-architectures that are self-supported after dissolution of the porous template. In addition, the local removing of the cathode gives rise to a two-probe design suitable for electric measurements, as shown in Fig. 1c. Indeed, magneto-transport measurements can be easily performed on such interconnected nanofiber network films, with the current flow restricted along the nanofiber segments. The magnetic and magneto-transport properties of crossed homogeneous nanowire (CNW), crossed nanotube (CNT), and crossed multilayered nanowire networks have been investigated. A close relation between the CNWs magnetic properties and their topological and structural properties have been demonstrated in Co CNW networks, where the tuning of the crystalline structure using the electrolyte pH allows an accurate control of the magnetic anisotropy [2,5]. Similarly, it has been found that the magnetic anisotropy of NiCo CNW networks depends on the alloying composition, in agreement with previous results obtained on bulk materials and films [3,4,6,7]. An analytical model inherent to the topology of 3D nanowire networks has been validated, allowing to extract the AMR ratio from the measured magnetoresistance curves along the in-plane (IP) and out-of- plane (OOP) directions of the CNW network film [2-4]. The AMR ratio variation with respect to the Ni content for the NiCo CNWs has been found to be coherent with previous results obtained on bulk materials and films, exhibiting large ratio for about 75% atomic of Ni [3,8]. Ni CNT have been obtained using the electrochemical dealloying method and the modification of the magnetic and magneto-transport properties due to the inner hollow cores of the NTs have been investigated. By variating the reduction potential in the range of -0.8V to -1.1V, different NT wall thicknesses have been achieved, in good agreement with previous works [9-11]. The magnetic properties of the CNT network, such as the effective anisotropy field, the remanence and the coercive field, have been found to be dependent on the NT wall thickness, as depicted in Fig. 2a. Magneto-transport measurements revealed a modification of the magnetization reversal mechanisms for the CNT networks, contrasting with the CNW networks, as depicted in Fig. 2b. For the CNT network, a large decrease of the resistance is observed at the coercive field. It can be attributed to a magnetization reversal dominated by the curling (vortex) reversal mode, where magnetic moments rotate progressively via propagation of a large number of vortex domain walls. Conversely, the magneto-transport curve of the CNW network displays a decrease of the resistance that doesn’t correspond to the resistance at coercivity. Instead, it appears for positive field values, starting from the saturated positive state, contrasting with previous work on arrays of parallel NWs [12]. This effect can be ascribed to the interconnected NW architecture and the presence of domain walls that are formed at the magnetic junctions once the external field is reduced. Finally, 3D interconnected NiCo/Cu multilayered NWs network films have been successfully fabricated, displaying large GMR responses (up to 85.8% at 10K) measured with the current flowing perpendicularly to the plane of the layers in the nanowire segments. 3D nanofiber network architectures offer a wide range of controllable parameters that can be used to tune the magnetic and magneto-transport properties of mechanically stable 3D interconnected nanofiber networks that have potential applications in various fields.

BF-05. Information Transfer and Trapping in a 3D Nano-printed Domain-wall Conduit. ***(Invited)***

D. Sanz-Hernández[1*], R.F. Hamans[2], J. Liao[1], A. Welbourne[1], R. Lavrijsen[2] and A. Fernández-Pacheco[1]
1. Cavendish Laboratory, University of Cambridge, Cambridge, United Kingdom; 2. Department of Applied Physics, Eindhoven University of Technology, Eindhoven, Netherlands

3D magnetic nanowire devices acting as domain wall conduits have long attracted attention. Devices in which domain walls move along a conduit have shown great potential for computing, biological and sensing applications, one example being the racetrack memory,[3] which could have a revolutionary impact in future computing devices. Until now, however, moving from 2D into 3D geometries has not been possible due to the limitations of traditional lithography and characterization techniques. In order to create and measure 3D nanowire devices, a leap in fabrication and characterization tools is required.[1] Two major experimental breakthroughs in nanofabrication and sensing of magnetic nanostructures are presented in this work: A first demonstration of a fabrication platform which can create functional high-quality 3D magnetic devices, and the development of a magneto-optical characterization method to probe individual 3D structures independently from the surrounding substrate.[2] These two breakthroughs will be presented by demonstrating how they can be used to produce and probe a functional 3D domain wall conduit. This device can extract magnetic domain walls from a 2D substrate and transport them vertically. In addition, we will provide a quantitative characterization of domain wall trapping mechanisms in such a 3D system, as well as showing how information flow can be controlled using 3D magnetic field sequences. Fabrication consists in a combination of state of the art non-magnetic 3D nanoprinting and traditional thermal evaporation of a thin film of magnetic material.[2] 3D nanoprinting is performed using Focused Electron Beam Induced Deposition, a technique in which the highly focused electron beam of a Scanning Electron Microscope is used to decompose a gas precursor in a very local and controlled way. By precise tuning of growth conditions, a high-quality interconnect region between the 2D substrate and the 3D interconnect can be achieved, critical for successful domain wall exchange between both. Precise control over conduit inclination over several micrometres with 300nm conduit widths is also demonstrated. Upon thermal evaporation of magnetic material (NiFe, 50nm) the nanoprinted 3D shape is fully transferred from the 3D scaffold onto the thin film. See Figure 1. Detection of individual 3D conduits is performed using a tailored dark-field magneto optical Kerr effect (MOKE) magnetometer.[2] In this instrument a linearly polarized laser is incident onto the conduit and surrounding 2D film. Due to the different inclination of the two systems, two separate reflections of the laser are obtained, a bright reflection corresponding to the large 2D film and a second 'dark-field' reflection corresponding to the 300nm wide conduit. The setup is tailored to detect both reflections, allowing to probe the magnetic state of the 2D film and the 3D conduit in parallel and without any cross-talk. By integrating the dark-field MOKE setup with a set of coils designed to apply magnetic fields in 3D we have been able to induce and detect the injection of domain walls from the 2D film into the 3D conduit. The low coercivity (0.2mT) 2D film is used as a source of domain walls and a systematic study of the fields necessary to inject the domain wall into the conduit has allowed us to identify the main domain wall pinning mechanisms in the system: pinning at the interconnection between the 2D film and the conduit, and pinning along the conduit.[2] In this talk we will describe how quantitative measurements of the pinning fields from 2D magnetic switching maps can be used to selectively trap domain walls either at the interconnect region or inside the 3D conduit. Finally, we will demonstrate how 3D field sequences may be used to further control information transfer in the system. As shown in Figure 2, a rotating field in the plane formed by the conduit and its supporting legs (x-z plane) may be used to periodically inject domain walls into the conduit, whereas a field along the plane of the film but perpendicular to the conduit (H_y) can be used to inhibit the creation an injection of domain walls, acting as a gate to information transfer. The methods presented in this work provide a new and powerful platform for the study of 3D magnetic nanostructures, naturally extensible to advanced materials and geometries. This presentation will therefore be of great interest to researchers and members of industry working in computing and sensing applications.

BF-06. From vanishing interaction to superferromagnetic dimerization: Experimental determination of interaction lengths for embedded Co clusters.

F. Tournus[1], A. Hillion[1], A. Tamion[1], C. Albin[1] and V. Dupuis[1]
1. Institut Lumière Matière, Université Lyon 1 & CNRS, Villeurbanne, France

Magnetic nanoparticles are of great interest in a wide range of disciplines, including magnetic fluids, catalysis, biotechnology/biomedicine, magnetic resonance imaging, data storage, and environmental remediation. Successful applications of such magnetic nanoparticles in the areas listed above are highly dependent on the stability of the particles under a range of different conditions. In particular, these nanomagnets might be used as magnetic media in future high-density magnetic storage devices with ultimate recording bits (i.e. single nanoparticles). Reading and writing of such a system requires to know perfectly its magnetic properties in particular its anisotropy constant. It is then crucial to be able to characterize the magnetic properties of nanoparticles, and to be able to separate the intrinsic behavior from other effects coming from interparticle interactions in an assembly. In this study [6], we present magnetic measurements of Co clusters (around 2.5 nm diameter) embedded in different matrices: carbon and two metallic matrices (Au and Cu). We will first show that by using highly diluted samples prepared by low energy cluster deposition, we can reach a situation where no interactions are detected. The intrinsic magnetic properties of the particles can then be accurately determined thanks to a "global" fitting procedure (see figure 1) relying on the theoretical description of various magnetometry measurements [1-5]: low-temperature(hysteresis) and high-temperature (superparamagnetic) m(H) loops, zero- field cooled (ZFC)/field cooled (FC) susceptibility curves, and isothermal remanent magnetization (IRM) curves. We show how both the magnetic size and magnetic anisotropy energy (MAE) can be impacted by the nature of the matrix. Then, by considering nanoparticle assemblies of increasing concentrations (still remaining in a diluted range, lower than 10% in volume), we discuss the different effects of interactions between particles on the magnetic measurements (see figure 2). The evolution of Δm curves (deduced from remanence curves) is found to be very different from that of susceptibility curves. In order to account for the observed evolution of the measurements, we propose a simple model where magnetic dimers are formed for distances lower than a given interaction length [6]. This super-ferromagnetic correlation, which can be consistently inferred for each matrix, thus modifies the magnetic size distribution which has a drastic effect (in particular on ZFC/FC curves) as soon as particles are close enough from each other. The deduced interaction length (of the order of one nanometer) is found to be larger for metallic matrices and could be ascribed to RKKY interactions between neighboring magnetic nanoparticles.

BF-07. The role of topologically non-trivial structures in magnetization processes of diameter modulated nanowires.

J. Fernandez-Roldan[1], C. Bran[1], R. Perez del Real[1], M. Vázquez[1] and *O. Chubykalo-Fesenko*[1]
1. Instituto de Ciencia de Materiales de Madrid, CSIC, Madrid, Spain

The future of domain-wall logic devices, registers or race-track-memories requires precise control of domain walls dynamics. The domain wall pinning can be achieved by artificial defects such as notches or by modulations in nanowire diameter. Cylindrical nanowires can be grown by electrodeposition inside the nanopores of anodic alumina templates and specifically designed for periodic diameter modulations [1,2] by a precise control of deposition parameters. Here, we consider the domain wall pinning in two-segment FeCo periodically diameter-modulated nanowire with large saturation magnetisation. The straight nanowires of this composition typically demagnetize through vortex domain wall propagation [3]. In addition, previous electron holography imaging at remanence has shown the presence of the vortex states at the ends of the large segments [4]. The measurements by Kerr-magnetometry on individual nanowires [1], when focusing on different spots along the wires, showed different local squared-shape hysteresis cycles with either a single or several jumps. With the aim to understand and to control the demagnetization processes and the pinning nature, we model the magnetization response under parallel applied field in FeCo periodically modulated polycrystalline nanowires varying the minor diameter. Our modelling indicates a complex behavior with a strong dependence on the polycrystalline disorder distribution and an important role of topologically non-trivial magnetization structures. The role of different non-trivial magnetization structures in hysteresis processes such as swirls, hedgehogs, helices have been discussed in the past. The helical magnetization domain wall, for example, has been introduced as possible magnetic configuration in iron whiskers [5]. In straight cylindrical nanowires topological defects in form of vortices nucleate at the nanowire ends due to curling magnetization instabilities [6]. Here we show that in modulated nanowires these structures nucleate at each segment end and as a consequence the whole magnetization process (and the pinning) is characterized by the existence of topologically non-trivial 3D magnetization configurations and their evolution and the applied field. In our model we consider magnetic nanowires modulated periodically in diameter with 5 segments. The largest segments have diameter D= 130 nm and length one micron (typical for the experimental situation), and the narrow segments have a variable diameter 40 nm < d <100 nm and length 300nm. The constriction between the two diameters is 50 nm long where the diameter is linearly varied from the smallest to the largest value. Nanowires are considered to have a granular bcc structure with random distributions. The latter is responsible for different nucleation-propagation sequences in each case due to the random vortex chirality patterns created at the end of each large segment for each particular distribution and different pinning sites. We demonstrate that modulated nanowires with a small diameter difference are characterized by an almost rectangular hysteresis loop but with an increased coercive field in comparison to the straight ones. The magnetization process is characterized by a formation of topologically protected walls formed initially by vortices with opposite chiralities at the end of each large segment. These structures propagate inside the whole nanowire in one field step and have the topology of 3D skyrmions (tubes). When two of these tubes with the opposite chiralities meet, the resulting structure is strongly topologically protected and the coercive field is increased. However, the most interesting case is when the diameter difference in modulations is large. The hysteresis cycle is characterized by an additional magnetization jump, a step corresponding to the depinning field. Here we report the occurrence of a novel pinning type called "corkscrew". As the field increases in the opposite direction, the initial vortices formed at the end of each modulation expand and form skyrmion tubes (with the magnetization core pointing against the field). Unlike the case above where the whole process is dynamical, in this case the tubes form a stable helicoidal structure along the large diameter segments only (see the Figure). The spiral amplitude and the oscilation frequency increases with the increase of the diameter difference and the tube core diameter size decreases. These structures are pinned at the constriction and the tube core size shrinks in order to penetrate into the narrow segments. In conclusion, the presence of topologically non-trivial configurations is inherent for the magnetization reversal processes in magnetic nanowires and defines the pinning nature in nanowires of modulated diameter. The magnetisation processes are characterized by the formation of skyrmion tubes. Unlike typical skyrmions stabilized by the Dzyaloshinkii-Moriya interaction, these "skyrmions" are of Bloch nature, i.e. have a pure dipolar origin and are stabilized by the finite-size effect in nano-objects. The new corkscrew pinning mechanism offers novel perspectives for nanowires engineering for multiple applications.

Magnetic cylindrical nanowires, NW, with constant diameter and multisegmented architecture are currently proposed in diverse nanotechnology applications as magnetoresistive reading heads, barcode units for security systems, specific tactile sensors, magnetoplasmonics, MRI markers or biochemical functionalization of different segments [1]. Interactions between adjacent segments have been recently proposed for engineering transport of information in logic devices and as 3D nanooscillators [2]. Such applications rely on a deep understanding and control on the magnetic response of individual NWs, particularly on the specific domain structure and remagnetization process in each magnetic segment. The magnetization reversal in uniform cylindrical NWs has been modeled to proceed by the nucleation of vortex-like structures at the ends of NWs followed by the propagation of a domain wall, DW, along the whole NW at given switching field [3]. In NWs with longitudinal uniaxial anisotropy (mostly shape anisotropy) the reversal requires the propagation of a Bloch-point like DW as a consequence of the singularity of the NW axis. For NWs with transverse anisotropy (overcoming crystalline anisotropy) the reversal also implies rotational processes. The reversal modes are also influenced by the NW diameter. The multisegmentation finally aims at the engineered periodical modulation of the magnetic anisotropy or the magnetic character of segments in order to control the magnetization reversal process. Cylindrical NWs were electrochemically grown under carefully controlled parameters inside self-assembled nanopores of anodic alumina membranes prepared by hard anodization. Afterwards, they were chemically released from the templates in order to investigate the magnetism of isolated nanowires. Magnetic characterization, at remanence and under longitudinal applied magnetic field, of those individual NWs was performed by magnetic force microscopy imaging, MFM, by magnetooptic Kerr effect, MOKE, and by photoemission electron microscopy, PEEM, combined with X-ray magnetic circular dichroism, XMCD. All these techniques supply magnetic information of the surface, while the latter one, XMCD-PEEM, provides in addition images that allow for the interpretation of the internal configuration of magnetic moments. The imaging of the magnetic domain configuration has been achieved at remanence and followed under constant applied field of variable amplitude [4]. Micromagnetic simulations were also carried out in order to further interpret and model the mainly vortex-promoted remagnetization process. Most recent results obtained in our laboratories will be overviewed for two families of multisegmented NWs: I) ferromagnetic/ferromagnetic, FM/FM (i.e., CoNi/Ni), and II) ferromagnetic/non-magnetic, FM/NM (i.e., CoFe/Cu). Importantly, the magnetic behavior finally depends on the crystalline nature of FM segments. Multisegmented individual cylindrical NWs with constant diameter (in the range of 100 to 150 nm) and total length up to 20 μm have been considered. The length of magnetic segments was up to 2 μm and that of non-magnetic segments was fixed to 20 nm. The analysis is focused on CoFe and CoNi FM segments exhibiting *bcc* or *fcc* cubic symmetry or *hcp* hexagonal structure depending on the relative Co content with significant magnetocrystalline anisotropy. That crystalline anisotropy can eventually enhance or balance the longitudinal shape anisotropy to result in segments from axial to transverse magnetization easy axis. After appropriate engineering of NWs (i.e., selection of segments composition and length), the following conclusions are outlined: Tipe I FM/FM NWs: a) The periodical modulation in magnetic anisotropy is observed (as an example, see the Figure), and b) Transverse or Axial domains are experimentally imaged together with Vortex domains (XMCD-PEEM), or Axial domains with Multivortex configurations (MFM) in CoNi/Ni NWs, as also confirmed by micromagnetic simulations. Tipe II FM/NM NWs: a) Vortex structures, with the same or opposite chirality, form at the ends of magnetic segments to determine the magnetic configuration and the magnetic switching of local segments which propagates under intersegments magnetostatic interactions, and b) Stepped and unidirectional propagation of the reversal process in CoFe/Cu NWs is confirmed (XMCD-PEEM, MFM, MOKE) by suitable geometric tailoring of magnetic segments. Micromagnetic modeling indicated that remagnetization takes place by complex vortex processes. Finally, the design and synthesis of nanowires with engineered multisegments represents a significant step forward towards advanced near-unidimensional magnetic nanostructures. They are intended for the controlled propagation of the magnetization reversal along the nanowires, which together with the role played by intersegments magnetostatic interactions, is expected to be of significant relevance in advanced media for transport of information.

Memory and logic concepts have been proposed, based on domain wall (DW) motion along one-dimensional conduits. In many designs it is important to be able to locate DWs at a specific location. In this context, the interaction of domain walls with protrusions and notches in nanostrips has been studied rather extensively(see eg [1,2]). Although the general trend is an increase of the pinning strength with the magnitude of the modulation, the physics sensitively depends on the nature of the wall: vortex or transverse, also with the circulation degree of freedom for the latter. Cylindrical nanowires is an alternative to flat strips. First, they provide a different physics due to the high magnetostatic energy and the occurence of novel walls such as the Bloch-point wall[3,4]. Also, due to the high magnetostatic energy it is expected that the type of DW matters less, and more general results may be derived. Second, from the synthesis point of view they would be the natural geometry for implementing conduits in 3D, such as for the original race-track proposal. On the side of theory there exists a handful of reports(see eg [5] as a pioneering work), however these concern specific geometries and do not provide a quantitative global picture. Experimental results are even more scarce, and again do not provide a quantitative picture[6]. We first report a theoretical study of DWs under the influence of a magnetic field within a cylindrical nanowire with diameter modulations. More specifically, we focus on a simple situation to highlight the physics at play: two long straight segments with different diameters, smoothly connected together in a fashion mimicking experimental cases (FIG1). This should provide a solid ground to understand more complex geometries. For both sakes of exchange and dipolar energy, it is expected that the DW tends to remain in the section with lower diameter, giving rise to a propagation field with finite value. We combine an analytical model and micromagnetic simulations performed in a finite-element scheme to smoothly describe curved geometries. The former is based on approximations to derive simple scaling laws, providing a global picture of the trends in terms of geometry and material parameter. Both exchange and magnetostatic energy are considered. We derive the very simple conclusion, that the DW depinning field is close to twice the magnetization value multiplied by the modulation slope (radius versus position)*. The latter is used to demonstrate the robustness of the scaling law, its range of application, and provide accurate figures. The two approaches agree particularly well in the case of gently sloping modulations (see eg FIG.2). These results validate the analytical scaling law, which may be useful to guide nanowire design and when analyzing experiments. Our approach is quite general and is being extended further to study the effect of other driving forces such as a spin-polarized current. * The exact scaling law reads: $H_c=[(9/20) * M_s(R_2-R_1)/\delta] * [1+(10/27)*(\Delta_d)^2\pi^2 /(R_1+R_2)^2]$. M_s is the material magnetization, Δ_d is the dipolar exchange length, and δ is one fourth of the modulation full width. This law is illustrated on FIG1.

The nanostructures based on templates fabrication have fascinated and provided facilities to researcher who work in material science to fabricate nanostructures such as nanotubes, nanoparticles and nanowires show optical, electrical and magnetic properties different from their bulk counterpart. Applications of ferromagnetic nanowires are in optical medium, electronic equipment and dense magnetic memories, [1,2]. Ferromagnetic nanowires arrays have applications in nanosensors [3], magnetic nanodevices [4] recording media[5]and micro circulator of magnetic nanowires is attracting a lot of attention[6]. In this method, magnetic nanowire arrays are produced by template-assisted electrodeposition into self-assembled anodic alumina pores, in which geometrical parameters as pore diameters, length, and center to center spacing between the pores can be easily controlled by varying the anodic electrochemical parameters. Highly arranged nanoporous alumina templates with pore diameters reaching from about 15 to 200nm and lengths from 100nm up to 50μm can thus be attained. Over the years, ferromagnetic non-magnetic multilayer nanowire arrays and CoAg, FeAg, CoCu, CoPd, CoPt binary systems, have been recorded in the literature [7] due to their motivating magneto transport and magnetic properties. From the vast variety of magnetic systems, FeCo nanowires show the necessary capability to be employed in generation of permanent magnets. FeCo magnetic alloy nanowires can be tuned by changing the alloy composition by adding further elements [8-10] or suitable thermal treatment [11]. In particular, high values of remanence and coercivity will be expected when the magnetic feild is applied parallel to the nanowires and will be assigned mainly to the magnetic shape anisotropy [12,13].Fabrication of FeCoCu nanowires into AAO templates by AC electrodeposition is very difficult due to mismatch of reduction potential and difference of ionic radii. It is the need of the hour to tune magnetic properties of FeCo alloy nanowires to discuss magnetization reversal process to abe employed in high density recording media and magnetic race track memory. Here in this work we have synthesized the $(FeCo)_{1-x}Cu_x$ (X=0.1-0.5) nanowire arrays by AC electrodeposition in anodic aluminum oxide templates (AAO). We also studied the effect of Cu substitution on structural, dielectric and magnetic properties of the nanowires. Surface properties, and particle size distribution was obtained by using a scanning electron microscope. The length and diameter of prepared nanowires is 18μm and 58nm respectively and the composition of Cu increased from 52 to 82 percentage as compared to Fe and Co atoms, was confirmed by energy dispersive X-ray spectroscopy (EDS). The crystallites size shows overall increasing trend from 44-54nm confirmed by XRD calculated using Scherer formula. The AAO seems to be amorphous while the metal nanowires are BCC and also observed FCC aluminum of substrate. The magnetic analysis was performed using a vibrating sample magnetometer, reveals that by increasing the Cu composition saturation magnetization and coercivity Hc of the nanowires decreased. Magnetic measurements exhibit strong magnetic anisotropy with magnetization easy axis parallel to the nanowires in as-prepared samples. The shape anisotropy remains dominant by overcoming on magnetostatic interactions and Magnetocrystalline anisotropy. The angle dependent coercivity and squareness decreases with the increase of angle and shows the maximum value at 0^0 and minimum. It is observed that magnetization reversal mechanism occurs by nucleation mode with the motion of domain walls. In order to use such nanowires in supercapacitor applications, the frequency dependent dielectric analysis of FeCoCu nanowire have been investigated thoroughly using an impedance analyzer in a wide range frequency. The behavior of dielectric parameters has been investigated using Maxwell-Wagner's model and Koop's theory.

BG-01. Design Optimization and Performance Comparison of Two Linear Motor Topologies with PM-less Tracks. ***(Invited)***

S. Aleksandrov[1], T. Overboom[1] and E. Lomonova[1]
1. Electrical Engineering, Eindhoven Univercity of Technology, Eindhoven, Netherlands

I. Introduction Linear Permanent Magnet Synchronous Motor (LPMSM) topology is the preferable choice for a linear motor in terms of high force density and good overall performance. However, its main drawback is the relatively high price caused by the extensive usage of rare-earth materials in the track. This factor is critically important, especially when this type of motor has to be used in a long-stroke application, such as storage or airport transportation lines where the main prerequisite is a low-cost, passive and robust track. Therefore, Linear Induction Motor (LIM) and Linear Flux-Switching Permanent Magnet Motor (LFSPMM) are two possible alternatives suitable for long-stroke applications. Considering only the price of the track, LIM topology, with its flat aluminum secondary is most attractive. Nevertheless, the absence of rare-earth materials limits the propulsion force generated by the LIM. Another attractive alternative is the LFSPMM topology, which also has a passive secondary, but it incorporates a limited amount of rare-earth materials in its mover, improving its force generation capabilities. As a relatively new topology, the research on LFSPMM is still limited [1-2]. The existing design solutions for LIM having relatively small volume, have lower force density [3], compared to the designs having much larger overall dimensions [4]. Therefore, a direct comparison between LIM and LFSPMM is very difficult. Based on the volume of a benchmark LPMSM topology, in this paper, a comparison between LIM and LFSPMM is performed. To obtain optimal designs within this volume, a fast converging, semi-analytical methods are used for modelling both topologies and the results are used to compare LIM and LFSPMM topologies. II. Modelling Fig. 1a shows one periodical section of the investigated LIM topology, which contains a three-phase coil unit with distributed winding and an infinitely long flat aluminum secondary. The chosen semi-analytical modelling technique is Complex Harmonic Method (CHM) [5], where the magnetic field distribution is obtained while accounting for the eddy current effect in the conductive secondary. The primary core is considered infinitely permeable and the coils are modelled as current sheets on the top boundary of the airgap. The effective airgap length is adjusted using Carter's coefficient to account for the primary slotting. In Fig. 1b, the analyzed LFSPMM topology is shown. It represents one periodical section of the motor, where the primary incorporates two three-phase coil groups with concentrated windings and six tangentially magnetized permanent magnets. The secondary is considered as an infinitely long teeth structure made from laminated silicon steel. A Hybrid Analytical Method (HAM), which combines CHM with Magnetic Equivalent Circuit (MEC) [6], is chosen for modelling. The magnetic field distribution in the airgap is obtained by the CHM, while the mover and the track are modelled using MEC. In addition, to increase the accuracy and to allow coupling between the regions, the MEC-region is discretized. III. Design Optimization and Performance Comparison Both topologies are designed for the same volume as the LPMSM. The overall length, height and depth of the mover are kept the same. A fixed value of the input current density is used. The forces acting on the track, the secondary losses and also the primary copper losses are used for comparison between the performance of LIM and LFSPMM. As the speed of these linear motors is in the range of 10 m/s, which is relatively low compared to their rotary counterparts, the iron losses in the primary are neglected for the purpose of this comparison. Both topologies are optimized for maximum propulsion force. LIM is modelled and optimized, considering the optimal slip frequency for each variation of the pole pitch. Optimization parameters are the mechanical clearance, the thickness of the conductive secondary, the coil-to-tooth width ratio in the primary and the height of the mover. In Fig. 2a, the generated propulsion force for different pole pitches is shown, while in Fig. 2b the ratio between the force and the power losses is depicted. As the comparison between different topology variations is performed for a fixed length of the mover, the results for smaller pole pitches are multiplied with the number of periodic sections, which could fit in it. The results of the parameter sweep for the LFSPMM and the comparison with the results from the LIM topology will be presented in the full paper. IV. Conclusion The conducted research shows the comparison of LIM and LFSPMM topologies, optimized for maximum propulsion force while considering their losses. Both topologies are modelled using fast converging, semi-analytical modelling techniques. Finally, the results are compared to a benchmark LPMSM in terms of force density and power losses as low-cost alternatives for long-stroke applications.

I. INTRODUCTION Free-piston energy converter, which integrates free-piston engine with a tubular permanent-magnet linear machine (PMLM), can generate electric power for applications like electric vehicles (EVs) [1]. As the key component of FPEC, the performance of the integrated PMLM has critical impact on the performance of FPEC. To improve the power density of the integrated tubular PMLM, the Halbach array which is composed by radially- and axially- magnetized PM rings is generally adopted. Since the radial magnetization of the homopolar PM ring is difficult, generally the homopolar PM ring is assembled by several cambered PM segments that are magnetized in radial direction, and these segments are banded by fabric bandages to improve the mechanical strength of the PM mover. But this manufacturing method will increase the air-gap length and compromise the performance of PMLM [1, 2]. To overcome the above disadvantages, we propose a kind of three-phase tubular PMLM which features hybrid Halbach/axially-magnetized permanent magnets (PMs), as shown in Fig. 1. II. MACHINE TOPOLOGIES AND OPERATING PRINCIPLE For the proposed machine, its mover structure can be regarded as a superposition of the conventional Halbach PM mover and the axially-magnetized PM mover, i.e., the proposed mover structure can be obtained by ringing the Halbach PM mover with an axially-magnetized PM mover. In comparison with the conventional Halbach array, the mover of the proposed machine has additional ferromagnetic poles which are sandwiched between the axially magnetized PMs. These additional ferromagnetic poles serve as magnetic path of the axially-magnetized PMs, and they also can confine the radial movement of the cambered radially-magnetized PM segments. Therefore, no extra fabric bandages are needed for the mover of the proposed machine, so the efficient air gap length can be smaller when it is compared with the conventional Halbach PMLM, i.e., higher power density can be obtained for the proposed machine. The stator of the proposed machine is similar to that of the conventional tubular PMLM, and annular windings are placed in the slotted stator. III. DESIGN AND OPTIMIZATION With the sinusoidal speed characteristic of the free-piston engine considered, the proposed machine is investigated under sinusoidal speed condition, and it is different from the design of the conventional PMLM which works under a constant speed. The back electro motive force (EMF), detent force, force, efficiency and power density, etc., are calculated by finite-element analysis (FEA). The main structural parameters, which include the outer radius of the mover, radial length of both the axially-magnetized PMs and the ferromagnetic poles, the axial length ratio of the radially-magnetized PMs to the pole pitch, etc., are optimized to improve the power density. To reduce the detent force which affects the dynamics of the mover, additional ferromagnetic teeth are attached on the stator core, and their dimensions are also optimized. IV. PERFORMANCE COMPARISON AND EXPERIMENTS Finally, the proposed machine is compared with two previously developed prototypes which are with the conventional Halbach mover and the axially-magnetized PM mover, respectively, as shown in Fig. 2. The tests of the conventional PMLMs have been done, and the mover of the proposed machine is still under construction, and the test results will be presented in the full paper. V. CONCLUSION A three-phase tubular PMLM with hybrid Halbach/axially-magnetized PMs is proposed and studied for FPEC. The machine topologies and operating principle are elaborately described. The influence of some main structural parameters on both the force capability and power density are investigated, and the detent force is reduced by attaching additional ferromagnetic teeth on the stator core. In comparison with the conventional Halbach and axially-magnetized PMLMs, the proposed machine features higher mass and volume power density. This machine topology is applicable to tubular PMLMs with any phases. BG-03. Design A Linear Flux-Switching Permanent Magnets Machine for Wave Energy Harvesting.

Y. Zou[1]
1. Electrical Engineering, The Hong Kong Polytechnic University, Hong Kong, China

I.INTRODUCTION Wave energy converters (WECs) that are considered to possess commercial values are the Pelamis from Ocean Power Delivery [1], the wave dragon from Wave Dragon APS [2], and the Archimedes Wave Swing from BV-AWS [3]. More and more researchers focus on oscillation wave energy harvesting by using linear machines such as linear synchronous permanent magnet generator (LSPMG) [4]. As a large number of permanent magnets (PM) are employed by the generator, the cost of the machines will be relatively high, compared with other PM-free machines. However, LSPMGs are hard to widely developed for large power volume application due to the limitation of the size of the PMs used for the machines. A linear flux-switching PM machine is designed in this study to create a cost-effective oscillation wave power generation. The machines, as a direct-drive generator, employs a few PMs so that the cost of the machine would be reduced dramatically. These PMs are embedded into the mover of the machine and it can generate electricity without excitation because of the utilization of the PMs. Without current excitation, the excitation current loss for the generator will be eradicated. The efficiency of the power generation system would be improved. Meanwhile, since the excitation current of the generator is zero and the excitation current loss can be ignored, this machine is suitable for low-speed operation. For wave power generation, the prominent feature is that the movement of the wave is rather low, around 1 m/s. Therefore, the designed machine is a promising candidate for wave energy harvesting. First, the structure of the machine is introduced and some basic principles for the machine are also given in this paper. Second, the structure of the power generation system based on the machine is introduced and the design procedure of the machine is elaborated. Also, the magnetic features of the machine are calculated by using finite element method (FEM). Last but not least, basic experiments for the machine is carried out, validated the effectiveness and feasibility of the designed machine for wave power generation. II.PROTOTYPE OF THE MACHINE The section view of the magnetic path of the machine and its prototype are shown in Fig.1(a) and (b). There are two phases of the machine, namely, phase A and phase B. The mover and the stator consist of a series of teeth. For the mover, PMs are sandwiched by two mover plates which are made of steel sheets. The mover is fixed by a solid aluminum. And this aluminum possesses eight wheels to guide the mover and guarantee the length of the air gap between the mover and the stator. The main specifications of the machine are listed in Table 1. The overall power generation system mainly consists of three parts: vertical flux-switching machine, energy converter, and storage part and a control part, as shown in Fig.1(d). A buoy can push the mover of the machine as the mechanical input. The stator is fixed on a spring installed at the end of the stator to avoid the colliding condition of the mover. The machine can absorb the wave energy via the buoy. The mover, pushed by the buoy, oscillates to against the magnetic force of the machine, generating electricity. A rectifier is used to regulate the generated electricity from alternative currents to direct currents and the electricity is stored by a capacitor. The operation principle of the machine is given in Fig.1 (e)~(f). When the mover moves, phase A and phase B will be induced terminal voltages and the voltages are alternative as the embedded PMs in the mover. III.BASIC THEORY According to Farad's law, the back EMF of each phase can be expressed as $d\Phi/dt=-N*v*d\Phi/dt$ (1) where λ is flux linkage of a phase and Φ is the flux of the phase. N represents the turns of the windings and x is the movement displace of the mover. v is the speed of the mover. It can be seen that the back EMF are proportion to N and v if the change rate of the flux keeps constant. If there is no local saturation for this machine, the flux of each phase without loading can be formulated as [5] $\Phi a=\Phi m*cos(2\pi x)$ (2) $\Phi b=\Phi m*cos(2\pi x+\pi/2)$ (3) where Φm and τ are the amplitude of flux of each phase with respect to the displacement and the length of the pitch. The flux distribution of the machine is given in Fig.2 (a). The density of the flux along the teeth aligned with the stator is bigger than that of the teeth unaligned. IV.EXPERIMENTAL VERIFICATION The experimental setup consists of the proposed machine, the energy storage system, the dSPACE DS1104 card based controller and loads, as shown in Fig.2(b). By using software package MATLAB/Simulink interfaced with DS1104, an emulated hardware controller for the power generation can be built quickly. The mover of the generator is driven by a linear machine via a metal rod. The generated electricity is stored in a capacitor. The open circuit voltage output and flux linkage of the machine are simulated as shown in Fig.2 (c), (d). The amplitude of the speed is 1 m/s. Under this speed, we can see that the maximum voltage is up to 12 V and the peak of the flux linkage is around 0.004 Wb. The linear machine is capable of producing electricity at such a low speed within 1 m/s. After rectifying, a controller is used to control the voltage by closed voltage control of the generator. The reference voltage is 6 V. the voltage response reaches the reference value and some fluctuations exist at the beginning. The mechanical force input for the machine is given in Fig.2 (f).

BG-04. Torque Characteristics of Interior Permanent Magnet Spherical Actuators.

K. Takahara[1], K. Hirata[1] and N. Niguchi[1]
1. Osaka University, Suita, Japan

I. Introduction Actuating systems with multi degrees of freedom (multi-DOF) are composed of several single-DOF motors, which results in large, heavy and complicated structures. Therefore, multi-DOF actuators are expected to become a key technology to solve these problems, and various spherical actuators have been proposed [1]-[7]. We have proposed a surface permanent magnet (SPM) type outer rotor spherical actuator as shown in Fig. 1(a) [7]. In order to avoid the increase of the size, as shown in Fig. 1(b), the mover is supported using pillars with a spherical ball at their tip. Due to this support device, the inner surface of the mover must be covered with a resin part, and this increases the air gap length. In order to solve the problem, an interior permanent magnet (IPM) type is employed. By embedding the permanent magnets inside of the mover, the resin part is removed and the air gap length is decreased. Due to this structure, a high torque can be realized. In this paper, the torque constant characteristics of the IPM type spherical actuator is investigated and compared with those of SPM type spherical actuator. II. Proposed IPM Structure and Modeling Method of Torque Constant The proposed IPM type rotor is shown in Fig. 1(c). In the IPM model, cuboid-shaped permanent magnets are embedded into the mover, and form V-shape arrangements. Their poles change by every 22.5 degrees in the latitudinal direction, and every 30 degrees in the longitudinal direction. 32 coils are arranged in the stator, and 16-phase currents are applied to rotate the mover. A torque equation is defined as (1), where T is a torque vector, K_m is a magnet torque constant matrix, K_r is a reluctance torque constant matrix, T_{cog} is a cogging torque vector, and i is a current vector. Each torque constant can be calculated from (2), where T(0A) is the cogging torque, and T(1A), and T(-1A) are torques when 1-A, and −1-A currents are applied. The magnetic torque is proportional to the current. However, the reluctance torque is proportional to the square of the currents. III. Comparison of Torque Constant Characteristics The torque constants of SPM and IPM models are compared. The torque constant is evaluated by rotating a simple magnetic pole model shown in Fig. 1(d) around the X axis (latitudinal direction) along the arrangement of the permanent magnets. The pole of the permanent magnets changes every 22.5 degrees, and the simple magnetic pole model is rotated every 2.25 degrees around the X-axis. Considering the symmetry of the structure, the mover is rotated by 90 degrees around the X axis. The computed magnet, cogging, and reluctance torque constants are shown in Fig 2(a). From Fig. 2(a), the effective value of the magnet torque constant is decreased by approximately 7% although the total volume of the permanent magnets is reduced by approximately 35% in compared with the SPM model. This is because the permeance of the magnetic path is increased by using the IPM model, and the working point of the permanent magnets is increased. Next, the effective value of the cogging torque constant of the IPM type is about 72% less than that of the SPM type. This is because the path of magnetic flux has changed. The reluctance torque is not created in the SPM model, and it is created only in the IPM model. Therefore, if the reluctance torque can be effectively utilized, the torque can be increased. However, the ratio of the reluctance torque constant is only about 5% of the magnet torque, and the increase of the reluctance torque is required by changing the structure. Finally, the torque constants are compared. In this paper, they are evaluated by an evaluation function shown in (3), where F is an evaluation value and *rms* indicates an effective value. This evaluation value is higher as the current torque is larger and the cogging torque is smaller. The evaluation results of the SPM and IPM models are shown in Fig. 2(b). As shown in Fig. 2(b), the IPM model has an evaluation value 3 times or more higher than that of the SPM model. V. Conclusion In this paper, an IPM spherical actuator was proposed. Due to the comparison between the SPM and IPM models, it was found that the IPM model has better torque characteristics than the SPM model. In the final paper, the torque characteristics in other positions and the cause of the difference of the torque characteristics will be discussed.

BG-05. Force Estimation Method for a Magnetic Lead-Screw-Driven Linear Actuator.

A. Heya[1], Y. Nakata[2], M. Sakai[1], H. Ishiguro[2] and K. Hirata[1]
1. Department of Adaptive Machine Systems, Osaka University, Suita, Japan; 2. Department of Systems Inovation, Osaka University, Toyonaka, Japan

I. Introduction A feed screw (e.g., slide-screw and ball-screw) is a transfer mechanism converting a rotation into a translation or vice versa, and is widely used in industrial fields. Some researchers developed muscle-like compliant actuators with a feed screw for robots [1][2]. The back-drivability of the feed screw is small because of the friction between the screw and the nut. Thus, the flexibility of the actuators is obtained by combining a mechanical spring. The actuators is expected to service robots and power-assist robots to increase the collision safety for human. However, a slide-screw and ball-screw have some problems such as a vibration, noise, and friction. In contrast, a magnetic lead screw (MLS) that can achieve a non-contact power transmission was developed [3][4]. Because of the power transition without contact, the MLS can be driven with a high efficiency, can achieve a maintenance-free operation, and has a force limiter function when overloaded. In addition, the MLS has a flexibility against external forces because it has the elastic characteristics due to a magnetic spring. Therefore, the MLS can be used as a flexible element of the actuator without using mechanical springs. Since conventional MLSs are composed of a spiral shape permanent magnet magnetized in the radius direction, they have problems of downsizing and low productivity. In order to solve these problems, we proposed a novel MLS that is composed of several pieces of arc-shaped permanent magnets and a linear actuator with the MLS. For realizing force control using the linear actuator, the force sensor is necessary. However, the size and weight of the actuator are increased by implementing the sensor system. In order to solve this problem, torque sensor-less control methods for electric motor have been proposed [5][6]. We have been studying about a force sensor-less control for the MLS driven linear actuator (MLSDLA). The force of the MLS is calculated by the magnetic phase difference between the nut part and screw part. Therefore, the output force of the MLSDLA is estimated by the phase difference of rotation and translation. In this paper, we propose a force estimation method using a magnetic phase difference for a force sensor-less control of the MLSDLA. The estimated force and measured force are compared, and the effectiveness of the proposed method is verified. II. Magnetic lead-screw-driven linear actuator (MLSDLA) The prototype of the MLSDLA is shown in Fig. 1 (a). The operating principle of the actuator is shown in Fig. 2 (b). The MLS consists a nut part and screw part. The permanent magnets are arranged only in the nut part. The actuator is driven by the translation of a screw thread caused by the rotation of the screw part using a rotary motor. A restoring force due to a magnetic attraction force is generated when a relative displacement between the nut and screw parts is created due to an external force. The nut part returns to an equilibrium position due to the restoring force. This restoring force works as an output force of the actuator. Since the MLS is composed of arc-shape permanent magnets, the MLS has the advantages of improving a productivity and is expected to be smaller than conventional MLSs. III. Force estimation method for MLSDLA In this section, a force estimation method using a magnetic phase difference is described. The magnetic phase difference is given as follows: $\phi = \theta-(2\pi/L)p$ where θ is the rotation angle of the screw part, p is the displacement of the nut part, and L is the lead of the screw. The estimated force expressed by a polynomial approximation using the least square method is given as follows: $F = 0.380\phi^5 + 0.172\phi^4 - 8.96\phi^3 - 2.55\phi^2 + 52.3\phi + 6.48$ IV. Comparison of the experimental and estimated results The comparison of the estimated and measured force by a force sensor is shown in Fig. 2. From these results, it is found that both show a good agreement with each other. The absolute average error of the estimated and measured force is 3.8 N. V. Conclusion In this paper, a force estimation method for the MLSDLA was proposed without a force sensor. The structure and operating principle of the MLSDLA were described. A force estimation method using a magnetic phase difference was described. In addition, the estimated and measured forces were compared, and it was found that both show a good agreement with each other. Our future goal is to develop a method for improving the estimation accuracy.

BG-06. Performance Investigation of a five-phase Multi-segment primary PMLSM for Ropeless Elevator.

Q. Jiang[1] and Q. Lu[1]
1. Zhejiang University, Hangzhou, China

I. INTRODUCTION With the increasing advance of construction engineering, there are higher and higher buildings across the city at present, so the high performance elevator becomes very important. Normally they are mostly driven by a rotate motor with cable. However, if the buildings exceeding to 300m, the cable consumes a lot of power and causes some fluctuations in the process of moving. In order to overcome this problem, the elevator driven by multi-segment primary permanent magnet linear synchronous motor (MP-PMLSM) is adopted, which also has many other many obvious advantages, such as high efficiency, simple structure, save space occupancy, etc. Its key technologies are high thrust density PMLSMs and control system. Several PMLSMs have been proposed [1], [2], [3], mostly focusing on the motor structure and the switching control of primary section. The segment winding power feeding method is studied [4], [5]. which adopting sectional winding permanent magnet linear synchronous motor. The primary is divided into sections, but the iron corn is continuous, so they are not segment primary PMLSM in some ways. This paper proposed a 2t vertical hoist system driven by novel five-phase PMLSM with segment winding power supply. Compared to three-phase PMLSM, the five-phase PMLSM can reduce the thrust force ripple and noise during operation. Moreover, it has higher fault tolerance and thrust force when supplied with same voltage or current resource. Therefore, the five-phase PMLSM is the better candidate. In order to facilitate the installation, the primary and iron core are divided into sections. II. MODEL Fig.1 (a) shows the segment-primary ropeless elevator, comprised of several five-phase PMLSMs. The length of primary section should equal to the even multiple of pole pitch, the length of secondary should be the integral multiple of the length between adjacent primary sections. It is important to setting these parameters a proper value, then the initial phase angle of excitation source not need to be changed, which is convenient for control strategy to obtain steady thrust force. Fig.1 (b) shows the simplify structure of PMLSM, which is a 60-slots/12-poles five-phase structure and adopts surface-mounted PMs and full-pitch armature windings. It should be noted that full-pitch winding can achieve much high power density. Fig.1 (c) exhibits the winding power feeding method, which simplifies each primary as twelve sets five-phase windings. To ordinary method shown in Fig.1 (a), when the secondary entering into primary II, both primary I and II are energized at same time, and the primary I is kept energized untill secondary leaving primary I. Apparently, the uncoupled energized armature windings waste a lot of power. Adopting proposed winding power feeding method can overcome this shortcoming, which feeds the coupled windings and powered off the passing windings by switch according to the secondary position signal. III. ANALYSIS Fig.2 (a), (b) exhibit the magnetic flux distribution of the two power feeding methods, respectively. As known, the thrust force mainly produces by the coupled magnetic field, so the effective winding is only under the secondary. That is to say, many uncoupled windings are useless. However, the segment winding power feeding method gets higher efficiency due to lower the number of uncoupled winding. Based on power feeding supply, the thrust force and currents have been calculated by FEM under five phase sinusoidal voltage source. Fig.2 (c) shows the instantaneous thrust force for the vertical hoist by two methods. It can be seen that the average thrust forces are 22.96kN, 22.56kN and thrust ripples are 22.07%, 19.39% respectively. These two methods almost have same average thrust force, but the proposed method has lower thrust ripple. Since the input voltage values are 100V, 10V respectively, the proposed method can reduce the bus voltage to achieve higher thrust force. Fig.2 (d) shows the FFT analysis of thrust force within a polar intervals. Obviously, the amplitude of proposed method is slightly larger than that of ordinary one, and higher harmonic in two methods both have produced less thrust fluctuation. Fig.2 (e) show the equivalent q-axis current. Apparently, the instantaneous current produced by ordinary method is 1.5 time that of proposed method, which may damage the performance of inverter. However, the proposed method not have big instantaneous current.

IV. CONCLUSION This paper proposes a ropeless elevator driven by a novel five-phase PMLSM. To this vertical hoist system, a novel segment winding power feeding method is proposed. With this method, although the cost is a little expensive, the length of energized windings is effectively shorten, which not only can save approximately half of power consumption and lower bus voltage, but also improves the system efficiency.

BG-07. A Novel Linear Stator PM Vernier Machine with Spoke-Type Magnets.

A. Nematsaberi[1] and J. Faiz[1]
1. Electrical and Computer Engineering, University of Tehran, Tehran, The Islamic Republic of Iran

Introduction: The linear magnetic geared vernier machines offer high efficiency and good performance for low-speed applications such as direct-drive wave energy conversion due to the capability of low-speed high-force operation [1]. Linear permanent magnet (PM) vernier machines can be designed in both forms of translator PM and stator PM. In the second form, both the armature winding and PMs are located in the stator and the translator is only made of iron. Hence, the problems of mechanical integrity and thermal instability of the PMs have been surmounted in linear stator PM vernier (LSPMV) machines. It must be noted that all LSPMV machines which have been presented so far in the literature employ conventional surface-mounted PMs with radial or quasi-halbach magnetization and none of them have utilized spoke-type PMs [2]–[4]. Nevertheless, the spoke-type PMs have been recently proposed for the dual stator translator PM vernier (DSTPMV) machines [5], [6]. The reason is the flux-focusing effect of the spoke-type magnets leading to improved air-gap flux density and therefore higher thrust force. In this paper, a novel linear vernier machine is presented in which spoke-type PMs and armature winding are located in a single stator and only one air-gap exists in its topology. In addition, in order to reduce the leakage flux and increase the flux linkage of the armature windings, a non-magnetic space between pole shoes and PMs is introduced in the topology of the proposed machine. Machine configuration: Fig. 1a. illustrates the topology of the proposed machine. It can be observed that the conventional radial surface-mounted magnets are replaced by spoke-type magnets. Unlike the DSTPMV machines presented in [5], [6] in which the PMs are located in translator, the translator of the proposed machine contains only solid iron which offers a simpler and more robust structure. Also, it can be seen from Fig. 1a that there is a space between the stator pole shoe and the magnets specified by green color. Since this space is located between two stationary parts, there is no need to use bearings, and it can be filled with non-magnetic materials. In order to clarify the reason for the presence of this non-magnetic space in the proposed machine, using finite element analysis (FEA), the magnetic field distribution caused by PMs in no-load condition, when the thickness of non-magnetic space is 0 mm and 1 mm, are shown in Figs. 1b and 1c, respectively. In the absence of the non-magnetic space illustrated in Fig. 1b, the flux produced by the PMs, Φ_{PM1} is twice as high as the case illustrated in Fig. 1c, Φ_{PM2}, ($\Phi_{PM1}=2\Phi_{PM2}$). However, only 16.22% of Φ_{PM1} crosses the armature winding while for Φ_{PM2}, this value is equal to 63%. The reason for this phenomenon is a significant reduction in the leakage flux caused by embedding the non-magnetic space. Hence, it can be concluded that in Fig. 1b, the amount of $0.1622\Phi_{PM1}$ reaches the armature winding and stator yoke, whereas in Fig. 1c, this value is equal to $0.63\Phi_{PM1}0.5=0.315\ \Phi_{PM1}$. Machine performance and comparison: Fig. 1d depicts the variations of no-load back-EMF of the proposed machine with the PM volume. It is clear that as the PM volume increases, the back-EMF increases correspondingly. Considering a compromise between back-EMF and cost, the PM volume is determined to be 150cm^3. The proposed machine and the existing LSPMV machine [2] are designed and quantitatively compared in terms of their electromagnetic performance. Table I lists the fixed and designed parameters of both machines. Fig. 1e depicts the waveforms of the three-phase no-load flux linkages for both machines. The amplitudes of flux linkage of phase A for the existing and proposed machines are 0.2 T and 0.283 T, respectively. Thus, by using spoke-type PMs and the non-magnetic space the flux linkage is increased by 41.5%. Fig. 1f illustrates the thrust force waveforms of both machines. The average thrust force in the proposed and existing machines are 2.2 kN and 1.73 kN, respectively. Hence, as listed in Table I, although the number of armature winding turns per phase is higher in the existing machine, the proposed machine offers 27.16% higher thrust force which is due to the more utilization of the PMs in the proposed topology. Moreover, the thrust force ripples for existing and proposed machines are 4.06% and 4.33%, respectively, which are very acceptable. The effect of increasing the total PM volume on the average thrust force for both machines is investigated in Fig. 1g. It can be seen that unlike the proposed machine in which the average thrust force is directly proportional to the PM volume, the thrust force of the existing machine decreases as the PM volume increases. The optimal value of PM volume for the existing machine is 90 cm^3. However, it must be noted that at this point, the iron core of the existing machine is highly saturated. Furthermore, by decreasing the PM volume, the PM blocks will be subject to irreversible demagnetization. Therefore, the proposed machine exhibit a more promising electromagnetic performance than the existing one over different values of PM volume.

BG-08. Development of a new rotary flux switching transverse flux machine with the ability of linear motion.

C. Liu[1,3], Y. Wang[1], J. Zhu[2], Y. Guo[2], G. Lei[2] and S. Wang[1]
1. Hebei University of Technology, Tianjin, China; 2. University of Technology Sydney, Sydney, NSW, Australia; 3. PMG Fussen GmbH, Fussen, Germany

I Introduction Soft magnetic composite (SMC) material is a new soft magnetic material, it is produced by using the powder metallurgy technology, and it has the advantages of the low eddy current loss and magnetic isotropy characteristic. With the SMC materials, various kinds of the electrical machines with 3D magnetic flux can be designed and prototyped [1-3]. Moreover, compared with the traditional electrical machines, the newly developed electrical machines with SMC cores can have higher efficiency and power density. Among them, the claw pole machine is a typical example, as the global winding and the 3D magnetic flux path are adopted. Nowadays, some special application are emerging, e.g. the robot arms with the capture ability, for this kind of application, the utilization of the rotary electrical machines with the ability of linear motion can save the required numbers of the electrical machines and reduce the complexity of the overall system, moreover the dynamic response characteristic can be improved. Thus, in this paper, a new rotary flux switching transverse flux machine (FSTFM) with the ability of linear motion is proposed. By using the finite element method, the basic electromagnetic properties of the proposed FSTFM are obtained; it can be found that the this machine can own the merits of the higher power density, low cost and good mechanical robust ability. II Topology and electromagnetic performance analysis The main topology of the proposed FSTFM is shown in Fig. 1(a) and Fig. 1(b), it can be found the complete machine includes the three single phase stator modules, and a long rotor module, each stator module shifts with the 120 degree electrically with the adjacent stator module. As shown in Fig. 1(b), the stator core is completed as the permanent magnets installed between the stator cores, and the adjacent PMs are magnetized along the opposite direction, and the winding of this machine is the global cylinder winding. By designed in this way, this machine can operate with the ability of not only the rotation motion but also the linear motion. Due to the very high flux concentration ability of the designed machine, the ferrite magnets are utilized to produce the PM flux, and the maximum flux density on the rotor teeth tips can reach to 2.0 T, as shown in Fig. 1(c) and Fig. 1(d). Fig. 2 shows the PM flux per turn of the designed FSTFM, it can be seen that the PM flux linkage of the FSTFM is in three phase distribution and each phase has the 120 degree in electrical with each other if the machine operated in the rotation way, however, if the machine operated in the linear motion way, the PM flux linkage of this machine is not distributed in the symmetrical three phase way. Moreover, accompanied with the linear motion, the PM flux magnitude of machine will be changed, and accompanied with the rotation motion; the PM flux magnitude of the machine will be changed as well, it is because of the FSTFM has the very strong magnetic coupled characteristic. III Conclusion With the designed structures of the FSTFM, this machine can have the ability in both rotation motion and the linear motion; it can be used in the special applications where both the rotary motion and linear motion are required. The designed structures of the FSTFM can be prototyped quite easy with the adoption of the SMC materials. However, the designed FSTFM has the strong magnetic coupled characteristic, and the electromagnetic force ripple of this machine in the linear motion is quite high, thus the rotor module of this machine is required to be optimized to make the machine have a overall good performance.

I. INTRODUCTION Due to high land prices in the metropolitans, such as Hong Kong, Tokyo and New York, high-rise buildings are mushrooming one after another. The conventional vertical elevators in multi-level or low-rise building, which usually adopt rotational electric motors plus hoist cables with counterweights, are no longer applicable. The cable for hoisting elevators have the strength and stability problems as it gets longer and longer [1, 2]. For solving these problems, a ropeless elevator system with self-propelled cars is proposed and testified. This system adopts the linear motor to drive the elevator car and omits the counterweight and cable [3, 4]. Thus, the efficiency and operation performances are dramatically improved. Moreover, areas of the elevator hoistway can be reduced [5]. According to the requirements, linear motors for ropeless elevators need to satisfy the following features: high power density, high force density, high reliability, high ratio of payload to self-weight and low force ripple. To achieve the above features, dual permanent magnet (PM) linear motors with fault-tolerant teeth (FTT) are good candidates. When the elevator car size is fixed, one way to further increase the force density with the same current density is to adopt the dual-PM structure [6]. Thus, in this paper, four dual-PM linear motors are proposed and compared for the application of ropeless elevator system. II. MACHINE TOPOLOGIES AND ANALYSIS The proposed linear machines have PMs on both the mover and stator, which can be termed as dual-PM structure. In this way, the internal space of the machine is fully utilized, leading to much higher force density and efficiency compared with the mover-PM or stator-PM motors. For ropeless elevator system, the proposed dual-PM linear motors are very suitable, owing to the high ratio of PM volume to the machine dimensions. In order to compare the machine performances, all four machine dimensions are designed to be the same, except for the installation position of mover PMs, as shown in Fig. 1. In general, the proposed dual-PM linear motors are designed with 24 slots and 22 poles. The double-stator or double-mover structure is adopted to reduce detent force, resulting in the reduction of propulsion force pulsation. Specifically, the double-stator slot-PM (DSSPM) linear machine is shown in Fig. 1(a), the double-mover slot-PM (DMSPM) linear machine is shown in Fig. 1(b), the double-stator tooth-PM (DSTPM) linear machine is shown in Fig. 1(c), and the double-mover tooth-PM (DMTPM) linear machine is shown in Fig. 1(d). In the stator, the iron cores are fixed to the hoist way, and the PMs are employed in the stator slot with upward magnetization direction. For the mover side, the fault-tolerant tooth (FTT) structure is used to improve the machine reliability. As can be seen, in the DSSPM and DMSPM linear machine, the PMs are placed on the mover slot openings with only the downward magnetization direction. For the DSTPM and DMTPM linear machine, the PMs are mounted on the mover teeth surface alternately, with only the downward magnetization direction. In order to apply the proposed machines for ropeless elevator system, there are practical space constraints. Thus, the mover length is chosen as 300 mm, the airgap is set as 1.5 mm and the mover velocity is 1 m/s. At first, the machine parameters are designed, such as the pole pitch, tooth length and semi-open slot size. Then four machines are optimized to achieve the best force performances. Furthermore, the mutual inductance characteristics are obtained to verify the fault-tolerant capability of the proposed machines. At last, the proposed four linear machines are compared. Fig. 2(a) shows the no-load EMF waveform of the proposed four dual-PM linear machines. The generated voltages of the DSSPM, DMSPM, DSTPM and DMTPM linear machines are 91.4 V, 92.7 V, 97.3 V and 97.8 V, respectively. As can be seen, the generated EMF of the tooth-PM machines are more symmetrical and sinusoidal than the slot-PM machines. Fig. 2(b) shows the thrust force waveform of the above four machine configurations. The generated average thrust forces of the DSSPM, DMSPM, DSTPM and DMTPM linear machines are 868.4 N, 1045.7 N, 1055.0 N and 1061.8 N, respectively. Since the PM volume in each machine configuration is the same, the average thrust force of the DSSPM machine is much lower than other three machines. In addition to the thrust force and force density, the force ripple is another important factor for the performance of the elevators. Furthermore, the force ripples of the above machines are 28.6%, 20.5%, 10.1% and 8.8 %, respectively. It shows that the force ripples of the tooth-PM machines are smaller than those of the slot-PM machines. More results such as force density and efficiency as well as experimental verification will be given in full paper. III. CONCLUSION A new class of linear machines, namely the dual-PM machine, has been proposed and analyzed, which is particularly designed for ropeless elevator system. By comparing four machine configurations, the double-mover tooth-PM (DSTPM) linear machine not only fully retains the advantages, but also achieves much higher force density, efficiency and lower force ripple. This work was supported by a grant (Project No. 17204317) from the Hong Kong Research Grants Council, HKSAR, China.

BG-10. Design, control, and comparison of low-energy solenoid valve actuators.

J. van Dam[1], B. Gysen[1], M. Dhaens[2] and E. Lomonova[1]
1. Electrical Engineering, Eindhoven University of Technology, Eindhoven, Netherlands; 2. Advanced Chassis Research, Tenneco Automotive bvba, Sint-Truiden, Belgium

Introduction An automotive, fluid-control solenoid valve is composed of an electromagnetic reluctance actuator and a near-constant-force spring. Reluctance actuators are applied as electromagnetic brakes in aerospace applications [1], as valves that perform fast sorting tasks by means of short air-pulses in the manufacturing industry [2], as accurate fluid-control valves in petrochemical processes [3], and in the automotive industry to achieve variable valve timing in camless engines [4]. Common desires are a fast switching and low noise upon impact. Preferably, these objectives are met with minimized energy consumption, especially during constant position operation. In addition, minimizing the impact velocity improves valve lifetime and reduces the audible noise, vibration, and harshness (NVH). This paper considers cylindrical reluctance actuators due to their low cost. However, this complicates the use of laminations to minimize eddy current effects in a cost-effective manner. Proper analysis, design, and optimization of the reluctance actuator can, therefore, only be performed if these dynamic effects in the actuator are accounted for. This paper will focus on incorporating the eddy current effect in the models and their effect on performance, as well as control methods to improve the performance and minimize energy consumption. The performance of a classical reluctance actuator (Fig. 1a) is compared to a PM-biased topology (Fig. 1b) which reduces the energy consumption. Modeling is performed using transient, axisymmetric, nonlinear finite element (FE) simulations, coupled to Matlab-Simulink. Actuator topology and constraints Two single-coil reluctance actuators are shown in Fig. 1. One is a classical reluctance actuator with a stationary coil and a moving plunger (CLA). A second actuator includes a permanent magnet atop the core (PMB) to allow zero-power latching by means of a passive attraction force [1],[3],[5]. In addition, the actuator height and diameter are 16 and 13 mm, with a stroke of 0.25 mm. Moreover, the plunger of mass 1.2 g experiences an opposing force of 4 to 12N. Finally, the closed-to-open transition can last maximally 4 ms, with a typical valve-open time of several seconds. Open-loop simulation results In an open-loop co-simulation between Simulink and FE software, predefined voltage profiles are applied to the actuators, while the current is limited. In Fig. 2a, the electromagnetic force develops 0.075 ms slower in cases with eddy currents, and the final position is reached 0.115 ms later. This indicates the inherent eddy current damping in the device, slowing down the plunger. In addition, once the movement commences and the airgap closes, the developed electromagnetic force increases rapidly while the opposing force decreases, resulting in a quickly moving plunger. As a result of applying the voltage profiles in Fig. 2b, the corresponding coil currents develop. Note that equal voltages are applied to CLA and PMB until 1.15 ms, after which CLA requires a small hold voltage (1V) to hold the valve open (latch), whereas PMB achieves this passively. Therefore, the hold power can be reduced to zero using PMB. Fig. 2c shows the (in)ability of the actuators to passively latch the valve. The plunger in CLA retracts quickly after (<0.2ms) the supply voltage is removed, as the developed electromagnetic force drops below the opposing force. On the other hand, PMB latches indefinitely, under equal operating conditions, because of the passive attraction force provided by the PM. In general, the predefined voltage profiles produce unnecessarily high forces, indicating that additional control can greatly improve the energy efficiency. Moreover, a significant energy consumption reduction can be achieved by latching passively, and, therefore, reducing to zero the coil current and the hold power using PMB. In addition, plunger closed-to-open movement takes under 0.3ms without achieving a soft landing, while 4ms is allowed. Together, these considerations require to investigate closed-loop feedback control. Conclusions and future work Analyses on two reluctance actuators have shown that open-loop control using predefined voltage profiles results in high energy consumption and no soft-landing. Furthermore, the eddy current effects further deteriorate the timing performance and increase the losses. To achieve soft-landing and further minimization of energy consumption during movement and holding, the final paper will consider cascaded closed-loop control. Inner and outer feedback loops are considered to control the current and position, respectively. Simulations are performed using a closed-loop co-simulation using Simulink and transient FE software incorporating eddy current effects. These simulations will be performed on both actuator types and analysis will target possible reduction of energy consumption and the ability to achieve soft-landing. Acknowledgments The 3Ccar project has received funding from ECSEL JU under grant agreement No. 662192.

BG-11. Design and Analysis of a Planar Flux-Switching Permanent Magnet Motor.

H. Hu[1], G. Cao[1], S. Huang[1], C. Wu[1], J. Guo[1], D. Liang[2] and R. Mai[3]
1. Shenzhen Key Laboratory of Electromagnetic Control, Shenzhen University, Shenzhen, China; 2. School of Electrical Engineering, State Key Laboratory of Electrical Insulation and Power Equipment, Xi'an Jiaotong University, Xi'an, China; 3. School of Electrical Engineering, Southwest Jiaotong University, Chengdu, China

I. Introduction For precision positioning applications such as semiconductor lithography and microscale manufacturing, planar motor is an attractive positioning device, because of its advantages of simple structure, high precision, low friction, and low cost [1], [2]. Planar permanent magnet synchronous motor (PPMSM), which is one kind of planar motor, shows the obvious advantages of high efficiency and high thrust force density [3]. However, the cost is increased and the reliability is reduced inevitably for the PMSPM, because a vast majority of the material is permanent magnet (PM) for PPMSM [4]. As another kind of planar motor, planar switched reluctance motor (PSRM) possesses the merits of low cost and high reliability; however, the PSRM has the drawbacks of low efficiency and low thrust force density [5], [6]. Combining both superiorities of PSPMMs and PSRMs to develop a kind of planar motor showing high efficiency, high thrust force density, high reliability, and low cost is significant in precision positioning applications. At present, a new kind of stator PM brushless motor, namely the flux-switching permanent magnet motor (FPMM), has received more and more attention. For the FPMM and the permanent magnet synchronous motors, they feature high efficiency and high torque density [7]. Simple structure, low cost, and high reliability are shows for the FPMM and the switched reluctance motors [8], [9]. The FPMM have been applied to develop linear motors for precision positioning applications [10]. There are two main structures of the linear FPMMs. One is mover/stator pole pitch ratio approximately equal to one, the other is equal to three [11]. For the two structures, the linear FPMM with mover/stator pole pitch ratio of three would perform lower thrust force ripple [11], which is significant for precision positioning applications. Therefore, the linear FPMM with mover/stator pole pitch ratio of three could be suitable for developing a kind of planar motor with superiorities of high efficiency, high thrust force density, high reliability, and low cost. In this paper, a planar flux-switching permanent magnet (PFPMM) with mover/stator pole pitch ratio of three is proposed. II. Motor Design *A. Modeling* The magnetic field of the PFPMMs consists of two components: magnetic energy generated by permanent magnet W_p; magnetic energy generated by energized silicon iron W_e, which is given as $W_m=W_e+W_p$ (1) In terms of virtual work method, the one-axis electromagnetic thrust force under linear magnetic field can be deduced as $f(t)=dW_e/dx(t)+dW_P/dx(t)=\partial\int_0^i(\psi(t)di)+dW_P/dx(t)=0.5dL(x(t))/dx(t)i^2(t)+dW_P/dx(t)$ (2) where x, i, ψ, and L are the position, current, flux linkage, and inductance in one axis. *B. Design Consideration* For the PFPMM, the relation of the mover teeth pitch τ_u, the stator pole pitch τ_s, and the mover pole pitch τ_m is given as $\tau_u = 1.5\tau_s = 0.5\tau_m$ (3) The relation of the mover width w_m and the stator pole pitch τ_s is expressed as $w_m = k\tau_s$ (4) where k is the positive integer. The relation of the distance between the adjacent mover λ and the stator pole pitch τ_s is expressed as $\lambda=l\tau_s\pm\tau_s/3$ (5) where $\lambda>0$ and l is the nonnegative integer. The geometric dimension of PM is determined by using the finite element analysis. The material of PM is NdFeB30, and the remanence of PM is 1.1 T. The main geometric dimension of the PFPMM is then determined according to (3), (4), (5), and finite element analysis, which is listed in Table 1. The overall structure of the designed PFPMM is depicted in Fig. 1(c) and (d). For the designed PFPMM motor, the moving platform consists of six movers. Three movers are responsible for one-axis motion. The stator sets are a network structure constructed from stator blocks combination, which is shown in Fig. 1(a). Each stator block constituted by the laminated silicon steels. The mover is shown in Fig. 1(b). The iron core of mover is constituted by the laminated silicon steels. III. Results and Analysis The proposed PFPMM is analyzed based on three-dimensional finite element model (FEM) via ANSYS Maxwell software. The magnetic induction intensity distribution is shown Fig. 2 (a). The flux linkage of PM is shown in Fig. 2(b). A sinusoidal flux linkage of PM is illustrated, which is desired for the PFPMM. Fig. 2(c) depicts the Fourier analysis of the flux linkage. The amplitude of the fundamental frequency of the flux linkage is 92 % of that the total amplitude. The cogging force is shown in Fig. 2(d), which indicates that the maximum cogging force is 1.2 N. The thrust force and normal force of one mover versus current versus position is shown in Fig. 2(e) and Fig. 3(f), respectively. The change of the thrust force and normal force is small because of the magnetic saturation under the current larger than 7 A. The maximum thrust force of one mover is 20 N. The PFPMM generally operates with the sinusoidal current. The thrust force density versus current of the PFPMM and the PSRM presented in [5], [6] is shown in Fig. 3(g). Compared to the PSRM, the proposed PFPMM shows higher thrust force density. The effectiveness of the proposed PFPMM is verified.

Fig .1 Structure of the PFPMM

Table 1 Parameters of the proposed PFPMM

Parameters	Value
τ_s (stator pole pitch)	7.2mm
w_{st} (width of stator teeth)	3.6 mm
h_s (high of the stator)	10 mm
h_{st} (high of the stator teeth)	4 mm
w_m (width of the mover)	43.2 mm
τ_m (mover pole pitch)	21.6 mm
h_m (high of the mover)	36 mm
l_{pm} (length of the PM)	18 mm
w_{pm} (width of the PM)	43.2 mm
d_{pm} (thickness of the PM)	3.6 mm
Number of turns	150
g (air gap of the PFPMM)	0.3 mm

The magnetic field is a commonly used physical quantity to develop sensors for a broad range of industrial applications such as positioning systems based on magnetic encoders. Its dependence on the source-sensor distance imposes strong requirements in the sensor technology and packaging. Magnetoresistive (MR) sensors standout as a magnetic sensor technology that surpass other magnetic field detection techniques like inductive and hall effect sensors due to an enhanced spatial resolution and high sensitivity, achieving detection levels around the pT range at low frequency[1]. However, the packaging solution influences the optimum sensor performance level. The sensor packaging is mainly implemented to protect the device from mechanical damage, the intellectual property and establish electrical connection with outer electronics. The combination of silicon based sensor technologies with Complementary Metal Oxide Semiconductor (CMOS) technologies is a reduced footprint method to integrate a full electronic system[2], but the non-fabricated CMOS area for the sensor integration increases the production cost. Wirebonding technology is a reliable method used to connected independent components and it doesn't compromise the production cost[3]. However, a high density of contacts and the interconnections overlapment demand a larger chip area. Furthermore, the vertical volume occupied by the wirebonding loop increases the sensor-source distance. An alternative for connection on the back side of the substrate is the through-silicon-via(TSV) technology. Although its implementation is extremely affected by the via height-to-width ratio, state-of-the-art TSV technology can achieve a high density level of vias with 20μm diameter, upon reducing the wafer thickness to 200μm[4]. An alternative to bringing the sensor contacts towards the back side of the substrate while maintaining the wafer thickness at optimum levels for handling robustness is proposed in this work. A new approach was developed for planar sensor architectures, aiming to fulfill the demand for high accuracy technologies for positioning systems and motion control applications. The implementation of this sensor technology can push the magnetic encoders towards a competitive solution for applications with high constraints (reading distance, angular dependence and harsh environment). The prototype is based on a hybrid technology with a rigid Si chip combined with a flexible polyimide (PI) connector. The MR sensors are composed of a magnetic tunnel junction stack based on a MgO barrier deposited by magnetron sputtering in a N2000 tool [5] with the following structure: Ta 5/[Ru 18/Ta 3]x3/PtMn 20/CoFe 2.2/Ru 0.7/CoFeB 3/MgO 1.6/CoFeB 1.55/Ru 5/Ta 10 (nm). Consequently, they are defined in a standard top-down microfabrication process[6]. A 600nm AlSiCu/30nm TiW(N) thick metal layer is deposited between a double coated 10μm thick PI layer. The electrical contact between the two elements is established by opening vias along the 1st PI layer, while the 2nd PI layer is used as a protective layer and to define the pad layout for electrical contact with the external electronics through a ffc/fpc connector. Finally, the PI layers are patterned according to the flexible connector shape, being the Si substrate removed by opening tranches around the sensing chip using an DRIE technique combined with HF vapor that selectively removes the underlying SiO_2 sacrificial layer and detach the device from the wafer. Figure 1(a) display a schematic of the device cross section while Figure 1(b) shows the device top view after the microfabrication process. The prototype was implemented as a linear analog sin/cos encoder using a 80μm pole pitch incremental scale with an out-of-plane magnetization manufactured at BOGEN. The magnetic scales are commercial 1mm thick and 10mm wide elastomer filled with ferrite coated on top of a stainless steel carrier tape[7]. The sin/cos analog output is obtained through a double Wheatstone bridge in a full bridge configuration, which reduces the background noise, offset voltage and is translated into a higher signal to noise ratio. Furthermore, to minimize the impact of inhomogeneous interferences along the scale, each magnetic sensor is composed of several sensing elements distributed across different poles to obtain an average signal and a higher accuracy. The sensor exhibits a tunneling magnetoresistance of 123%, an intrinsic R-A product of 1.1MΩ.μm^2 and a minimum resistance of 1109±31kΩ. Despite a coercive field of 0.62±0.02mT, the sensor displays a sensitivity at zero field of 453±19 kΩ/mT in the most sensitive branch. Figure 2(a) shows the magnetotransport curve for a magnetic sensor of the Wheatstone bridge while Figure 2(b) displays the sin/cos output measured by the prototype along the magnetic scale at a reading distance around 80μm. Within a high yield microfabrication process, the sensors maintained all magnetic and electrical properties and were successfully implemented as a magnetic encoder. Furthermore, an outstanding configuration allows a 20μm sensor-source distance since the PI flexible connector establish electrical contact away from the Si chip since it can be bent towards a lower level or the opposite side.

BH-02. Busbar current transducer with suppression of external fields and gradients.

P. Ripka[1], A. Chirtsov[1] and J. Vyhnanek[1]
1. Czech Technical University, Prague, Czechia

Yokeless busbar current sensors are cheap and compact, but they are sensitive to external magnetic fields and field gradients [1,2]. We have described current transducer based on a couple of microfluxgate sensors [3] inside the cylindrical hole in the busbar [4,5]. The advantage of this transducer is high range and small size compared to similar transducer based on circular sensor array around the conductor [6]. Compared to Hall current sensors [7,8], fluxgate current sensor has 10-times better stability. Solution based on AMR has 10-times lower range due to the small saturation field of AMR sensors [9]. We have suggested that a partial suppression of the magnetic fields generated by external currents can be achieved by using four microfluxgate sensors: two of them are active and they measure y-component of the field at points A and C (B_{Ay} and B_{Cy}) the other two measure both field components at point B (B_{Bx} and B_{By}) [10]. This approach can be effective for the case of known geometry of the external currents or when the external currents are also measured. However, in general case the position and size of the external current is not always known and the interference field can be generated by several currents simultaneously. Significant magnetic fields can also by generated by coils and by magnetic materials (both hard and soft in external field) in the vicinity of the transducer. In this paper we therefore suggest current sensor which is immune to external homogeneous fields and first order field gradients. This means that our new solution does not perfectly compensate the field from external conductors, but effectively suppresses their influence, as higher order gradients from distant currents are small. Fig. 1 shows the current busbar with fluxgate sensor array inserted into the hole and field distribution shown on a busbar cross section. The size of the copper busbar is 6 x 1 cm and the hole diameter is 19 mm. The DC current value for this simulation was 1000 A. The sensor array shown on the photograph consists of six sensors - three of them are visible as a row with 6 mm pitch, which measures By in positions A,B and C. The other 3 sensors are on the opposite side of the PCB and they measure Bx at the same points. By moving the sensor array in y direction we can scan the field values at other positions above the central plane and verify the simulations. In general the fit between our measurements and FEM simulations is within 5%. After performing the simulation and measurement exercise we fixed the sensor optimum position for the final transducer design. All previously published current transducers of this type such as [3] and [7] used sensors in the central line (positions A and C) measuring By. The fact that B_{Ay} and B_{Cy} have opposite sign was used to suppress homogeneous external field B_0. However, field distribution of By along the A-C line is linear (Fig. 2 left) and this means that external dBy/dx field gradient cannot be suppressed. Possible solution of this problem would be to change the busbar geometry in order to achieve significantly non-linear field profile and evaluate second-order gradient from the measured current. We have made extensive simulations with various geometries but we never achieved significant non-linearity. Instead of that we decided to find alternative sensor positions. The novelty of our approach is that we use Bx instead of By. Bx response to the measured current does not change sign when mirroring around the y axis. At H and I points the sensitivity is the same, 5mT/1000 A. Due to the 2 mT maximum range of the DRV425 sensor the actual current range will be 400 A. Summing $B_{Hx} + B_{Ix}$ therefore does not suppress homogeneous external field B_{0x}, but instead of that it suppresses dBx/dx field gradient. This type of gradient is not typical for long conductors, but for dipolar sources such as coils and permanent magnets. This setup is also completely insensitive to external currents in x direction. The dependence on B_{0x} can be suppressed by using the third x-sensor at the central point A. Remaining is the dependence on dBx/dy field gradient. Here we face the similar problem as before, because Bx response to the measured current change sign when mirroring around the x axis. Fortunately, field distribution along the DE line is strongly non-linear and thus the external dBx/dy field gradient can be suppressed. This is documented by the Bx profile along the DE line (Fig. 2 right). We achieve the required compensation by using additional sensor located at J and eventually also K point. While $B_{Jy} - B_{hy}$ is insensitive to the measured current, this value depends only on dBy/dx field gradient. The resulting formula for the measured field B_m is $B_m = B_H + B_I - (B_J + B_K)/2 - B_B$ and in our example the lateral (x-direction) current is suppressed completely, while the superior (y direction) current in the vicinity of 20 cm is suppressed by the factor of 167. In conclusion, by using novel geometry of the fluxgate current transducer we achieve compensation of external fields and first order field gradients.

BH-03. Small Eddy Current Testing Sensor Probe using Tunneling Magnetoresistance Sensors for Detection of Cracks in Steel Structures.

K. Tsukada[1], M. Hayashi[1], Y. Nakamura[1], K. Sakai[1] and T. Kiwa[1]
1. Okayama University, Okayama, Japan

Eddy current testing (ECT) is a nondestructive testing (NDT) method, and is widely used to detect flaws in metal structures. ECT involves the use of a pair of detection and induction coils. The detection coil is used to measure the secondary magnetic field generated by the eddy current in the metal due to the applied AC magnetic field of the induction coil. In the case of a nonmagnetic material, since the magnetic field detected by the detection coil is generated only by the eddy current, ECT using a detection coil is suitable for detecting any abnormality in the eddy current distribution caused by a flaw. However, in the case of ferromagnetic materials, the magnetic field detected by the detection coil arises not only from the eddy current but also from the magnetization of the material itself, thereby making it difficult to apply ECT in such cases. The magnetization of the material can lead to detection errors in ECT; this is referred to as magnetic noise. Thus, a measuring technique that can minimize the signal arising from the magnetization of the material compared to that arising from the eddy current is required. Recently, instead of detection coils, magnetic sensors are being increasingly used for NDT. We also reported NDT using magnetoresistance sensors, such as extremely low-frequency ECT for evaluation of corrosion via thickness detection, and unsaturated AC magnetic flux leakage testing for detection of inner cracks. In this work, we have developed an ECT method using a small magnetic sensor probe with tunneling magnetoresistance (TMR) sensors to address the problem of magnetic noise in ferromagnetic materials. The signal arising from the magnetization of the material can be minimized with respect to the signal arising from the eddy current by minimizing the detection area and thereby, increasing the ratio of the area with a crack to the area without a crack. In our method, we reduce the detection area by using a micromagnetic sensor instead of a detection coil with a larger area. Thus, we developed a small single-channel magnetic sensor probe using TMR (Fig. 1(a)), and evaluated its performance by detecting cracks of different depths. The single-channel sensor probe consists of a TMR sensor mounted on a 2 mm wide amplifier circuit board and an induction coil. A nanogranular in-gap magnetic sensor, which is a type of TMR sensor with an even response function, was used. To obtain linear magnetic response, a magnetic bias was applied using a magnet, and a sensitivity of 0.3 V/mT was obtained in the sensor probe output. The induction coil was square-shaped with a cross-sectional area of 2.3×2.3 mm^2 and 32 turns. The applied magnetic field was maintained at a frequency of 1 kHz using a function generator. A 7 mm thick SS400 steel plate with 20 mm long and 1 mm wide cracks of different depths ranging from 0.5-7 mm was used as the test sample. To evaluate the performance of our detection system, the sensor probe was used to scan lines over the positions of the cracks. The output signal was detected using a lock-in amplifier, and analyzed using magnetic vectors with real and imaginary components. When the magnetic sensor is attached to the induction coil, the applied magnetic field is directly coupled to the former. Therefore, the applied magnetic vector signal in the absence of a sample was subtracted from the detected magnetic vector signal of the sample. Our analysis revealed an apparent signal change at the crack position in all the signals obtained after line scanning over the crack regions. However, a base line drift was observed in scanning experiments performed over a large distance. Such a drift can be attributed to an in-plane permeability fluctuation of the steel plate and the consequent magnetic noise. To address the problem of base line drift, a dual TMR sensor probe was developed (Fig. 1(b)). Two TMR sensors were attached to one long side of a rectangular induction coil with a cross-sectional area of 2.5×6.0 mm^2 and 60 turns. In Fig. 2, we show the magnetic vector intensity change observed in scanning experiments over a crack with a depth of 5 mm. Each signal change exhibited a waveform similar to that observed in case of a single-channel sensor probe. We also observed a drift, i.e., the base line showed different values at the start and end points (Fig. 2(a)). To determine whether the signal change arises due to the crack, knowledge of the absolute value of the signal at the crack position without any offset and base line drift is necessary. For this purpose, a differential magnetic vector (Fig. 2(b)) was calculated to obtain the true signal arising from the crack by subtracting one detected signal from the other. The line-scanned differential magnetic vector intensity exhibited a simple peak at the crack position without any base line drift. In conclusion, a reliable signal change due to a crack was obtained in ECT of a ferromagnetic material using a dual TMR sensor instead of a detection coil. The developed TMR sensor is small and can be easily incorporated inside the induction coil. Thus, ECT probes using multiple TMR sensors with only one induction coil can be easily realized.

BH-04. Nondestructive testing of wire rope based on shoving magnetic field structure.

X. Yan[1] and D. Zhang[1]
1. Electrical Engineering and Electronics, Harbin Institute of Technology Shenzhen Graduate School, Shenzhen, China

I. INTRODUCTION The methods for wire rope or pipe nondestructive testing commonly include: eddy current testing, radiographic testing, optical testing, acoustic testing, electromagnetic testing, and so on. The structure of electromagnetic testing device is simple, and various types of magneto sensors can be used. In addition, the wire rope belongs to ferromagnetic components, with the application of electromagnetic excitation, the electromagnetic characteristics of the defects are different from the intact wire rope, where magnetic sensors can be used for data acquisition for defect detection. The electromagnetic testing is not affected by the oil or mud stains on the wire rope surface, so the internal and external defects can be detected. The electromagnetic testing of wire rope is common and cost effective for many wire rope operators, and it has been developed and recognized as the most reliable and effective wire rope NDT method [1,2]. At present, for wire rope or pipe nondestructive testing, usually uses the structure of magnets and a magnetic yoke as an excitation to excite the tested component to saturation state. A magnetic sensor [3] or magnetic sensor arrays [4] are used to pick up the defect electromagnetic signal, realizing the wire rope or pipe non-destructive testing. The participation of the yoke increases the weight of the detection probe and also increases the probe volume. In addition, the wire rope or the pipe is a rod-shaped structure, in order to achieve a better excitation effect, the arc-shaped magnet which is radical magnetizing needs to be designed for magnetization. This is increases the complexity of the magnetization. In this paper, a new excitation method based on shoving structure is proposed to simplify the magnetizing structure, and eliminate the use of magnetic yoke. The whole nondestructive testing probe is more compact and lightweight, at the same time can achieve a good detection effect. II. TOPOLOGY AND SIMULATION The nondestructive testing of ferromagnetic components based on shoving magnetic field structure is shown in Fig. 1. The two magnets is magnetized the tested component along its length. That is, the direction of the magnetic pole is along its thickness. In the field application, the structure of magnets can be two halves, and it is very easy for its magnetization. The two magnets should be as closer as better, in the premise that the magnetic sensors can be installed between them. The internal side polarity of the magnet should be same, are both N or both S. The simulation result is shown in Fig. 2. Conclusions obtained from it: in the squeeze structure, the magnetic sensor placed in the center of the two magnets can detect flaw magnetic flux leakage signal, which is used for defect inversion analysis. In the following simulation work, we will extract the magnetic flux leakage signal in the middle of the two magnets, and analyze the influence of sensor arrangement position on the test result to determine the optimal placement position of the sensor. III. EXPERIMENTAL RESULTS The prototype of the nondestructive testing probe based on shoving magnetic field is shown in Fig.3 (a). A steel iron rod whose diameter is 10mm is tested, there are 7 defects on it. 10 hall sensors is arranged around the pipe in the middle of the magnets. One of the hall test result is shown in Fig.3 (b). From the Fig3 (b), the defect signal has high signal-to-noise ratio, the defect size and the signal peak value has a proportion relationship. That means, the nondestructive testing of wire rope based on shoving magnetic field structure has remarkable detection effect.

BH-05. Magnetic detection of steel corrosion at a buried position near the ground level using a magnetic resistance sensor.

K. Tsukada[1], T. Tomioka[1], S. Wakabayashi[1], K. Sakai[1] and T. Kiwa[1]
1. Okayama University, Okayama, Japan

Accurate and easy inspection methods are in high demand to ensure the safety of social and industrial infrastructure. Corrosion and cracks are often detected in steel infrastructure, and they can be inspected using ultrasonic or magnetic testing. However, surface treatment, such as paint or rust stripping, is necessary to perform ultrasonic testing in order to maintain good acoustic matching contact. Therefore, it is difficult to apply ultrasonic testing to deteriorating and corroding steel structures, which are in serious requirement of corrosion detection. On the other hand, pulsed eddy current (PEC) testing methods and our recently reported extremely low frequency eddy current (ELECT) can be applied to perform thickness detection of thick steel plates without conducting surface treatment. Recently, the corrosion of steel structures, such as the illumination and road marker poles that are located in close proximity to the ground level, have become a social problem because serious traffic accidents may occur due to the collapse of poles that may be caused due to corrosion. Corrosion is observed to easily occur near the ground level. It is very difficult to detect corrosion because corrosion may be hidden by the soil, concrete, or tiles in many situations. Conventional inspection methods, such as digging to detect buried objects, requires a plenty of time along with a sufficient number of workers. Therefore, a method to detect such corrosion at hidden positions under the ground level is required. In this study, we develop a magnetic method that can be applicable to corrosion detection at the hidden positions under the ground. To achieve this objective, we use the noncontact characteristics of our developed ELECT method. For the purpose of detection, apart from the magnetic sensor probe, the probe was tilted in order to point it in a direction that is not perpendicular to the steel surface, but rather to the underground part (Fig. 1). This configuration produces an extensive exposure to the magnetic field. Subsequently, the eddy current occurs in the underground part. In many cases, it is located within 5 mm below the ground level. However, the location of corrosion is not always located just within the aforementioned region below the ground level. Therefore, we have developed two methods to detect the changes in location and thickness. The first method is the measurement of the changing distance from the ground level (Fig. 1(a)), while the second method performs the corresponding measurement with a different tilt angle (Fig. 1(b)). The developed measurement device consists mainly of a sensor probe, sensor circuits, current source for an induction coil, and personal computer for data acquisition and signal analysis. The sensor probe consists of an anisotropic magnetic resistance (AMR) sensor, induction coil, and a small cancellation coil, which was used to minimize the applied magnetic field at a particular position of the sensor to obtain a higher signal-to-noise ratio. Further, the applied magnetic field was operated using an AC current of 0.15 A, from 1 to 100 Hz. To analyze the thickness of the steel plate, we used our developed spectroscopic analysis of magnetic field (SAM). The test samples of the SS iron plate having a length of 350 mm, width of 200 mm, and thickness of 4 mm were used. Further, the test samples had a partially thinning zone from 0.5 to 3.0 mm, with a different length from 20 to 80 mm. The sensor probe was titled to the surface of the test sample by 30°, and the distance dependence of the magnetic spectrum was measured (Fig. 2). Each magnetic spectrum was adjusted to the zero point at a frequency of 1 Hz to reduce the magnetization signal of the ferromagnetic material. Fig. 2(a) depicts the distance dependence of the magnetic spectrum, when the test sample having a thinning depth of 3 mm and width of 60 mm were used to perform the measurement. The distance dependence was observed to be apparent and the magnetic strength gradually decreased, while the spectrum was shifted clockwise in order to be closer to the thinning part. Further, the magnetic spectrum was varied using the thinning depth. To evaluate the quantitative change of the magnetic spectrum, the differential magnetic vector was obtained by subtraction of a magnetic vector of 1Hz from the magnetic vector of 20 Hz. These dependencies of the thinning depth and distance on the differential magnetic vector's magnetic signal intensity are depicted in Fig. 2(b). Through the diagram that is depicted in Fig. 2(b), the corrosion depth and distance from the ground level were estimated using a pair of magnetic sensors that were separated by a constant distance. As an alternative method, corrosion detection was evaluated using a magnetic sensor with different tilt angles of 30° and 45° (Fig. 1(b)) by varying the tilt angle and eddy current distribution region. Further, similar results were obtained by performing the distance dependence test using a pair of separated magnetic sensors. To summarize, the change in thickness that was caused by corrosion was successfully detected using magnetic sensors with a different position or tilt angle.

Understanding the behavior of free-living marine species is essential for conservation efforts and predicting how environmental changes may influence marine ecosystems [1]. Despite the recent advances in autonomous recording tags, which are usually attached to free-living animals, acquiring quantitative datasets of their behavior is still technically challenging [2-4]. Magnetic sensing systems are recently becoming popular for underwater animal monitoring [5]. The main advantages of the magnetic approach are a high tolerance of fish to magnetic fields [6] and the measurable magnetic properties exhibited by magnets in water [7]. Such magnetic measuring systems typically consist of small neodymium magnets coupled with a magnetic field sensor to examine the feeding behavior [7], limb movements [8], respiration [9], defecation and heart rates of a number of underwater vertebrates [10]. We have optimized this system by introducing flexible, lightweight and less intrusive NdFeB-PDMS composite magnets, which conform to the body curvature of any marine animals and easily follow their body movement [11]. The corrosion-free composite magnets function effectively for monitoring the belly size of model fish in aquarium (Fig 1a) and study the behavior of the ecologically important giant clam (*Tridacna maxima*) (Fig 1b) in a wired configurational setup [11]. In order to provide a more versatile solution that can be applied to free ranging underwater animals, we have developed a wireless data acquisition system for the magnetic sensing system. To this end, a three-axial magnetometer (MAG3110, Sensors Freescale Semiconductor, Inc.) has been utilized to measure the magnetic stray field of flexible NdFeB-PDMS composite magnets. The magnetometer has been interfaced with a Bluetooth chip (nRF52832, Nordic Semiconductor) through a I^2C communication interface on a miniaturized PCB that was coated with 10 um biocompatible and waterproof Parylene C. The Bluetooth chip is utilized to wirelessly transmit the sensor's reading to any Bluetooth enabled smart device, such as smart phones or tablets. Three axes (x,y,z) of the vector magnetic field are sent over Bluetooth protocol at a refresh rate of 10 Hz (Fig 2a). An Android-based smart phone application was also developed to visualize the vector magnetic field in the form of its 3 (x,y,z) coordinates. The smart phone application scans for those Bluetooth devices, whose service UUID (Universal Unique Identifier) matches with the one assigned to our custom designed magnetometer service. The mobile application (acting as master) then connects to the Bluetooth device (acting as slave) and retrieves the data obtained by the magnetometer, once the notification is received from the devices. The data can be transferred to up to 100-150 meters, which is sufficient to realize real-time indoor monitoring applications. The developed system enables investigating the behavior of different marine species for which the traditional blogging devices, which use heavy, bulky and mechanically inflexible systems and satellite-linked dive recorders are not applicable. The system provides simple and cheap means for animal studies in aquariums. Due to the miniaturized PCB and lightweight, flexible composite magnets the opportunities have also greatly expanded to include tagging of smaller marine animals.

BH-07. High-performance micro magnetic sensors installed in wearable electronic compasses and I-o-T magnetic sensors promoting new information society - Amorphous Wire CMOS IC Magneto-Impedance Sensors -.

K. Mohri[1,2]

1. Graduate School of Engineering, Nagoya University, Nagoya, Japan;
2. Division of Research, Nagoya Industrial Science Research Institute, Nagoya, Japan

INTRODUCTION The Magnetics research, technology, and industry has been rapidly shifted in these years to the field of micro magnetic sensors due to the world-wide competing production of micro geo-magnetic sensors installed in the electronic compasses for Smart phones and mobile phones with the production number of more than 1 billion per year since 2014. OHSHIMA/ HARADA'S LEADING PRINCIPLE FOR CREATION OF MICRO GEO-MAGNETIC SENSORS A conception of "Electronic Compass" installed in mobile phones was proposed by Dr. S. Ohshima, late president of KDDI Corp., Japan on around 1985, the telecommunication liberalization year, after that Prof. K. Harada, Kyushu Univ. proposed a necessity of the creation of "magnetically sensitive and electrically high-impedance magnetic elements" for constitution of sensitive micro magnetic sensors. TEN REQUISITE CONDITIONS FOR MICRO MAGNETIC SENSORS INSTALLED IN WEARABLE ELECTRONIC COMPASSES We summarize the ten requisite conditions for micro geo-magnetic sensors installed in Smart phones and wrist watches : (1) micro sizing of the magnetic head less than 1 mm, (2) small power consumption less than 1 mW including the signal processing calculation power consumption in CPU, (3) high sensitivity with the resolution better than 0.1 mG, (4) high linearity (high directivity) with wide dynamic range more than ± 4 G, (5) anti magnetic shock of more than 40 G, (6) quick response, (7) high temperature stability, (8) high maximum operating temperature more than 80 deg.C, (9) mass productivity using Integrated Circuit processing, (10) reasonable cost. Only the high-performance micro magnetic sensors satisfying these ten conditions simultaneously can be adopted to the wearable micro magnetic sensors, that matches to human daily self-willed behavior. MAGNETO-IMPEDANCE EFFECT IN AMORPHOUS WIRE One of the most successful examples to create the high-performance micro magnetic sensors is the Amorphous Wire CMOS IC Magneto-Impedance Sensor based on the Magneto-Impedance effect in amorphous wires. The Magneto-Impedance effect in zero-magnetostrictive amorphous wires is a basic principle to create the magnetically sensitive and high-impedance element suitable for the high-performance micro magnetic sensors as expressed in the wire impedance Z_w : $Z_w = R_{dc}\, kr\, J_0(kr) / 2\, J_1(kr) \fallingdotseq (\rho\, L^2\, \omega\, \mu / 8\, \pi^2\, r^2)^{1/2}$ for δ sufficiently smaller than r (strong skin effect) (1), where J_0 and J_1 : 0^{th} and 1^{th} Bessel' s functions, respectively, R_{dc} : wire DC resistance, ρ : wire resistivity (130 μΩ–cm), L : wire length, ω : angular frequency of the wire current, μ : wire maximum differential permeability along the circumferential direction in the surface layer, r : wire radius, and δ $(= (2\rho/\omega\mu)^{1/2})$: skin depth. The wire impedance proportional to $(\mu(H_{ex}))^{1/2}$ sensitively changes with the external magnetic field H_{ex} at only the strong skin effect case (δ sufficiently smaller than r), in which the wire permeability μ sensitively and quickly changes with the magnetization rotation at the wire surface layer without any crystalline anisotropy, and simultaneously the wire impedance is very high. Thus the Magneto-Impedance effect in zero-magnetostrictive amorphous wire is suitable to constitute the sensitive and quick response micro magnetic sensors. Moreover, the zero-magnetostrictive amorphous wire is the highly robust material. AMORPHOUS WIRE AND CMOS IC MAGNETO-IMPEDANCE MICRO MAGNETIC SENSOR However, the Magneto-Impedance effect in amorphous wires using high-frequency wire current is so-called "Analog stage discovery" (science stage finding), which must be developed to so-called "Digital stage technology" (engineering stage) in order to use the Integrated Circuit processing technology for the mass productivity. We adopted the wire pulse current instead of the wire AC current having equivalent effect on the skin effect (Pulse current Magneto-Impedance effect). The unidirectional pulse train wire current forms the single domain structure for the magnetization rotation suppressing the Barkhausen magnetic noises, that results the high signal to noise ratio (S/N) magnetic sensors having a wide dynamic range. Furthermore, we adopted a pick-up coil set around the amorphous wire for constitution of a highly linear micro magnetic sensor suppressing the ringing electrical noises using an analog switch as a synchronous rectifying element. The digital type Magneto-Impedance micro magnetic sensor, named *MI sensor*, has been in mass production by Aichi Steel Corp, since 2002 as electronic compass chips for mobile phones, Smart phones, and wrist watches satisfying all the 10 requisite conditions expressed above. MULTI-DIFFERENTIAL OPERATION MI SENSOR ARRAY MODULE IN MAGNETIC GUIDANCE SYSTEM FOR CAR SELF DRIVING A robust magnetic guidance system for the car (bus) self driving has been developed by Aichi Steel Corp. and provided to the verification tests at Shiga pref. Hokkaido, and Okinawa pref. managed by Japanese Government on 2017. In the magnetic guidance, multi differential operation MI sensor array set to car underbody detects the weak magnetic field generated from a small ferrite magnet marker set on the road surface with 2 m interval cancelling road environmental various magnetic noises. Application of the MI sensors to the bio magnetic sensing using a pico-Tesla resolution and a high speed gyro sensing such as a Professional Baseball Pitching Ball Spin Analyzer with 50 rps detection (I-o-T sensing) have been also developed.

BH-08. A localization method of submarines by using an airborne three-axis magnetometer carried on cruising aircraft.

Y. Shangguan[1], J. Yuan[1] and J. Zou[1]
1. Dept. of Electrical Engineering, Tsinghua University, Beijing, China

Abstract: A localization method for submarines is proposed in this paper, which can detect and locate submarines in a large area of sea rapidly by using an airborne three-axis magnetometer carried on cruising aircraft. The method is divided into three phases. First, a detection method based on the orthonormal basis function decomposition algorithm is applied in aircraft cruise to detect if submarines exist around. Second, a navigation method is to direct the aircraft flying toward the submarine to reduce the distance rapidly between the aircraft and the submarine. Third, a linear algorithm is to calculate the positon parameters of the submarine precisely. The theoretical analysis and numerical simulation examples are employed to verify the effectiveness of the method. 1. Introduction The submarine built of ferromagnetic materials will be magnetized by the geomagnetic field, resulting in an additional induction magnetic field, which can be detected and located by magnetic measurement. However, the geomagnetic field will seriously interfere with both the detection and the localization of submarines because it is much greater than the submarine induction field and will change slowly with the solar activity. Besides, the submarine induction magnetic field decays sharply with the distance, which results difficulties with accurate measurement in remote sensing. This paper presents a localization method for submarines, which takes advantage of the fast mobility of the airborne detection to achieve a wide range of detection and precise localization of submarines during aircraft cruise. 2. Localization method during aircraft cruise The method is divided into three phases: detection, navigation and localization. The first phase is based on the orthonormal basis function (OBF) decomposition method to determine whether submarines exist in the target area during aircraft cruise. After determining the existence of the submarine, a navigation method is proposed to direct the aircraft flying toward the submarine. When the aircraft is close to the submarine, the position parameters of the submarine are calculated with a linear algorithm. By alternate use of the navigation and the localization method in cruise, the direction of the aircraft cruise can be modified to be more accurate, which helps to achieve a result of localization with higher precision. The general flow-chart of the method is shown in Figure 1. 2.1 First phase : detection The first phase is based on the OBFs method to detect submarines in the target area during aircraft cruise. A detection point far from the target area is chose as the reference point and the geomagnetic field can be canceled by differential operation. The total field of the submarine induction magnetic field is decomposed into a set of orthonormal basis functions, out of which the dominant basis function is chosen as the detector. The detection occurs when the decision index value exceeds a predetermined threshold. In addition to determining whether the submarine exists, the minimum distance from the submarine to the cruise track, named the closest proximity approach (CPA), is estimated with a multi-channel manner. 2.2 Second phase : navigation When the detection occurs, a navigation method is proposed to guide the aircraft to approach the submarine to sense the submarine induction magnetic field at a close distance, as depicted in Fig. 2. First, the positon of the submarine is approximately estimated based on the CPA distance and parameters of the cruise. And then, a new cruise track is formed, where the CPA distance is remarkably reduced. At last, the aircraft is flying toward the submarine along the new track. 2.3 Third phase : localization When the aircraft is close to the submarine, the submarine induction field is relative stronger, and the accuracy of the measurement is high enough for localization calculation. In this paper, a linear localization formula is deduced based on the simplified mathematical model of the submarine in magnetic localization. A system of linear equations can be formed with the magnetic measurements of the three-axis magnetometer at four points on the cruise track. The position parameters of the submarine can be calculated by the solutions of the equations and the gradients of the magnetic field at a special point on the cruise track, where the horizontal components of the position parameter meet the direct proportion relationship. The simulation examples show that through this algorithm and a three-axis magnetometer with a sensitivity of 10pT, the relative error is less than 5.62% for localization when the CPA distance is 500m. The detailed results will be shown in the full text. 3. Conclusion (1)The orthonormal basis function decomposition method is suitable for detecting whether submarines exist by the measurement results of three-axis magnetometer, which can remarkably expand the effective detection range. (2)With the navigation method, the aircraft can be guided to approach the submarine, so that the localization of submarine with high accuracy can be achieved. (3)The linear localization algorithm presented in this paper has the advantages of low complexity, good real-time performance and easily implemented, which is suitable for locating submarines by cruising aircraft. (4)By the joint use of the three phases of the method in the aircraft cruise presented in this paper, submarines in a large area of sea can be detected and located rapidly.

BH-09. Efficient wireless power transmission to medical implant using Wiegand sensor.

K. Takahashi[1], T. Yamada[1] and *Y. Takemura*[1]
1. Yokohama National University, Yokohama, Japan

1. Introduction We present a power receiving module of 21 mW using a magnetic wire as the core material in the detection coil. This power is equivalent to the power consumption of implantable medical devices, *e.g.*, capsule endoscopy. It is a novel concept and yields higher transmission efficiency than a conventional ferrite-core coil. Wireless power transmission to a medical implant deeply located in the human body is significant for developing therapeutic and diagnosis technology. It is normally difficult to design an excitation coil equal to the size of a human body for feeding sufficient power owing to the relatively high intensity and frequency requirements of the applied alternating magnetic field. The magnetic field required for achieving the power transmission of 21 mW was 4.8 kA/m at 10 kHz, which can be realized by a body-sized excitation coil [1]. The power receiving module developed in this study is also applicable to a battery-less sensor [2] and relating modules, which are the key devices designed for the Internet of Things. 2. Wiegand effect for power generation A magnetization reversal in magnetic wires with bistable magnetization states induces pulse voltage in a pick-up coil. The amplitude of the voltage is independent of the applied field down to zero frequency. This fast magnetization reversal is accompanied by a large Barkhausen jump, which is known as the Wiegand effect [3]. Currently, integrated circuits (ICs) powered by energy harvesting from Wiegand wires are commercially available for multiturn counters/encoders [4]. A twisted FeCoV wire, an optimum material yielding this effect, was used in this study. We achieved a battery-less Hall sensor operated by energy harvesting from a single Wiegand pulse [2]. As the pulse voltage induced in the pick-up coil is independent of the applied field frequency, a constant output voltage is generated even through a single event pertaining to the extremely slow movement of an excitation magnet, or through the application of an alternating magnetic field at low frequency. 3. Power receiving module using Wiegand effect An 11–mm-long $Fe_{0.4}Co_{0.5}V_{0.1}$ wire, supplied from Nikkoshi Co., Ltd., Japan, is used as the core material in the pick-up coil [5]. Its diameter is typically 0.25 mm. A pick-up coil with 400 turns is wound around the wire. When an alternating magnetic field is applied to the wire, a pulse voltage is induced in the pick-up coil. The peak voltage is approximately 1 mV per turn of the pick-up coil. The details related to the magnetic structure of the soft and hard layers in the wire and output voltage characteristics have been reported in Ref. 2. In this study, the positive and negative pulse voltages corresponding to the magnetization reversal of the wire under the applied alternating magnetic field were rectified and regulated to DC voltage as illustrated in Fig. 1. The configuration of the pick-up coil with a wire-core, excitation coil, rectifying circuit, and load resistor is also shown in the figure. Figure 2 shows the generated electric power, which was measured as power consumed at the load register of 2 kΩ. The applied alternating magnetic field was 4.8 kA/m in the frequency range of 0.01–50 kHz. The power was normalized by the area of the core. The power generation using a MnZn ferrite core with an effective permeability of approximately 50 was also evaluated. The frequency dependence of the result using the ferrite-core coil complies with the conventional theory of electromagnetic induction. As for the Wiegand wire core, the pulse voltage is independent of the applied field frequency, which results in efficient power generation at low excitation frequencies. The maximum power of 21 mW was achieved with using a 3000–turn pickup-coil. The wireless power transmission of 21 mW to a medically implantable device with a diameter on the order of 1 mm by an externally applied field of 4.8 kA/m at 10 kHz is a significant achievement because these field conditions are accomplished by a body-sized excitation coil with practical power supply. The experimental results of field intensity dependence, load resistance dependence, excitation by body-sized coil, and other possible applications including battery-less modules are also demonstrated in the presentation.

BH-10. Accurate Position Detection in Wireless Power Transfer Using Magnetoresistive Sensors for Implant Applications.

W. Han[1], K. Chau[1], C. Jiang[1] and W. Liu[1]
1. Electrical and Electronic Engineering, The University of Hong Kong, Hong Kong, Hong Kong

I. INTRODUCTION Recently, the utilization of magnetic resonant coupling (MRC) mechanism for wireless power transfer (WPT) has been actively investigated. Among numerous applications of WPT technology, the energization of implanted biomedical devices wirelessly and uninterruptedly from external supply is important because it can eliminate possible device replacement due to battery depletion. Given the implanted receiver is invisible from the external transmitter, the coil misalignment occurs easily which results in low transfer efficiency and high magnetic field leakage, and consequently endangers the human health [1]. Thus, the development of accurate position detection of the implanted receiver from the external transmitter is highly desirable. Presently, most studies of the position detection in WPT are focused on the application of electric vehicles. Although the corresponding technologies such as coil sets [2] or auxiliary multi-coils [3] have achieved fruitful outcome, they are too bulky and complicated to be used in implant applications. Due to the advantages of high stability, small size, low power consumption and high precision, the magnetoresistive (MR) sensor has been widely used in many industrial applications [4]. Generally, they are arranged in an array style to measure the magnetic field vector [5] or a moving magnetic object [6]. To the best of authors' knowledge, the application of MR sensors in WPT is absent in literature. In this paper, a new position detection approach in WPT is proposed and implemented, which is particularly suitable for implant applications. The key is to use a MR sensor array to directly measure the variation of magnetic field so as to precisely detect the relative position of the implanted receiver from the external transmitter. Therefore, the advantages of efficient and compact WPT for implant applications can be achieved. II. METHODOLOGY Fig. 1 shows the structure and equivalent circuit of the proposed WPT system using a MR sensor array. The transmitter and receiver are connected to their compensation capacitors in series, and operate at the same resonant frequency to achieve the desired MRC. And 12 single-axis MR sensors are distributed evenly along a circular array in the inner part of the transmitter. The MR sensor array is arranged along the vertical sensing direction and is energized by a low DC voltage. For simplicity, the coil misalignment is assumed to be along the horizontal direction only. Hence, the position detection can be considered as the detection of the misaligned orientation and departed displacement. The MR sensor output is amplified by the operational amplifier (OP) and then collected by the data acquisition (DAQ) card. Consequently, based on the proposed MR sensor array detection system, the external transmitter can be adjusted to achieve accurate alignment with the implanted receiver so that the transfer efficiency can be improved while the magnetic field leakage can be suppressed. Firstly, theoretical equations of the proposed system are deduced to assess the relationship between the distribution of magnetic field and the relative position of the implanted receiver. Secondly, the magnetic field distributions under different misalignments are analyzed by using finite element method based software JMAG. As shown in Fig. 2 (a), two typical cases of misalignment are analyzed: Case 1 is 30 mm misalignment along the 225^0 direction; Case 2 is 20 mm misalignment along the 90^0 direction. The corresponding magnetic field distributions are shown in Fig. 2 (b) and (c), respectively. Meanwhile, the magnetic flux densities at 12 points that can be captured by the MR sensor array are shown in Fig. 2 (d). It can be observed that the misaligned orientation is in coincidence with the location of the maximum sensor output and the departed displacement is in inverse proportion with the sensor output. Therefore, both the misaligned orientation and departed displacement can be detected by measuring the magnetic field distributions to accurately locate the position of the implanted receiver. III. CONCLUSION In this paper, an accurate position detection in WPT using MR sensors has been proposed and implemented for implant applications. The crucial point is to employ a MR sensor array to detect the variation of magnetic field so that the implanted receiver position can be accurately located. Theoretical analysis, numerical simulation and experimental results are given to validate the proposed system. This work was supported by a grant (Project No. SFBR 201511159096) from the University of Hong Kong, Hong Kong.

BH-11. Traffic Flow and Vehicle Speed Measurements using Magnetoresistive Sensors.

B. Santoso[1], Y. Bo[2], O. Chun Lian[1] and Y. Zhimin[1]
1. Non-volatile Memory, Data Storage Institute, Singapore, Singapore;
2. Institute of High Performance Computing, Singapore, Singapore

I.Introduction The magneto-resistive (MR) sensor is a good candidate for vehicle detection sensor which is low cost, scalable in deployment and reliable. Most vehicles have ferrous materials which distort the uniform earth magnetic field. A low field MR sensor can be used to detect this distorted field whenever vehicles are present [1]. In addition, when the MR sensors are deployed in an array, more information about the traffic flow can be obtained. This information is critical for the traffic light regulation used in traffic flow control. II.Experiment Setup A.Sensor Selection Magnetic sensor detects magnetic field and quantifies its magnitude by producing changes in electrical output. The state of art magnetic sensing element is made of layers of thin film material. The available magnetic sensors include Hall sensor, anisotropic magneto-resistive (AMR) sensor, giant magneto-resistive (GMR) sensor, and tunneling magneto-resistive (TMR) sensor [2]. The ambient earth magnetic field is uniform with a strength typically in the range of 0.5-0.6 Gauss. The AMR sensor fits the range with a good sensitivity. The 3-axis AMR sensor is preferred to map out magnetic field changes along *x, y and z* directions. Honeywell magnetometer HMC5883L is selected in this work. The sensor has a selectable operating range of minimum setting at +/-0.83G with 2mG typical root-mean-square (RMS) noise. B.Setup for Roadside Vehicle Detection Due to the spacing loss, the intensity of magnetic field is sensitive to the spacing between surface magnetic charges on vehicle body and the sensor [3]. In this work, we deploy the sensor nodes at the road side on curbs to demonstrate the feasibility of using magnetic sensors for the traffic flow and density measurements. A typical road lane in Singapore is about 3-4 m wide with a kerb height of 20 cm. The 3-axis sensor is installed in the directions of x axis cross the road, y axis down the road, and z axis out of ground. III.Results and Discussion When the vehicle passes by the sensor, all three channels of 3-axis AMR sensor measuring the change of magnetic field in *x,y,z* directions register as an event. To extract the precise vehicle information, the timestamp of detected vehicle signal must be as accurate as possible. Using the collected timestamp, the traffic flow or the number of vehicles passing through the road section per unit time can be calculated. The accuracy of timestamp is critical for the calculation of precise velocity of each passing vehicle. A.Signal Processing The signals of low cost sensors need to be processed to improve the signal-to-noise ratio and extract the velocity signal of the vehicle. A moving average window is used to remove the random and periodic noises. The processed signals are clean enough to identify the specific timestamp of the vehicles based on the signal profile, such as peaks or the steepest ascent/descent, etc. Both the sampling frequency and the signal amplitude resolution are critical to determine the accuracy of vehicle velocity. B.Velocity Accuracy Validation with High FPS Videos In the velocity measurement, two identical AMR sensor nodes are allocated at 1m spacing along the road. Concurrently, a video of the vehicle movement on the road is taken using a high resolution, high framerate video camera operating at 250 fps (frames per second) as shown in Fig. 2. There are 2 white markers placed on the road corresponding to the position of AMR sensors, which are also 1 meter apart. The white marker is used as the reference position to calculate the velocity from video images of the vehicle. The margin of timing error from the video is on the order of 4 ms, which has a speed accuracy of 0.04 m/s at 10 m/s velocity or of 0.12 m/s at 30 m/s velocity. It is accurate enough to validate the velocity accuracy measured by AMR sensors. C.Power Line Interference The AMR sensor is sensitive to the magnetic field being produced by various sources. In some cities, the electricity cables are buried right under the road. The powerline creates magnetic field alternating at 50/60 Hz. This interference field becomes a source of noise that manifests in the raw data of the sensor. The sensitive signals for vehicle detection lie in the *x-y* plane. First, cancellation of signals from both x-axis and z-axis is applied.The median filter is used to remove the spikes noise to get the final clean signal. The signals of y-axis and x-axis are used to calculate the vehicle velocity. D.Real Time Detection of Traffic Flow and Density For practical application, a software has been developed for the real-time processing and analysis of the traffic flow based on the raw data obtained from the AMR sensor nodes. The traffic flow is measured with one set of AMR sensor nodes at the side of a road for an hour. To understand real traffic behaviour, one can calculate the flow from the velocity of the detected vehicle as shown in Figure 2. The traffic flow time series indicates the number of vehicles passing through the road section per unit time and it is useful to deduce the traffic density on a particular road junction. IV.Conclusion Two of AMR sensor nodes separated at 1m spacing is able to measure the velocity of vehicles with good accuracy. The setup is of low cost and low power and is easily deployable in a large scale for traffic flow measurement. Due to the sampling frequency limit of on-the-shelf digital AMR sensor, the setup can only measure the vehicle speed below 100 Km/h.

Isolated magnetic skyrmions have recently attracted a lot of attention in the scientific community as a potential candidate for storage and for logic devices. It has been demonstrated that an isolated skyrmion can be a stable configuration in a nanostructure, that it can be locally nucleated by injection of a spin-polarized current and that it can be displaced by current-induced spin torques, even in the presence of large defects [1]. According experiments demonstrate the applicability of topological charge as a carrier of information by showing the feasibility to write and erase such spin textures in a controlled fashion using local spin-polarized currents from a scanning tunnel microscope [2]. Single skyrmions or chains of skyrmions can be nucleated as a metastable state in thin films and the controlled creation and annihilation of these isolated skyrmions is opening a path to new concepts of spintronic devices. In these applications, the temporal stability of the encoded information is an important measure for their feasibility. The energy required to create or annihilate skyrmions is directly related to their stability and therefore is of high interest. Due to their topological protection, skyrmionic spin configurations cannot be continuously deformed to other magnetic configurations such as spin spirals or ferromagnetic states. This property gives rise to their comparably high annihilation energy and thus stability. Even though micromagnetic simulations are capable of describing skyrmion configurations, they cannot account for skyrmion creation or annihilation processes as they are mediated by a change of topological charge via Bloch points. This is in contradiction with the main assumption of micromagnetics, which states that the magnetic field can be approximated as a continuous field. Therefore, we consider an atomistic spin model to account for such skyrmion creation and annihilation processes. The atomistic model implies a considerably higher computational effort due to the increased number of elements in order to account for the high spacial resolution required by the atomic lattice. For this reason we develop a GPU-accelerated finite-difference code which solves the Landau–Lifshitz–Gilbert equation for an atomistic spin model considering dipole-dipole, exchange, uniaxial-anisotropy and Dzyaloshinskii-Moriya (DM) interactions. We further apply the improved string method [3] in order to calculate the creation and annihilation energy of magnetic skyrmions. The string method yields the most-probable transition path between two chosen magnetic configurations. This path corresponds to the minimum energy path in configuration space and therefore allows for the calculation of the energy barrier between those two configurations. For the calculation of skyrmion creation and annihilation energies a meta-stable skyrmionic magnetic configuration represents the first configuration and a homogeneous field configuration the latter configuration. Figure 1 depicts such an energy path for each iterative step performed in the string method. After several hundred iterations the string method converges and yields the energy-barrier. The performance gain obtained by the usage of a GPU-accelerator allows for an extensive parameter study. Figure 2 shows a phase diagram of the calculated annihilation energy for various values of the DM interaction energy d and the uniaxial-anisotropy energy k. High values of d favor the formation of domain walls whereas high values of k suppress domain walls. In the region with low values of d and high values of k, the creation of skyrmions is suppressed and no energy barrier occurs. In the region with high values of d and low values of k surrounded by a dashed polygon, the initial homogeneous configuration used in the string method is no longer a local energetic minimum and evolves to a skyrmionic configuration itself, thus yielding higher order transitions. Skyrmion annihilation processes mediated by a Bloch point are observed in the intermediate region and feature straight lines of equal energies in the phase diagram indicating a linear relation between the two trends.

Importance of high-performance permanent magnets with high coercivity and remanence, which is indispensable for electric motors, increases due to shifting toward electric vehicles. Magnetization dynamics within the permanent magnet has been investigated over the years. However, there is a discrepancy between coercivities of theoretical calculations and experiments. When applied magnetic field exceeds the coercive field, magnetic nucleation cores are formed in some grains of the permanent magnet, and magnetization reversal regions expand into the magnet. Thus, it is important to reveal a mechanism of the formation of the nucleation cores. In this study, we performed ultra-large-scale micromagnetics simulations based on Landau-Lifshitz-Gilbert equation to clarify the mechanism of formation of the nucleation cores inside the hot-deformed permanent magnet. Figure 1(a) shows a simulation model for the hot-deformed permanent magnet with the size of 2048 × 2048 nm × 512 nm which consists of 3,391 tabular grains whose thickness is 32 nm and averaged diameter is 160 nm. We assumed magnetic materials of the grain is $Nd_2Fe_{14}B$ [1]. For inter-grain exchange interaction, the strength of exchange interaction was set as 1% of the intra-grain exchange interaction. The easy axis of each grain is tilted by 11.6 degrees on average from the c-axis. We simulated magnetization dynamics using our simulation code under periodic boundary condition to calculate magnetization inside the hot-deformed permanent magnet [2]. Figure 1(b) shows the simulated demagnetized curve. The hysteresis curve has a high square ratio, and coercivity of this simulation model is 28.0 kOe. When the external field reaches the coercive field, the nucleation cores are formed in some grains as shown in the inset of Fig1(b), and magnetization reversal regions expand across the grain boundaries. Finally, interaction domain structure appears inside the hot-deformed permanent model as shown Fig. 1(c) [3]. As can be seen from the inset of Fig. 1(b), the nucleation cores occur in grains with special characteristics. We plot the magnetization and the effective field under zero external field. Figures 2(a)-(d) show the magnetization and exchange, anisotropy and dipolar fields under zero external field. The magnetization of the grains in which the nucleation core are formed largely tilts from the z-axis. The tilt angle of magnetization does not affect the exchange and anisotropy fields in this simulation system. In contrast, the dipolar field is influenced by the tilt angle of the magnetization from adjacent grains in the z-direction that indicate white dotted lines. In this place, strong negative dipolar fields from the adjacent grains in contact at the top are applied onto edges of the grain where the nucleation core will be formed. The tilt angle of easy axis and the dipolar field at the edges on the top and bottom sides of the grains should be a good descriptor for the grains in which formation the nucleation cores are formed. Figures 2(e)-(g) are scatter plots as a function of the tilt angle of easy axis and minimum dipolar field at the edge of the grains during magnetization reversal process at 0.12 ns, 0.28 ns, and the interaction domain structure, respectively. Color indicates the magnetic domain configuration of the grains. The grains with multi-domain structure (blue circles) appear in large tilt angle and strong negative dipolar field region (a region surrounded by a dotted line) because the nucleation cores are formed in the grains. The number of the grain in this area is around 20. Thus, we can distinguish the grains that have a possibility of the formation of the nucleation core from other around 3000 grains using this scatter map. As time elapses, the grain having multi-domain structure appears in the high dipolar field region. Finally, the grains having the single-domain structure with positive or negative magnetization along the z-direction have almost same distribution.

The temperature plays an essential role in many novel and exciting phenomena such as domain wall motion under thermal gradients, temperature-assisted magnetization switching, ultra-fast magnetization dynamics, etc. In standard micromagnetics temperature is included as the white noise represented by random fields, however, this approach is valid for temperatures far from the Curie temperature only. At high temperatures the micromagnetics based on the Landau-Lifshitz-Bloch (LLB) equation which includes longitudinal magnetization dynamics has been developed in recent years [1,2]. Typically the influence of temperature on the magnetization dynamics is studied. However, there is an inverse effect when the magnetization dynamics produces temperature change, for example in the magnetocaloric effect or during the heating under an ac applied field. A promising application in this respect is the magnetic hyperthermia treatment for cancer. In the modeling of the temperature rise during the ac-field application, the released heat is usually evaluated in the global sense from the hysteresis cycle area, which corresponds to the whole thermodynamic ensemble. However this does not allow to describe, for example, the timescale of the temperature rise or the local individual heating around one nanoparticle, aspects that may play a key role in the development of accurate and safe biomedical protocols. As a different example, in the domain wall dynamics one can expect large local magnetization changes (especially if the domain wall has high velocity as is the case of antiferromagnets). These can lead to a local dynamical temperature rise. Recently, the self-consistent micromagnetic dynamical approach for both magnetization and temperature has been developed [3]. The approach consists in the simultaneous solution of the (quantum) LLB micromagnetic equation coupled to the equation for the temperature dynamics. The latter equation is derived from the self-consistent quantum mechanical treatment of the spin-phonon Hamiltonian and the density matrix approach. A more simple derivation considers simple thermodynamical reciprocity relations. In this talk we will discuss the main features of the novel micromagnetic approach. Not too close to the Curie temperature and in the absence of precessional effects, the global temperature rise coincides with that of the quasi-static hysteresis area evaluation. The temperature rise exists only for non-reversible processes, i.e. when the local magnetization torque is zero, consequently the magnetisation precession always produces some temperature change. Another source of the temperature change is the presence of the longitudinal relaxation term, active either in short timescale or close to the Curie temperature. Finally, any moving magnetic object (such as a domain wall) also produces some heat release. Furthermore, we will discuss some examples of recent modeling using this approach. Fig.1 presents modeling of dynamical temperature release during the ac-field treatment of an individual magnetite nanoparticle for several values of the energy relaxation times into the environment. The magnetization switches precessionally and during this time the temperature increase takes place. Importantly, the new approach allows to distinguish the individual heating of each interacting nanoparticle, for example, we study how the switching of one nanoparticle produces the temperature change on its neighbor. Particularly, we will present an example of coupled temperature/magnetization dynamics of two dipolar coupled nanoparticles. Here the magnetization switching of one nanoparticle produces a small irreversible change in magnetization of its neighbor during which the heat is also released. We believe that the model presented in this work constitutes a step forward towards more realistic modeling of many interesting phenomena where the magnetic and temperature dynamics are relevant, like heat-assisted magnetic recording, ultrafast magnetism, magnetic refrigeration, magnetic hyperthermia or spincaloritronics.

Beyond the current envisaged roadmap for magnetic recording involving heat assisted magnetic recording (HAMR) and then potentially allied to bit patterned media (BPM) is the possibility of all optical magnetic switching (AOMS) as either a future or alternative, ultrafast, high density data storage mechanism. To date most studies in AOMS rely on rare earth alloys [1] or, more recently, complicated synthetic structures [2]. To design and create synthetic ferrimagnet systems requires knowledge and control of the interaction of several fundamental magnetic parameters such as M_S(T), H_c(T) and exchange J. Simulation of an idealised exchange-coupled Fe/FePt synthetic ferrimagnet demonstrated a short heat-pulse was sufficient to induce ultrafast heat-induced switching [3] but the simulation relied on inferred materials parameters such as weighted average to deduce the exchange J, between the two ferromagnetic layers. Therefore, there has been limited exploration and validation of atomistic models using data arising from realistic ferromagnet/metal/ferromagnet synthetic ferrimagnet structures. In this paper we have successfully corroborated, in simulation and experiment, unexpectedly novel, magnetic response of a simple perpendicular synthetic ferrimagnet Ni_3Pt/Ir/Co. The ferromagnetic layers being exchanged coupled via a metallic non-magnetic spacer layer through the Ruderman-Kittel-Kasuya-Yosida (RKKY) interaction and fabricated via UHV sputtering using the atomistic simulation package, VAMPIRE [4]. To do this we first describe the parametrisation of VAMPIRE from experimental data. It is necessary to obtained simulations of the constituent magnetic layers (Ni_3Pt & Co); this requires determination of the dimensions and simulation size that is appropriate for the individual layers but also representative of the synthetic structure to be designed. In Figure 1 we show both experimental and the simulated hysteresis loops for Ni_3Pt and Co layers. That along with M_S(T) experimental data, allows the identification of combinations of Ni_3Pt and Co that would lead to above room temperature magnetic compensation. Figure 2 shows the VAMPIRE simulation of a Ni_3Pt (100Å)/Ir (5Å)/Co (10Å) perpendicular ferrimagnet. The setup for the VAMPIRE simulation comprised 100Å x 100Å x 110Å cell, comprising ~106,000 spins, parameterised from experimental data and with the exchange parameter J, derived from a hysteresis loop taken at 10K for the Ni_3Pt (100Å)/Ir (5Å)/Co (10Å) multilayer. A suitable roughness at the interface of the magnetic layers is also included. In executing the simulation, the multilayer is perpendicularly statured, at each temperature point, and then allowed to relax to a remanence magnetisation determined at 2ns. The experimental SQUID derived M_R(T) data on Figure 2 agree very well with the simulation. Further, by adjusting the thickness of the Ir coupling layer the system was seen to remain ferromagnetically coupled across the temperature range. This gives us further confidence that both parametrisation and simulation are accurate. Unexpectedly, we observe that the overall simulated M_R(T) does not show a single 'compensation' point, but rather a magnetic reversal region between two temperatures where there is a magnetic compensation. This is confirmed by the SQUID data that shows negative remanence between these temperatures. In, addition, the SQUID data shows clear negative reversal switching [5] in that region as illustrated in the inset of Figure 2 and this will be discussed further. In summary, we demonstrate the integration of atomistic based modelling using VAMPIRE and experimental synthetic ferromagnetic structures to directly influence and direct the synthesis of novel magnetic materials.

BI-06. Evaluation of Thermal Stability of Spin-Transfer Torque based Magnoresistive Random-Access Memory for Cache Applications in Advanced Technology Nodes.

H. Dixit[1], S. Agarwal[1], D. Datta[1], A. Jacob[2], D. Shum[3] and F. Benistant[3]
1. Globalfoundries Engineering Pvt. Ltd., Bangalore, India;
2. Globalfoundries, Malta, NY, United States; 3. Globalfoundries Singapore Pte. Ltd., Singapore, Singapore

Modern computing systems require enhanced performance; however, the conventional memories such as Static Random Access Memory (SRAM) are inadequate to support this demand. This is mainly due to the fact that SRAM density cannot be increased commensurately with Complementary Metal–Oxide–Semiconductor (CMOS) transistor scaling. For example, typically the six-transistor (6T) SRAM, which has long been the workhorse of high-performance caches, requires a cell size of 120-200F^2, where F is the feature size [1]. On the other hand, Spin-Transfer Torque based Magnetoresistive Random-Access Memory (STT-MRAM) have emerged as universal memory technology due to its non-volatility, endurance, low operating voltages and ultrafast switching [2]. Further, they occupy much less area with 1T design comparable to DRAM with cell size of 6-10 F^2 [1]. Thus, STT-MRAM is most suited for on-chip cache applications with highest possible density. One of the most important factors that determines the data retention time of STT-MRAM towards cache applications is the thermal stability of magnetization. It is known that with shrinking Magnetic Tunnel Junction (MTJ) dimensions, commensurate with CMOS scaling, the thermal stability of magnetization also decreases. This results in reduced retention times and increased bit error rates, posing significant challenges towards its application as cache memory. Hence, it is important to evaluate the thermal stability of magnetization as a function of decreasing MTJ diameter, to address their scalability and performance in advanced cache technology. In this article, we focus on perpendicular-MTJ and perform Micromagnetic simulations to evaluate the thermal stability factor at reduced MTJ diameter. Currently, the 22 nm nodes uses MTJ with 55-75 nm diameters [3]. First, we discuss the thermal energy barrier (E_b) necessary for 7/21 days of data retention for L3-cache applications at different failure in time (FIT) rates. The requirement for the thermal energy barrier is given by: E_b=-*ln*[-(t_0/t_p)**ln*(1-FIT/N_b)], where, FIT is failure in time, N_b are no. of bits, t_0 is the attempt frequency (assumed to be 1ns) and t_p is desired data retention time span (7/21 days). Figure 1 shows the calculated thermal energy barrier at different FIT's and data retention spans for various sizes of cache memories ranging between 1MB to 1GB. From this Figure, it is evident that the minimum thermal energy barrier should be greater than 20 KT for 1000 FIT's and 27 KT for 0.1 FIT's. Next, we calculate the thermal energy barrier of p-MTJ device to assess whether these demands can be satisfied with shrinking MTJ diameters. For this purpose, we use standard MTJ stack consisting of CoFeB as free layer with 0.85 nm thickness and its diameter varying between 5 - 60 nm to understand the scalability aspect. We perform E_b calculations using a monodomain and domain wall assisted switching mechanism as mentioned in Ref. [2]. The thermal energy barriers are evaluated at three different values of temperature namely, 25°C (room temperature), 100°C (operational temperature) and 260°C (solder reflow temperature). The required values, saturation magnetization (Ms), uniaxial anisotropy (Ks) and exchange constant (Aex) are used as measured in the GLOBALFOUNDRIES hardware [4]. Further, their temperature dependence is computed using Kinetic Monte Carlo simulations. The calculated thermal energy barriers, with varying MTJ diameters, are plotted in Figure 2 a). The MTJ diameters are varied between 5 - 60 nm which essentially encompasses 7, 10, 14 and 22nm CMOS technology nodes. The blue, red and green curves represent the data obtained at temperatures of 25, 100 and 260°C, respectively. We observe that the lowest thermal barrier of approximately 30 KT can be achieved at 15 nm diameter for the highest solder reflow temperature. This implies that the MTJ diameter can be scaled down to 15 nm without compromising the thermal stability as required by 0.1 FIT's for 21 days. However, the energy barriers are drastically reduced below 15 nm diameter. Figure 2b) shows the switching efficiency figure of merit for p-MTJs, which is defined as the ratio of the energy barrier and switching current. Here, the critical switching current is calculated using the macrospin model described in Ref. [5]. From this plot it can be observed that the switching efficiency of MTJ saturates at smaller diameters. These diameter values, at which the switching efficiency saturates, reduces with increasing temperatures. In summary, we presented a comprehensive benchmarking of STT-MRAM for cache applications. The data shows that STT-MRAM is indeed scalable and can be integrated with advanced CMOS nodes. Our results clearly show that the thermal stability requirements for L3-cache can be met at even smaller MTJ diameters. Finally, the critical diameter at which the switching efficiency saturates is also dependent on temperature.

BI-07. Stable Bloch point in helimagnetic nanostructures containing boundary between grains with different chirality.

M. Beg[1,2], D.I. Cortés-Ortuño[2], R.A. Pepper[2], M. Bisotti[2], G. Downing[2], B. Atie[2], O. Hovorka[2] and H. Fangohr[1,2]

1. European XFEL GmbH, Schenefeld, Germany; 2. Faculty of Engineering and the Environment, University of Southampton, Southampton, United Kingdom

Dzyaloshinskii-Moriya interaction (DMI) in helimagnetic materials can give rise to a large number of different non-trivial magnetisation configurations. One of them is the magnetic skyrmion. Recent research showed that confined helimagnetic nanostructures can host ground state skyrmionic states at zero external magnetic field and in the absence of magnetocrystalline anisotropy [1, 2]. However, the epitaxial growth of thin films from which the skyrmion hosting nanostructures should be etched, are usually granular. More precisely, they contain grains with different chirality and consequently different sign of the DMI constant. One of the questions is what magnetisation configurations can emerge in confined geometries containing such boundaries (interfaces). In order to address this, we perform finite element micromagnetic simulations on a 150 nm diameter FeGe disk containing grains with different chirality. The disk consists of two layers with different chirality and consequently different sign of DMI energy constant D. We fix the thickness of the bottom layer with D<0 to be 20 nm and vary the thickness of the top layer with D>0 between 2 nm and 18 nm. For every thickness of the top layer, we relax the system starting from the uniform magnetisation configuration. We use a full three-dimensional model, do not assume any translational invariance of magnetisation, and perform full demagnetisation field computation. We show the skyrmion number S values for individual layers in Fig. 1 (a). We notice that there is a sharp decrease in the S value for both layers at approximately 8.5 nm thickness of the top layer and in Fig. 1 (b), we investigate what is the difference between these two different magnetisation configurations. For thicknesses of the top layer below 8.5 nm, the energy contribution of the top layer in the total energy of the system is too small, and because layers with different sign of D are coupled by ferromagnetic exchange interaction, the top layer follows the magnetisation of the bottom layer. More precisely, both layers have the same chirality and the same orientation of the vortex state formed in them. However, above 8.5 nm, the energy contribution of the magnetisation state in the top layer becomes significant, and the system now relaxes to the state where both layers still have the same chirality, but now different orientation. The chirality-orientation states are now in accordance with the rules for different values of D in different layers. We find that between two layers (at the interface) a stable Bloch point (BP) [3, 4] is formed at zero external magnetic field and we show its detailed structure in Fig. 1 (c). Because micromagnetic models assume constant magnetisation magnitude, the precise magnetisation configuration at the BP cannot be obtained using micromagnetic simulations [5]. However, it is known how to identify the signature of the BP in such situations: the magnetisation direction covers any sufficiently small closed surface surrounding the BP exactly once [6, 7] and we illustrate that property in Fig 1 (c). After we explored the stability of a Bloch point at the interface between two grains with different chirality, we study the hysteretic behaviour of the system. We fix the thickness of the bottom layer to be 20 nm and set the thickness of the top layer to be 10 nm. The diameter of the disk is 150 nm. We vary the external magnetic field between −1 T and 1 T in steps of 100 mT. In Fig. 2 (a), we show the average out-of-plane magnetisation component as a function of external magnetic field and the hysteretic behaviour is evident. In Fig. 2 (b) we show the states at B=0 between which we can switch using an external magnetic field. We identify two different types of Bloch points. The first one is composed of two vortices with orientations pointing to each other which results in a head-to-head BP. However, in the other state vortices point away from each other and we name this state as a tail-to-tail BP. We conclude that the confined helimagnetic nanostructure containing the boundary between grains with different chiralities undergoes hysteretic behaviour when an external magnetic field is applied. Moreover, we can switch between two different zero-field stable BP (head-to-head and tail-to-tail) using an external magnetic field. Our demonstration of the stability and hysteretic behaviour of Bloch points, apart from being of fundamental physical interest, suggests a possible use in future spintronics, data storage and processing devices. BI-08. The effect of antisite disorder on magnetic and magnetocaloric properties of Ni-Co-Mn-In alloys: ab initio and Monte Carlo studies.

V. Sokolovskiy[1], V. Buchelnikov[1] and P. Entel[2]

1. Condensed matter, Chelyabinsk State University, Chelyabinsk, Russian Federation; 2. Duisburg-Essen University, Duisburg, Germany

Nowadays, the Ni-Co-Mn-In Heusler alloys have drawn a much attention due to a series of functional properties such as the shape memory effect, giant magnetoresistance and magnetocaloric effects etc., which are promising for future technologies [1-3]. Usually, the most of unique properties are associated with the martensitic transformation between the martensite with complex magnetic order and the austenite with ferromagnetic order. Moreover, there are strong competing magnetic interactions in the vicinity of magnetostructural phase transition, which are responsible for the change in magnetization. Evidently, the manipulation of magnetic interactions in both martensite and austenite leads to change the magnitude of the magnetization drop and to achieve the better magnetocaloric properties across the martensitic transformation. The present theoretical study is addressed the question of effect of competing magnetic interactions on magnetic and magnetocaloric properties of Ni-Co-Mn-In alloys through the addition of structural defects. Evidently, samples prepared experimentally without an additional annealing can contain many impurities and defects. Opposite, the influence of additional annealing can result to a highly ordered structure with minimum defect concentration. In this connection for compositions without additional annealing, we focused attention on the formation of structural (antisite) disorder between In and Mn atoms on the corresponding In and Mn sublattices with concentration *y* (which can be described by $Ni_2Mn_{1+x}In_{1-x}$ = $Ni_2Mn_{1-y}Sn_yMn_{x+y}In_{1-x-y}$, where *x* is the Mn excess concentration and *y* is the degree of antisite disorder) [4]. While for the samples upon additional annealing, the ordered structure (without defects, $y = 0$) is proposed. Our methodology consists of ab initio calculations and Monte Carlo (MC) simulations based on the Potts-Blume-Emery-Griffiths model allowing to simulate austenite-martensite transformation as well as magnetic and magnetocaloric properties [5-7]. Two subsequent steps were used in our calculations. Firstly, we calculated the exchange coupling constants (J_{ij}) using the SPR-KKR package [8] within the general gradient approximation in the form of Perdew-Burke-Ernzerhof. The chemical and structural disorders were simulated in the coherent potential approximation. The *Jij* calculations were done for cubic austenite (c/a = 1) and tetragonal martensite (c/a = 1.21) of $Ni_{43}Co_7Mn_{37+y}In_{13-y}$. Here, *y* takes values as follows: 1.5, 3.25, and 6.5. We note that the equilibrium lattice parameters for austenite and martensite were taken from our previous calculations (See Ref. [7]), and we supposed that lattice parameters change no with increasing degree of anisate disorder (*y*). Secondly, using the calculated exchange constants as a function of distance between interacting atoms, the MC simulations were performed. The model lattice that contains a real unit cell of Heusler alloy includes 3925 atoms with periodic boundary conditions. The configurations of excess Mn atoms (x + y) at the In sublattice and In atoms (y) at the Mn sublattice are chosen randomly and the total number of Mn and In atoms are fixed by a nominal composition $Ni_{43}Co_7Mn_{37+y}In_{13-y}$ (y = 1.5, 3.25, and 6.5). The MC simulations were performed using the Metropolis algorithm and 500 000 MC steps. Note that all model parameters expect the magnetic moments and J_{ij} constants were fixed and taken from [7]. Let us discuss the effect of additional annealing in the framework of theoretical approach assuming the presence of antisite disorder between In and Mn sublattice in $Ni_{43}Co_7Mn_{37}In_{13}$ alloy. In Fig. 1a we present calculated nearest exchange coupling constants for austenite of $Ni_{43}Co_7Mn_{37+y}In_{13-y}$ as a function of antisite defect concentration. As can be seen that all interactions with Mn_1 (Mn_2) atoms decrease (increase) with increasing *y*, respectively. Here $Mn_{1(2)}$ atoms denote Mn atoms located at Mn (In) sublattice, respectively. This observation is associated with the fact that the number of Mn_1 atoms becomes smaller with an increase of antisite disorder. MC simulations of thermomagnetization curves for $Ni_{43}Co_7Mn_{37+y}In_{13-y}$. (y = 0 and 1.5) in magnetic field of 2 T under the heating and cooling protocols are shown in Fig. 1b. The inset contains the M(T) curves for $Ni_{43}Co_7Mn_{37+y}In_{13-y}$ under heating. Thermal hysteresis between M(T) curves around the magnetostructural phase transition for the heating and cooling processes is clearly seen. Moreover, both the magnetization and Curie temperature of austenite are found to decrease compared to the ordered case (y = 0) with increasing degree of structural disorder. Generally, theoretical magnetization trend as a function of antisite disorder is provided by the recent experiments for both ordered and disordered $Ni_{50}Mn_{34.5}In_{15.5}$ alloys [9, 10]. In the framework of theoretical approach involving first-principles and Monte Carlo methods, a set of magnetization curves for the studied system are calculated. It is shown that the account of structural disorder (anti-site defects) results to decrease the magnetization and magnetocaloric properties around the magnetostructural transformation. Magnetization switching in nanoparticles and thin-films is the fundamental issue to deal with in order to obtain high speed and energy-efficient recording devices[1]. The optimization of switching mechanisms is constrained in the framework of the so-called magnetic recording trilemma. On one hand, one would like to have the magnetized bit occupying a smaller area on the recording medium and, at the same time, magnetization remaining stable over long enough time for reliable data retention. These two constraints are competing since thermal stability decreases with decreasing active volume of the magnetic bit. On the other hand, circumventing this issue would require higher coercivity of the magnetic material and, consequently, larger current feeding the write head. However, the maximum current amplitude is constrained by technological limits in the realizations of the pole tips and, thus, one cannot meet the aforementioned requirements. For these reasons, several strategies have been investigated in the last decades to realize fast magnetization switching with greater efficiency, such as microwave-assisted switching[2] and precessional switching[3]. In particular, the latter occurs through the application of a field transverse to the initial magnetization and yields much smaller switching times than conventional switching[4], [5]. However, to achieve successful switching, an extremely precise design of the field pulse is needed to switch off the field at the right moment [6]. Then, the equilibrium magnetization is reached after a relaxation from a high-to low-energy state[7]. This mechanism is probabilistic even when thermal fluctuations are neglected, due to multistability and small dissipation in magnetization dynamics[8]. When also thermal fluctuations are considered, the stochasticity of the switching process is even more pronounced[3]. On the other hand, magnetic recording devices must undergo strict reliability requirements in terms of extremely low write-error rates, which can be realized at expense of the speed of the write process. In this paper, we theoretically analyze the magnetization switching for a single magnetic grain of the recording medium subject to the write head field pulses and room temperature thermal fluctuations, as it is the case of perpendicular magnetic recording. This situation, in the absence of thermal fluctuations and for special symmetry of the magnetic particle, has been studied in a pioneering paper[9] and is referred to as damping switching. In this paper, by using analytical techniques, we derive expressions for the switching times distribution functions in terms of material, geometrical and external field properties. These analytical results provide a tool to quantify the write-error rates as function of design parameters, which may help the optimization of switching processes. To this end, we consider the Landau-Lifshitz-Gilbert (LLG) equation augmented with a thermal field of stochastic nature[10], whose intensity is given by the fluctuation-dissipation theorem. We assume that the magnetization is spatially-uniform during the dynamics, so that the magnetic particle can be described within a macrospin approximation. In the absence of excitation, the energy barrier separating the equilibria is much higher than the thermal energy. This hypothesis is suitable when the uniaxial anisotropy is large enough as it is the case for magnetic recording grains. The external field pulse amplitude is assumed to be above the critical switching field of the device. In this situation, the switching time can be evaluated considering the deterministic magnetization motion acting on a random initial magnetization distribution due to thermal fluctuations. In the absence of external field, the magnetization is distributed according to the stationary solution of the Fokker-Planck equation, which can be simply expressed in terms of the small tilting angle θ ($\sin\theta \approx \theta$) with respect to the particle's easy axis. Then, considering a rotationally-symmetric particle (z is the symmetry axis) and neglecting the thermal fluctuations during magnetization evolution, the LLG equation can be integrated by separation of variables[9] in order to determine the switching time t_s defined as the time interval between the application of the field pulse (the initial z-component of the magnetization is m_{z0}) and the time instant where the z-component of the magnetization is equal to a given value m_{zf}. By using appropriate derivation (details will be given in the full paper), it can be shown that the relationship $t_s(m_{z0},m_{zf})$ allows one to derive the probability and cumulative distribution functions for magnetization switching times as function of geometrical, material and excitation parameters. Such functions can be used to compute the write error-rate of the switching process for given switching duration t_s. The analytical predictions are compared with macrospin and micromagnetic simulations of magnetization switching (an example computation for a circular nanodot with 30nm diameter, 1nm thickness and perpendicular anisotropy is reported in fig. 1) in order to show the effectiveness of the approach.

BI-10. *Ab initio* prediction of giant perpendicular magnetic anisotropy at Fe/$CuIn_{1-x}Ga_xSe_2$ interface.

K. Masuda[1], S. Kasai[1], Y. Miura[1,2] and K. Hono[1]
1. National Institute for Materials Science (NIMS), Tsukuba, Japan;
2. Electrical Engineering and Electronics, Kyoto Institute of Technology, Kyoto, Japan

Perpendicular magnetic anisotropy (PMA) at the interface between ferromagnetic and barrier layers is an essential property in magnetic tunnel junctions (MTJs) to realize sufficient thermal stability and low critical current in non-volatile spin transfer torque magnetic random access memories (STT-MRAMs) [1]. The PMA is also advantageous for reducing write error rates in voltage-controlled MRAMs [2].Therefore, it is of importance to find heterostructures which give rise to stronger interfacial PMA. Up to now, strong interfacial PMA has been observed in heterostructures consisting of ferromagnets (FMs) and insulator MgO. Ikeda *et al*. obtained a large interfacial anisotropy constant K_i of ~ 1.3 mJ/m^2 at the interface of CoFeB/MgO [3]. In a subsequent work, Koo *et al*. observed higher interfacial PMA with K_i ~ 2.0 mJ/m^2 in Fe/MgO [4]. However, no previous studies have reported such strong interfacial PMA on heterostructures with non-MgO barrier layers. Recently, Kasai *et al*. succeeded in fabricating novel MTJs where semiconductor $CuIn_{0.8}Ga_{0.2}Se_2$ (CIGS) is sandwiched between ferromagnetic Heusler alloys [5]. They observed both high magnetoresistance (MR) ratios and low resistance-area products (*RA*), which are also required for MRAM and hard disk drive (HDD) applications. In particular, when we consider the application of this MTJ to STT-MRAM cells, the possibility of obtaining high interfacial PMA should be investigated; however, no theoretical and experimental studies have focused on this issue. In this work, we theoretically studied interfacial magnetocrystalline anisotropies in various Fe/semiconductor(001) heterostructures including Fe/$CuIn_{1-x}Ga_xSe_2$(001). As semiconductor barriers, 14 types of semiconductors were considered in the present study (see Fig. 1 for details). We calculated values of K_i in these heterostructures by means of first-principles calculations based on density-functional theory, which is implemented in the Vienna *ab initio* simulation program (VASP). We first prepared supercells composed of 7 layers of Fe and 17 layers of the semiconductor barrier. Since quite thin Fe electrodes are used in experiments on PMA, we fixed the in-plane lattice constant of each supercell to the experimental lattice constant of the barrier. In all the supercells, we confirmed that Se, S, or As layer is energetically favored as the termination layer of the semiconductor barrier. In addition, all the atomic positions and the distance between ferromagnetic and barrier layers were optimized so that the total energy of the supercell is minimized. The values of K_i were calculated using the force theorem as $K_i = (E_{[100]}-E_{[001]})/2S$, where $E_{[100]}$ ($E_{[001]}$) is the sum of the eigenenergies of the supercell for the magnetization along the [100] ([001]) direction, S is the cross-sectional area of the supercell, and the factor 2 reflects the fact that two interfaces are included in the supercell. From this definition, a positive (negative) K_i shows the tendency toward perpendicular (in-plane) magnetic anisotropy. We used 10×10×1 k points to calculate total energies of the heterostructures with chalcopyrite semiconductors. We used more k points for other heterostructures owing to their smaller supercell sizes. Figure 1 shows the values of K_i obtained for various Fe/semiconductor systems. For comparison, we also show K_i for Fe/MgO(001) with a similar barrier thickness. It is found that most of the Fe/semiconductor systems investigated in this study have positive K_i. Particularly, Fe/$CuInSe_2$ has the largest K_i of 2.305 mJ/m^2, which is about 1.6 times as large as that of Fe/MgO (1.396 mJ/m^2). In Fig. 1, we also show the values of anisotropy of orbital magnetic moment $\Delta M_{orb,i}$ at interfacial Fe atoms. By comparing K_i and $\Delta M_{orb,i}$, we see that Bruno's relation ($K_i \alpha \Delta M_{orb,i}$) holds for almost all the systems considered in this study. This implies that the interfacial PMA in the present systems comes from the structure of the minority-spin local density of states (LDOS) of interfacial Fe atoms [6]. Figure 2 shows the projected *d*-orbital LDOSs of interfacial Fe atoms in Fe/$CuInSe_2$. We find some sharp peaks in the minority-spin LDOSs both just above and just below E_F, which enable excitations with quite small energies. In addition, these peaks have favorable *d*-orbital components for yielding large PMA [6]. These features are consistent with the largest K_i in Fe/$CuInSe_2$. Furthermore, we revealed that the positions of Se atoms at the interface is the key for such favorable *d*-orbital components in the LDOSs [6]. In summary, using *ab initio* calculations, we predict the largest K_i of 2.305 mJ/m^2 for Fe/$CuInSe_2$, which is about 1.6 times as large as that of Fe/MgO (1.396 mJ/m^2). Thus, Fe/$CuInSe_2$/Fe MTJ may be suitable for application as perpendicular MTJ for high capacity MRAM application with a small cell size. 1. Corporate R&D Center, Toshiba Corporation, Kawasaki, Japan

In recent years, writing data in magnetic random access memory (MRAM) utilizing voltage controlled magnetic anisotropy (VCMA) has attracted much attention for its potential low power consumption [1]. We proposed voltage-control spintronics memory (VoCSM) which had high-efficient and deterministic writing properties [2]. In order to realize those memories, three features of a large VCMA, a large surface anisotropy Ks, and a large tunneling magnetoresistance (TMR) should coexist. In addition, a large spin-Hall angle is a must for VoCSM. Many challenges based on MgO tunneling barrier/ferromagnetic layer (FL) such as CoFeB thin films combined with various materials as an insertion layer at the MgO/FL interface or as an underlayer of FL showed improved VCMA but were concerned to fail in the coexistence of the feature because of very thin storage-layer or degraded lattice growth between MgO and CoFeB [3], [4], [5]. As a result, none of them have had a practical meaning as a memory cell so far. In this study, the experiments were conducted in which the insertion position of Ir was changed in MgO/CoFeB/Ta thin films. Each of the interface layer, the interlayer and the underlayer of Ir showed an increase in VCMA, and the largest VCMA was obtained in the case of inserting the Ir interlayer into the CoFeB layer. In addition, both the resistance-area product (RA) and TMR ratio decreased greatly when using the Ir interface layer, but clearly improved by employing the Ir interlayer. The base multilayer structure for VCMA measurement was Ta (5 nm)/MgO (~3 nm)/CoFeB (1–2 nm)/Ta (5–8 nm), which was deposited on a thermally oxidized Si substrate. The CoFeB layer was set to in-plane magnetization, and the base stack of IrMn/CoFe/Ru/CoFeB /MgO/CoFeB/Ta with a reference layer was prepared for RA and TMR measurement by using current in-plane tunneling (CIPT). The multilayers for VCMA were patterned and etched into the device size with one side of 3 to 50 μm and their hysteresis curves were measured using the magneto-optical polar Kerr effect. The effective perpendicular magnetic anisotropy field Hk_{eff} of the CoFeB layer was measured while bias voltage was applied to the device, and the variation of Ks depending on the electric field E was evaluated as the VCMA coefficient. Figure 1 shows the VCMA coefficients (–dKs/dE) of the MgO/CoFeB/Ta thin films as the “Base” sample, “Interface” sample in which Ir (0.2 or 0.3 nm) is layered at the MgO/CoFeB interface, “Interlayer” sample in which Ir (0.3 nm) is inserted in the middle of the CoFeB layer, and “Underlayer” sample in which Ir (0.5 nm) is formed between the CoFeB and the Ta layer. All coefficients of the “Interface”, “Interlayer”, and “Underlayer” samples increased more than that of the “Base” sample in terms of each average value, although each coefficient had a certain degree of dispersion. The Ks in the “Interface” sample also increased more than in the “Base” sample at each average value, however, the largest Ks (maximum of 2.2 erg/cm^2) and VCMA (maximum of 190 fJ/Vm) were obtained in the “Interlayer” sample. The relationship between RA and TMR ratio in the MTJ samples similar to Fig. 1 with the reference layer is plotted in Fig. 2. Both RA and the TMR ratio in the “Underlayer” sample were almost the same as those in the “Base” sample, but both decreased in the “Interface” sample and further decreased by increasing the Ir layer thickness from 0.2 to 0.3 nm. In the “Interlayer” sample, the deterioration of RA was not observed, and although the TMR ratio decreased, it still showed a high value of more than 120%. By comparison at the Ir thickness of 0.3 nm, it can be seen that both RA and TMR are clearly improved by changing from the Ir interface layer to the Ir interlayer. In summary, we successfully found the practical MTJ structure as a memory cell which realized coexistence of a large VCMA, a large Ks, and a large TMR for the first time. The structure is expected to have a large spin-Hall effect as well. This work was partly supported by the ImPACT Program of the Council for Science, Technology and Innovation (Cabinet Office, Government of Japan).

Ionic liquid (IL) gating on functional oxide has drawn significant attention, since it can provide reversible changes in carrier concentration (~10^{14} cm^{-3}) at the interface, permitting the manipulation of electrical and magnetic properties via a low voltage [1-3]. In this work, we demonstrate the electric-field manipulation of transport properties in the dilute magnetic oxide (DMS) of $Zn_{0.98}Mn_{0.02}O$ (MZO) using an electric-double-layer transistor (EDLT) geometry through IL of N,N-diethy1-N-(2-methoxyethy1)-N-methylammonium (DEME+) and bis(trifluoromethylsulfony1)-imide (TFSI-). By the application of different gate voltages (V_g) through the top electrolyte, the accumulated and depleted charge carrier in the MZO channel lead to a reversible control in the transport phenomena at the interface. 10 nm-thick MZO thin films were deposited on (0001) Al_2O_3 single crystal substrates by pulsed laser deposition. The growth of MZO films was conducted at 300^{o}C with an oxygen pressure of 5 x10^{-4} Pa. To study electrical-field manipulation of MZO devices, the films were patterned into Hall bar patterns (channel width: 50 μm, channel length: 110 μm) by photolithography and wet etching using dilute HCl as etchants. Au (50 nm)/Ti (5 nm) coplanar electrodes for IL and contact electrodes for MZO were prepared by electron beam evaporation. Prior to the gating experiment, IL was baked at 80 ^{o}C in a high vacuum chamber to get rid of water contamination. A drop of IL was placed on the top of the as-grown film, serving as the top gate electrode. The devices were immediately cooled down to 230 K for the gating process. By applying different V_g (-2, 0 and 2 V), the charge carriers were accumulated and depleted in the channel surface. Then the devices were immediately cooled down to 180 K (below the freezing point of IL at 230 K) before V_g was removed. After the transport measurements, the devices were heated up to 230 K before changing the V_g for another measurement. Fig. 1 illustrates the profile of the longitudinal resistance (R_{xx}) of MZO EDLTs with alternating V_g between -2 and 2 V at 230 K. R_{xx} increases (decreases) sharply upon the application of V_g = -2 V (2 V), which is consistent with the scenario of accumulated (depleted) electron charge carrier at the MZO interfaces [4]. Such modulations of R_{xx} are due to electron charge movement in MZO rather than the contribution of gate current: the drain-source current is higher than the gate-source current by at least two orders of magnitude. Magnetotransport behavior of MZO at 10 K after the application of different V_g (-2, 0 and 2 V) are shown in Fig. 2, which shows the magnetoresistance (MR) with out-of-plane applied field for MZO EDLT. Here MR is defined as MR=(R_{xx}(H)-R_{xx}(0))/R_{xx}(0), where $R_{xx}(H)$ and R_{xx}(0) are the R_{xx} values with external magnetic fields of *H* and zero, respectively. The peak positive MR increases from 0 to 1.8% and the negative-MR (measured at 9 T) decreases from –4.5% to -0.6% when V_g increases from -2 to 2 V. Enhancement in positive MR in the low field regime (<1 T) implies that the ferromagnetic state of MZO is enhanced, as the electron carrier concentration in MZO increases upon switching the V_g from -2 to 2 V [5]. The present results, therefore, demonstrate controllable movement of anions and cations in IL by electric-field effect plays an important role in the manipulation of magnetism in the MZO. Financial support by RGC, HKSAR (PolyU 153015/14P) and PolyU (1-ZE25) are acknowledged.

Introduction Utilizing highly spin-polarized materials is a key to enlarge tunnel magnetoresistance (TMR) ratio of a magnetic tunnel junction (MTJ) and therefore, half metallic materials have been eagerly studied for decades. Among the various candidate substances of half metals, magnetite (Fe_3O_4) is attractive because of its high Curie temperature of ~850 K. Although much efforts had been paid for fabricating MTJs with Fe_3O_4 electrodes, the reported TMR ratios were not as high as ones expected for its half metallicity[1]. The origin of the significantly lower TMR of the MTJs with Fe_3O_4 electrodes is still controversial, but the characteristic film growth of $Fe_3O_4(001)$, particularly generation of high-density anti-phase boundaries (APBs) in $Fe_3O_4(001)$, could significantly reduce the local spin polarization at the interface. In order to solve the issue, building an all-spinel-type epitaxial MTJ by introducing a magnesium-aluminate $MgAl_2O_4$ tunnel barrier would be effective. Since ultra-thin $Fe_3O_4(001)$ films on $MgAl_2O_4(001)$ show the fewer anti-phase boundaries[2], we can simply expect to improve the microstructure at $Fe_3O_4(001)$ and $MgAl_2O_4(001)$ interfaces. In this study, we developed the growth technique of a fully epitaxial $Fe_3O_4/MgAl_2O_4/Fe_3O_4(001)$ structure by optimizing reactive sputtering method. Experiment We deposited $Ru(10)/Co(14.4)/Fe_3O_4(21.2)/MgAl_2O_4(3)/Al(0.3)/Fe_3O_4(127.2)$/substrate (thickness in nm) films on MgO(001) substrates. All the oxide layers were deposited by a reactive RF magnetron sputtering technique and the metal layers were deposited by a DC sputtering technique. The $MgAl_2O_4$ barrier with a nominal thickness of 3 nm was deposited at room temperature (RT). Both the top- and bottom-Fe_3O_4 electrodes were deposited at 573 K. The thin Co layer was deposited on the top Fe_3O_4 electrode to obtain different coercivities between the top and bottom electrodes. During the deposition, the surface structures were monitored by reflection high energy electron diffraction (RHEED). Magnetization(M)-magnetic field(H) curves of the MTJ stacks as well as a single Fe_3O_4 layer on an MgO(001) substrate were measured at RT. The magnetic field was applied along in-plane easy axis of [110] of Fe_3O_4. The film was patterned into ellipsoidal pillars (size: 20x10 mm^2) by photolithography and Ar ion milling. Magnetotransport properties were characterized by a DC four-probe method at RT. Results and discussion Figure 1(a) shows the RHEED pattern of the MgO(001) substrate. The spacing between the streaks indicated by the arrows corresponds to the lattice spacing of MgO (a~0.4 nm). Figures 1 (b), (c), and (d) show the patterns of bottom Fe_3O_4, $MgAl_2O_4$ barrier, and top Fe_3O_4, respectively. They indicate that the epitaxial growth of the electrodes and the barrier; therefore, an all-spinel structured MTJ was achieved. From the MH-curve of the single Fe_3O_4 on MgO(001), the saturation magnetization M_s of Fe_3O_4 was estimated to be 463 kA/m, comparable to the bulk value (480 kA/m) within an experimental error. Figure 2 shows the MH-curve of the MTJ stack. Both top and bottom electrodes showed sharp and independent magnetization reversal, and thus magnetically parallel/antiparallel configurations were realized. This behavior is in contrast to the results in most of previous reports, where an incomplete magnetic separation in MTJs was observed. Therefore, the achievement of the all-spinel MTJ using an $MgAl_2O_4$ barrier may promote the formation of high crystallinity and small interfacial flatness of an MTJ. However, the $MgAl_2O_4$ barrier of this MTJ stack is too thick to evaluate its TMR ratio due to its very large resistance-area-product (RA) > 20 GΩ●μm^2. The inset of Fig. 2 shows a typical current-voltage (IV)-curve of the MTJ. The nonlinear IV curve indicates the tunneling behavior of the $MgAl_2O_4$ between the Fe_3O_4 electrodes. Using the Simmons model[3], the effective barrier height and the effective thickness were estimated to be 1.1 eV and 2.4 nm, respectively. The barrier height is smaller than the reported values of $MgAl_2O_4$ (2-3 eV)[4], indicating that further improvement in the $MgAl_2O_4$ crystallinity may be needed for good spin-dependent transport properties. Summary In this study, we developed an all-spinel-type MTJ structure with $MgAl_2O_4$ and Fe_3O_4. The RHEED patterns indicated that both the $MgAl_2O_4$ and Fe_3O_4 were epitaxially grown with a spinel structure. In addition, the good magnetization process between top- and bottom-$Fe_3O_4(001)$ layers was demonstrated. Since a TMR ratio could not be evaluate due to the significantly large RA, further optimization of each film thickness and growth condition is necessary. This study suggests that the use of an all-spinel structure will be promising for improving microstructures of Fe_3O_4-based MTJs toward better TMR performance.

I. Introduction The scarcity of room-temperature multiferroics has led researchers to develop two-phase magnetoelectric (ME) composites combining the ferroelectric and ferromagnetic phases via strain engineering [1, 2]. However, the process is involved in high temperature sintering and may create defects and diffusion, which will hamper their practical use. Recently, a new tunnel-type magneto-dielectric (TMD) effect was discovered by our group at room temperature [3]; this provides new dawn for ME effect, which is caused by the oscillation of the charge carriers between super-paramagnetic granules in films. Nevertheless, the reported TMD ratio ($\Delta\varepsilon'/\varepsilon'_0$), to date, attained 3% under magnetic field $H = 10$ kOe [3]. Even though we have realized the low-field enhancement of TMD effect in a two-dimensional Co/AlF granular nanostructures [4], the TMD response is still far from satisfactory and their further enhancements remain an open question. Here, we have, for the first time, realized large enhanced TMD response (3.7% at $f =$ 15 kHz) in Co–MgF_2 granular nano-composites by means of nonmagnetic Si dopant. This work may be of importance in high-performance ME device applications. II. Experimental The Co–MgF_2 films with different concentration of Si (x) were deposited on Si(100) and Pt/Ti/SiO_2/Si substrates by a triple-source magnetron sputtering method in a sputtering Ar gas pressure of 0.5 Pa, wherein the Co target, MgF_2 target and Si target were used. Film thickness was regulated at ca. 350 nm and Si concentration (x) was regulated in the range of 0–3.7 at. %. HAADF–STEM was used for structural characterization. Chemical compositions and state of all samples were analyzed by XRF and XPS, which revealed a stoichiometric MgF_2 matrix and Co granule contents of *ca.* 16 at. %. Magnetic, dielectric and magneto-dielectric properties were measured by VSM and LCR meters. III. Results and discussion The Co–MgF_2 film shows a nano-granular structure, wherein the bright areas correspond to Co granules because of its high Z number, and the areas with the dark contrast is probably related to Mg–fluorides (MgF_2) (Fig. 1a). To verify this suggestion and analyze the dispersion of Si, EDX mapping and spectra for several granules are shown in Figs. 1(b–e), indicating that there is an ubiquitous match between Co and Mg, and the Si is distributed uniformly. XPS spectra has confirmed the pure Si instead of Si-oxides in as-deposited samples. Frequency dependence on the real part of dielectric constant (ε'_0) show that there is no obvious change in ε'_0 as increasing the Si content. With the application of magnetic field $H = 10$ kOe, there is a slight increase in ε'_0, denoted as positive TMD ratio $\Delta\varepsilon'/\varepsilon'_0$. $\Delta\varepsilon'/\varepsilon'_0$ of the Co–MgF_2 films retains at 0.7%, and it increases to a maximum value of 3.7% with small Si addition of 0.7 at.% (Fig. 2a). Further increasing the Si content led to a decrease in $\Delta\varepsilon'/\varepsilon'_0$, concluding that there exists an optimum Si dopant content for a given Co content. By fixing the frequency of ac field to 15 kHz, magnetic field dependence of $\Delta\varepsilon'/\varepsilon'_0$ is shown in Fig. 2b. A gradual increase in $\Delta\varepsilon'/\varepsilon'_0$ with the application of magnetic field is observed. It is noted that samples with $x = 0.7$ has largest magnetization values ($M_s = 1.4$ kG). We may infer that the enhanced $\Delta\varepsilon'/\varepsilon'_0$ by means of Si dopant is related to the increase in magnetization values, which is probably caused by the change in the size and atomic ordering of magnetic granules. This study offers a new route for high room temperature magneto-dielectric response in nano-composites and may have potential application in spintronic devices.

BP-05. Giant zero-biased magnetoelectric coupling characteristics in flexible Metglas/poly(vinylidene fluoride) heterostructures.

Y. Long[1], *J. Qiu*[1], X. He[1], Q. Chang[1], Z. Hu[1] and H. Liu[1]
1. College of Optoelectronic Engineering, Chongqing University, Chongqing, China

Magnetoelectric (ME) effect have intrigued dramatic research interests in the past decades, owing to its potential applications in a large number of new multifunctional devices, including magnetic storage, energy harvesters, magnetic field sensors, transformers, and microwave devices, among other. [1,2] It exists in materials by different principles: through the elastic coupling between magnetostrictive and piezoelectric phases (in ME composites) or through the coupling of electric dipole and magnetic moment (in single-phase ME material). In general, ME single-phase materials are not suitable to be utilized in technological application, owing to their low ME response which typically occurs at low temperatures. Compared with single-phase ME materials, ME composites have exhibited commendable ME coupling characteristic at room temperature. Furthermore, among ME composites, laminates show the largest ME response, thus being the most suitable structure for industrial applications. However, in spite of laminated ME composites have shown high ME conversion coefficient and strong ME responses, the external dc bias magnetic field (H_{dc}) is indispensable due to the saturation magnetostrictive coefficient of magnetostrictive material can be obtain only under a high H_{dc}, which will improve production costs and increase technical difficulty in industrial production. To overcome these shortcomings, some researchers have focused on zero-biased ME composites. In particular, Mandal *et al*. have reported zero-bias ME coupling for samples of PZT and magnetization-graded ferromagnetic layers, the grading in the magnetization is achieved with the use of Ni and Metglas. [3] Chen *et al*. demonstrated that a multiferroic heterostructure consisting of piezoelectric ceramic PZT, giant magnetostrictive material Terfenol-D, and different thickness soft magnetic alloy FeCuNbSiB shows an enhancement in the ME coefficient at zero bias. [4] Although those works have investigated zero-biased ME response of the laminates, they require complicated synthesis process. Moreover, conventional ceramic based laminated ME composites consisting of piezoelectric ceramics (e.g., PZT and (PMN-PT)) are usually fragility, non-bendable, fatigue, and expensive, which do not meet the increasing industry demands in terms of flexibility, complicated shape, and cost, hindering them from being used in rapidly growing technological areas such as wearable devices. Bearing these in mind, in this paper, the flexible zero-biased laminated ME composites consisting of FeSiB (Metglas)/poly(vinylidene fluoride) (PVDF) is presented, whose zero-biased ME coupling characteristics and ME sensing performance have been investigated. The optimum size of composites have determined by optimizing the resonance magnetoelectric voltage coefficient, αME,r, values. It is found that an appropriate size of composites is propitious to the zero-biased ME coupling characteristics due to the demagnetization effect. In addition, to evaluate the ability of composites to be used in bend status, the relationship between the resonant MEVC with H_{dc} under different bend conditions have also been investigated, for which have never been or just partially discussed. As shown in Fig. 1, the zero-biased resonant MEVC showed an attenuation of approximately 76%, with increasing θ up to 50°. Although the zero-biased resonant MEVC shows substantial decline under bend status, it still has very large value. Meanwhile, the proposed composites also have a commendable ac magnetic field (H_{ac}) sensing performance. The induced zero-biased ME voltage have an excellent linear relationship to ac magnetic field both at the low frequency (1kHz) and the resonant frequency (57.3kHz) as shown in Fig. 2. Obviously, it clearly indicated that the proposed zero-biased FeSiB/PVDF composite have great potential of being applied to wearable devices.

BP-06. Study of magnetic and electrical properties of $Zn_{0.9}Mn_{0.1}Fe_2O_4$-$BaTiO_3$ multiferroic composites.

A. Farheen[1] and R. Singh[1]
1. School of Physics, University of Hyderabad, Hyderabad, India

Generally, magnetic and electric dipoles are mutually exclusive in crystalline materials. But the composite multiferroics offers a way to attain magnetic and ferroelectric ordering simultaneously. Also, the composites are important for the advancement of magneto-electronic devices, magnetoelectric sensors, random access memory, etc. [1]. In the present work, the room temperature multiferroic property was verified through magnetic hysteresis (M(H)) and ferroelectric hysteresis (P(E)) loop measurements. The composites (1-x) BaTiO3+(x) Zn0.9Mn0.1Fe2O4 (x = 0, 0.10, 0.20 and 1) were synthesized by using the nanoparticles of Zn0.9Mn0.1Fe2O4 (ZMF) and BaTiO3 (BTO) by sintering at 1200°C for 6 hours. The nanoparticles of BTO and ZMF were synthesized by hydrothermal method and by co-precipitation method respectively as described in our earlier works [2,3]. The crystal structure of the nanoparticles of ZMF and BTO are cubic spinel and tetragonal phase respectively as confirmed by X-ray diffraction (XRD) analysis (Fig.1a). The XRD of the composite (x = 0, 0.10, 0.20 and 1) samples confirm the co-existence of BTO and ZMF phases. It is observed from the field emission scanning electron microscope (FESEM) micrographs (fig.1a inset) that the composite system consists of two kinds of regions: one corresponds to ferromagnetic (FM) phase and the other one to ferroelectric (FE) phase. Fig. 2(a) shows the magnetization vs. magnetic field (M(H)) plots for the FM-FE composites at 300K with x = 0.10, 0.20 and 1 respectively. An increase in magnetization is observed with the inclusion of ZMF. The samples exhibit magnetic hysteresis behaviour with very low coercivity values indicating their soft ferromagnetic nature with much lower magnetization value than pure ZMF (inset of Fig. 2(a)). This indicates the existence of non-magnetic FE phase along with FM phase. The ferroelectric particles surrounding the magnetic particles influence the magnetic coupling among the magnetic particles. The presence of M(H) hysteresis loop confirms the magnetic ordering in the FM-FE composites. Fig. 2(b) shows the change of saturation magnetization (Ms) and coercivity (Hc) as a function of ZMF percentage (x %) for all the FM-FE composites. The gradual increase in Ms-values with the increase in ZMF content indicates that the Ms-values for the composites follow the mixture rule. Therefore, the magnetic response of composites depends on ZMF percentage [3]. Also, the increase in coercivity observed with decreasing ferrite percentage may be due to the diamagnetic nature of BTO. The observed multiple resonance in the ferromagnetic resonance (FMR) spectra (Fig.2(c)) of the composites is attributed to the coexisting magnetic states of the cations and cation distribution between A and B sublattices of spinel ferrites. It can also be attributed to the presence of heterogeneities in the composites. The decrease in resonance field (Hr-value) is related to the increase in internal magnetic field which indicates the increase in magnetic response with increasing ZMF percentage. Fig. 1(b) shows the ferroelectric hysteresis (P(E) loop) at room temperature for FM-FE composites (x=0.10 and 0.20). The shape of P(E) loop confirms the ferroelectric ordering of the composites at room temperature. The positive curvature of the P(E) loop shows that the leakage current contribution is minimal. The remnant polarization and coercive field increases with increase in ZMF percentage. Since in the FM-FE composites, the ferroelectric grains are surrounded by the ferrite grains or vice versa. Therefore, the heterogeneous microstructure may be a possible reason for alteration in the interaction among the internal poles of the FM-FE composite. The FM-FE composites show a decrease in dielectric constant (ε) value (solid lines in fig.1c) with an increase in dielectric loss (tan δ) (symbol lines in fig.1c) with an increase in ZMF-content. It is observed that the dielectric constant and loss values decrease with increasing frequency approaching to a lower saturation value at high frequencies. The variation of ε-value with frequency is attributed to the fact that the electric dipoles are unable to follow the fast alternate electric field oscillations under high frequencies. At lower frequencies, the FM-FE composites have higher ε and loss values. The FE-FM distribution makes two types of inter grain connectivity impling two types of ionic relaxations in the low frequency region confirming the results from FESEM micrographs. It is clear from the results that magnetic, electric and dielectric properties of composites strongly depend on the microstructure of the sample. And the multiferroic properties of ferromagnetic-ferroelectric composites are due to the induced electric polarization in the magnetic order or vice versa.

BP-07. Theory of electrically tunable thin-film electromagnetic crystals based on a coplanar waveguide.

A.A. Nikitin[1,2], A. Nikitin[1,2], A.B. Ustinov[1], E. Lähderanta[2] and B.A. Kalinikos[1]

1. Physical Electronics and Technology, St. Petersburg Electrotechnical University, St. Petersburg, Russian Federation; 2. Laboratory of Physics, Lappeenranta University of Technology, Lappeenranta, Finland

Artificial magnetic materials with a spatial periodic modulation of their physical properties or geometry, known as magnonic crystals, are promising for new microwave devices such as phase shifters [1, 2], various spin-wave logic elements [3, 4], high-sensitivity magnetic sensors [5, 6], and others [7, 8]. Recent advances related to the thin-film technology have resulted in fabrication of the multilayered *multiferroic structures* that combine advantages of the ferrites and ferroelectrics. Owning to the dual tunability of wave spectra by both electric and magnetic fields, such structures were widely used in microwave devices [9]. Different kinds of ferrite-ferroelectric all-thin-film structures were suggested based on coplanar or slot transmission lines [10-12]. In these structures, spin-electromagnetic waves (SEW) are originated from the electrodynamic coupling of the electromagnetic wave propagating in the transmission line with the spin waves (SW) propagating in the ferrite film. However, up to now the periodic multiferroic structures based on coplanar waveguides (CPW) were investigated only experimentally [10]. The purpose of this work is to develop a theory of hybridized spin-electromagnetic waves in the thin-film regular and periodic multiferroic waveguiding structures based on CPW. In order to distinguish the *periodical* multiferroic waveguides from known ferrite magnonic crystals, as well as from photonic crystals, below we name them as *electromagnetic crystals* (EMC). A studied EMC structure is shown in Fig. 1. It is composed of several layers enumerated with index j, namely, a sapphire substrate ($j = 1$), a barium strontium titanate (BST) ferroelectric film ($j = 2$), an epitaxial yttrium iron garnet (YIG) film ($j = 3$), and a gadolinium gallium garnet substrate ($j = 4$). The periodic segments of the CPW form the thin-film EMC. Here the central metal strip of width h and two conducting ground planes are positioned in the plane z between *ferroelectric* and *ferrite* layers. The segments of narrow w_1 and wide w_2 slots has the period Λ. Application of control voltage U to the periodic CPW electrodes provides a reduction of the ferroelectric film permittivity ε_2 and so maintains an electric tunability. The hybridized waves are considered to propagate along x-axis, i.e. along CPW, which is magnetized to saturation by a uniform magnetic field H along z-axis. Due to the symmetry of the fundamental CPW mode its dispersion relation can be found through analytical solution of the full set of Maxwell's equations utilizing the method of approximate boundary conditions described in details in Ref. [12]. The obtained dispersion relation for a *regular* CPW was used for a numerical calculation of the transmission characteristics of the EMC using the transfer-matrix method [13]. Note that this method takes into account the insertion losses and is suitable for the finite-length periodic structures. Following the outlined theory, Fig. 2(a) illustrates the effect of hybridization of two principal electromagnetic modes for the *regular* CPW and *regular* slot-line structure. One can clearly see that the area of the maximum hybridization of SEWs in the CPW shifts to the higher wavenumbers in comparison to the slot-line structure. This behavior is determined by a sufficient reduction of the phase velocity of the microwave electromagnetic waves due to additional "magnetic wall" boundary condition applied at the central metal strip. Note that the calculations were carried out for the typical parameters of YIG and BST films commonly used in microwave devices (see, e.g., Ref. [9]). A reduction of the CPW slot width w shifts the SEW dispersion characteristic to the higher wave numbers. Consequently, the SEW formed in the EMC accumulate the different phase shifts in different segments of the periodic structure at a fixed frequency (see Fig. 1). The band-gaps appear at the frequencies where this phase shift is a multiple of π. As a result, a major part of the spin-electromagnetic wave power will be reflected from the electrodes of EMC at the frequencies that satisfy to the Bragg condition. This effect is visible on the transmission characteristic shown in Fig. 2(b). The characteristic was calculated for the EMC with number of periods $N = 10$ and $\Lambda = 1$ mm with the use of the transfer matrix method. In this case, the width of the first band gap (denoted by I in Fig. 2(b)) is 24.6 MHz at a level of 3 dB from the maximum loss at 33 dB. In addition, this figure illustrates electric tuning of the EMC band gap positions for a reduction of the ferroelectric film permittivity ε_3 from 1500 to 750. In summary, a novel EMC based on CPW were studied. In particular, it was found that a high microwave signal rejection of more than 30 dB appears for the periodic structures. Furthermore, the electric tuning for the first band-gap reaches values of 10.45 MHz by the dielectric permittivity reducing of the ferroelectric film by half. All these advantages make this kind of EMC perspective for development of new microwave devices. The work in SPbETU was supported in part by the Russian Science Foundation, Grant 14-12-01296P. The work in LUT was supported by the Academy of Finland.

The dielectric relaxation process, conduction mechanism and the micro-structure-electrical property relationship in the multiferroic M-type hexaferrites have not been well understood until now[1-2]. In this work, the dielectric relaxation and conduction properties of polycrystalline hexaferrite BaFe10.2Sc1.8O19 (BFSO) have been investigated as a function of temperature from 253 to 473 K with impedance spectroscopy. The frequency dependent impedance and modulus spectra show that the dielectric responses of BFSO are thermally activated. In addition, there is a distribution of relaxation times in the sample. The scaling behaviors of Z^" and M^" spectra further suggest that the distribution of relaxation times is temperature independent. The frequency dependent conductivity spectra follow the universal power law at high temperatures but deviate slightly at low temperatures. The large increase of activation energy above 413 K indicates that at high temperatures, relaxation/conduction processes may be contributed mainly by the diffusive oxygen vacancies, while at low temperatures electron hopping dominates. The fitting results of σ' spectra further suggest that electron/oxygen vacancy-related small polaron hopping is the most probable conduction mechanism for BFSO.

Materials exhibiting large magnetodielectric (MD) couplings could be potentially used in many devices, such as tunable filters and magnetic sensors. Hexaferrites has been discovered as a class of multiferroic materials [1]. The MD properties of the bulk Z-type and M-type hexaferrites have been studied [2-3]. It has been shown that the physical properties of the oxide thin films, especially epitaxial thin films, could be drastically different from those of the polycrystalline bulk materials due to the differences in size and microstructures. However, the MD properties of multiferroic hexaferrite thin films have not been well understood, especially at room temperature. In this work, the MD effects of epitaxial hexaferrite $BaFe_{10.2}Sc_{1.8}O_{19}$ (BFSO) thin film have been investigated around the room temperature. The frequency dependent dielectric constant and MD analysis at room temperature show that in the low frequency regime (f <100 Hz), the MD effect exists but it is very small. When the frequency is higher than 1 kHz, two strong MD peaks exist which should be contributed by the magnetic field dependent sample/electrode interface polarizations (1 kHz < f <100 kHz) and electric dipole rotations in the film (f >100 kHz), respectively. Further temperature dependent MD analysis at 1 MHz shows that the magnetic-field-induced electric dipoles dominate the MD effect below the conical magnetic transition temperature (T_{cone} = 306 K), while the lattice-type dipoles dominate the MD effect above T_{cone}. The above findings further the potential applications of multiferroic hexaferrite thin films in the magnetoelectric devices.

Multiferroic materials, which exhibit rich and fascinating physics such as the combination of ferroelectric and ferromagnetic characteristics, have gripped considerable attention due to their unusual physical properties in new device application [1]. $0.5LaFe_{0.5}Co_{0.5}O_3$-$Bi_4Ti_3O_{12}$ (0.5LFC-BTO) multiferroic thin films were prepared via a sol-gel method on (111)Pt/Ti/SiO_2/Si(100) substrates. Bismuth nitrate [$Bi(NO_3)_3.5H_2O$], lanthanum oxide (La_2O_3), iron acetylacetonate ($C_{15}H_{21}FeO_6$), Cobalt acetylacetonate ($C_{15}H_{21}CoO_6$), and Tetrabutyl orthotitanate [$Ti(OC_4H_9)_4$] were used as the precursors materials for Bi, La, Fe, Co, and Ti, respectively. The La_2O_3 was dissolved in nitric acid (HNO_3) by constant stirring. Both $C_{15}H_{21}FeO_6$ and $Bi(NO_3)_3.5H_2O$ were dissolved in a compound solution of n-propanol ($CH_3CH_2CH_2OH$) and glacial acetic acid (CH_3COOH) was used to regulate the stability of solution as a stable agent. About a 4% excess of bismuth nitrate was added to compensate because of the volatilization of Bi during annealing process in high temperature. Precursor solution was spin-coated on substrates at 3500 rpm for 30 s. After that, the wet films were pulpless at 200 °C for 240 s and pyrolyzed at 320 °C for 360 s. Then the deposited films were followed by the rapid thermal annealing process at 780 °C for 480 s in oxygen atmosphere. The above steps were repeated six times to obtain the ultimate thickness of ~ 400 nm. To measure the electric properties, Au dots were sputtered on the film surface as top electrodes through the shadow masks. The hysteresis loops reach saturation gradually with the amplitude of applied electric field E being increased (Fig. 1(a)). The remanent polarization $2P_r$ and the coercive field $2E_c$ are 48 μC/cm² and 196 kV/cm under E of 360 kV/cm. The spontaneous polarization vector P_s is ~ 50 μC/cm², as much as 2.5 times over that of $Bi_5FeTi_3O_{15}$ thin films (~ 20μC/cm²) [2], larger than that of $0.5LaFeO_3$-$Bi_4Ti_3O_{12}$thin films (~ 37μC/cm²) nearly by 35% [3]. The better ferroelectric property of $0.5LaFe_{0.5}Co_{0.5}O_3$-$Bi_4Ti_3O_{12}$ thin films may owe to the reduction of chemical defects such as oxygen and bismuth vacancies, which is caused by the substitution of La^{3+} for Bi^{3+}. The $2P_r$ has a very slight trend with increasing f which indicates that the ferroelectric domain in 0.5LFC-BTO thin film has good frequency stability (Fig. 1(b)). In addition, the 0.5LFC-BTO thin films show weak ferromagnetism with the saturation magnetization M_s ~ 2.0 emu/cm³ (Fig. 2(a)), which is larger than that the $0.5LaFeO_3$-$Bi_4Ti_3O_{12}$ thin films (M_s ~ 0.90 emu/cm³) and BFTO films (M_s ~ 1.7 emu/cm³) [3,4]. The 0.5LFC-BTO thin films with layered perovskite structure is similar to that of $Bi_6Fe_{2-x}Co_xTi_3O_{18}$ [5], the concentration ratio of Fe/Co is also 1: 1, therefore, we speculate that the magnetic enhancement of 0.5LFC-BTO thin films is mainly related to the ferromagnetic interaction between the adjacent Fe-O and Co-O octahedrons. It is evident that the dielectric constant of 0.5LFC-BTO thin films change after H is applied at room temperature, indicating a magnetic dielectric coupling effect (MDC). The MDC can be defined as MDC = %, where $e_r(H)$ and $e_r(0)$ are the dielectric constants at magnetic field and zero field, respectively. The MDC coefficient is about 0.75% under H = 0.5 T (Fig. 2(b)). The MDC may stem from the spin reorientation under the magnetic field by affecting the interaction between the local dipoles of Fe^{2+} and Fe^{3+}. The MDC weakens with increasing frequency. It is because that the response of local dipoles of Fe^{2+} and Fe^{3+} to applied electric field needs longer time [6]. The coexistence of Fe^{2+} and Fe^{3+} was further confirmed by X-ray photoelectron spectroscopy (not shown here). Lorentzian-Gaussian curve fitting was used to evaluate the Fe^{2+}: Fe^{3+} ratio, which is ~80: 20 as estimated from the integrated intensities. In conclusion, 0.5LFC-BTO thin films were prepared via a sol-gel method. The films have a single-phase Aurivillius perovskite structure with space group *Fmm2*. As expected, the room-temperature multiferroic properties with $2P_r$ of ~48 μC/cm² and M_s of ~ 2.0 emu/cm³ were detected. Furthermore, a MDC effect with MDC ~ 0.75% was observed under a low magnetic field of 0.5 T at room temperature, resulting from the charge ordering of Fe^{2+} and Fe^{3+}.

BQ-01. Micromagnetic model analysis of spin-torque oscillator (STO) integrated into recording write head for microwave-assisted magnetic recording–Oscillation of STO vs. rise time of in-gap field–.

Y. Kanai[1], R. Itagaki[1], S. Greaves[2] and H. Muraoka[2]

1. Information and Electronics Engineering Department, Niigata Institute of Technology, Kashiwazaki, Japan; 2. RIEC, Tohoku University, Sendai, Japan

Introduction Microwave-assisted magnetic recording (MAMR) [1] is one candidate for next-generation perpendicular magnetic recording [2]. Stable oscillation is one of the most important factors for spin-torque oscillators (STOs) used in a MAMR system. We performed micromagnetic simulations and found that stable STO oscillations were hard to obtain when the STO was inserted into the main pole – trailing shield (MP–TS) gap, primarily due to the strong magnetostatic interactions between the STO and write head [3]. We also showed that the rise time of the field applied to an isolated STO greatly affected the STO oscillation [4], i.e. a shorter rise time gave better, more consistent STO oscillation. In this paper, we show that the rise time of the in-gap field acting on the STO is critical to stable STO oscillation. We also show that the combination of a tilted STO and a tilted main pole – trailing shield gap results in stable STO oscillation due to weaker magnetostatic interactions between the STO and write head. Calculation Model A micromagnetic model analysis was carried out considering a double-layered STO utilizing transmission spin torque. We used commercial micromagnetic software (Fujitsu, EXAMAG v.2.1) [5]. The thickness of the field generation layer (FGL) was 10 nm, whilst the spin injection layer (SIL) was 2 nm thick. A 2 nm thick, non-magnetic inter layer was located between the FGL and SIL. The saturation magnetization ($4\pi M_s$) was 20 kG for the FGL and 6 kG for the SIL. The anisotropy fields (H_k) of both the FGL and SIL were 31.4 Oe. The exchange constants, A, were 2.5×10^{-6} erg/cm^3 for the FGL and 0.75×10^{-6} erg/cm^3 for the SIL. The Gilbert damping factor, α, was 0.02 for both the FGL and SIL. The write head model had overall dimensions close to those of commercial write heads (3.25 μm × 2.55 μm × 4.5 μm). Results and Discussion When the Gilbert damping factor, α, of the write head was increased from 0.02 to 0.2 the rise time of the MP–TS in-gap field (0 – 90 %) was shortened from 0.23 ns to 0.15 ns, and the stability of the FGL rotation improved, as shown in Fig. 1. The obtained FGL rotation frequencies were 23 GHz for α = 0.02 and 34 GHz for α = 0.2. The primary reason for the improved rotation came from the applied field reaching equilibrium with the spin-torque field in a shorter time. The second model we considered was a write head with a 20 nm MP–TS gap and a small STO (20 nm wide × 20 nm high). It is necessary to generate a high head field gradient to obtain high linear recording densities. In that regard, the MP–TS gap should be as small as 10 nm [6], while maintaining space to accommodate the STO. It is often believed that a large STO is needed to generate a large high-frequency FGL field. However, using an isolated STO model we found that the FGL field did not decay in proportion to the area of the STO facing the medium and it was easier to obtain coherent, stable oscillation in smaller STOs. In the head model with a 20 nm MP-TS gap, changing α did not affect the rise time (0.15 ns for α = 0.02 and 0.14 ns for α = 0.2) and the FGL rotation was unstable. The reason for this was that reducing the MP–TS gap made the magnetic circuit of the write head more efficient and there was no further room to reduce the rise time by changing α. In addition, the magnetostatic interactions between the STO and write head were larger compared with the 30 nm gap model, making the STO oscillation unstable. To decrease the magnetostatic interactions, we used a third write head model whose MP–TS gap was tilted with respect to the medium surface [7]. The STO was also tilted at the same angle. In the model, the trailing edge of the main pole was perpendicular to the medium surface, while the edge of the trailing shield was tilted. We varied the angle of tilt from 0° to 50° and found that 40° was the best with respect to obtaining stable FGL oscillation. Note that the applied field perpendicular to the FGL became weaker, but more uniform, as the angle of tilt increased. In Fig. 2, the FGL oscillations are shown for (a) a perpendicular STO and (b) a STO tilted by 40° with respect to the medium surface. It was found that the FGL magnetization rotated stably in the tilted STO model. The obtained FGL rotation frequencies were 24 GHz for the perpendicular STO and 30 GHz for the tilted STO. This shows that tilting the STO was quite effective to realize stable STO oscillation. It was also noted that a smaller head coil current and a smaller injected current density, J, to the STO were sufficient. Head coil current (MMF) was 0.12 AT$_{pp}$, $J = 3.0\times10^8$ A/cm^2. FGL: 20 nm × 20 nm. The obtained FGL rotation frequencies were (a) 24 GHz and (b) 30 GHz.

BQ-02. ***Effect of SIL magnetic design on STO optimization in MAMR.***

I. Tagawa[1]
1. Electrical and Electronics, Tohoku Institute of Technology, Sendai, Japan

Uniform and stable oscillation of magnetization is one of the most important factors for the spin-torque oscillator (STO) in microwave assisted magnetic recording (MAMR) [1][2]. Impact of magneto-static interaction between STO and recording head have been discussed often [3][4], but the interaction including spin torque effect is not understood well even just between the field generation layer (FGL) and the spin injection layer (SIL) in STO. In this paper, we focused upon an effect of SIL magnetic design, i.e. the saturation magnetization and layer thickness, on STO optimization for uniform and stable oscillation and tried to understand the magnetic interaction with spin torque. A commercial micromagnetics software (Fujitsu Examag v2.1.1) was used, in which the effective field due to spin transfer torque is considered by the equation shown in Fig.1. In this analysis, a uniform alternative field was applied to STO and magneto-static interaction between STO and head was neglected as shown in Fig.1. The dimensions and magnetic properties are as the followings; FGL&SIL width and height= 30x30 nm, FGL thickness= 6 nm, FGL Bs= 2 or 1 T, FGL&SIL Hk= 1 Oe, Polarization= 0.5, Exchange= 1.0E-6 erg/cm, Damping= 0.02, SIL thickness and SIL Bs are variables. An alternative rectangular field with 1 GHz frequency and 14 kOe magnitude was applied and the injection current density was set at 4.0E+8 A/cm^2 with a direction to SIL from FGL. Results are shown in Fig.2 for (a) FGL Bs= 2 T and (b) FGL Bs= 1 T, respectively. Here, since the reduced cross-track component (My/Ms) of averaged FGL magnetization alternates at a microwave frequency, the root mean square (rms) value was calculated and multiplied by √2 to get 1 at the perfect sine-wave oscillation. In Fig.2(a) for the FGL Bs= 2 T, we can see that the optimum Bs of SIL is around at 1.5, 0.8, 0.6 and 0.4 T for the SIL thickness of 6, 3, 2 and 1, respectively. It's very interesting that the optimum Bs of SIL decreases simply according as SIL thickness increases, and these SIL design impacts significantly to FGL oscillation. In the case for FGL Bs= 1 T, as shown in Fig.2(b), all optimum points have moved to larger Bs positions compared to Fig.2(a). Mechanism for these characteristics is not fully understood yet, but it should relate to both the magneto-static effect and the spin transfer effect, which interact each other. From these figures, once FGL Bs is given, the optimum Bs and the thickness for SIL can be designed. We also confirmed that these optimum positions for the SIL doesn't change even if FGL thickness was changed, and it depends only upon the FGL Bs.

BQ-03. Magnetic recording using a spin torque oscillator.

S. Greaves[1]
1. Tohoku University, Sendai, Japan

Introduction Microwave-assisted magnetic recording (MAMR) is a promising technology that may be introduced into recording systems in the future. In a MAMR system a spin torque oscillator (STO) generates a high frequency (HF) field that assists the head field during recording. However, it is also possible to reverse the magnetisation of a grain using only the HF field [1], [2]. This work investigates how the probability of magnetisation reversal can be maximised using only the field from a STO, i.e. when no head field or other external magnetic fields are present. The Model In most of this work the STO was assumed to consist of only a uniformly-magnetised field generating layer (FGL) in which the magnetisation rotated at a constant frequency. The FGL was 30 nm wide, 30 nm high and 10 nm thick with M_s of 1591 emu/cm^3. Subsequently, a full micromagnetic model of the STO and grain was used to confirm the results. In the full model a 5 nm thick spin injection layer (SIL) with M_s of 637 emu/cm^3 and K_u of 8×10^6 erg/cm^3 with an easy axis along the *y* (down-track) direction was used in addition to the FGL. A single magnetic grain, 8 nm across and with M_s of 750 emu/cm^3, was placed at various positions underneath the STO, with a 4.5 nm vertical spacing between the two. The grain had an exchange coupled composite (ECC) structure with magnetically hard and magnetically soft layers exchange coupled together. A 4 ns field pulse from the STO was applied to the grain and the switching probability was calculated as a function of STO position, HF field frequency, soft layer thickness (d_{soft}) and soft layer K_u (K_u soft). The temperature was 300 K in all simulations. Results First, the switching probability of the hard layer by itself was calculated as a function of thickness and K_u. It was possible to achieve switching probabilities close to 1, but only when the hard layer K_u was sufficiently small and under such conditions the thermal stability would be inadequate for long-term data storage. Next, the hard layer thickness was fixed at 4 nm with K_u of 7.7×10^6 erg/cm^3. The optimum STO frequency was sought for various soft layer thicknesses and soft layer K_u. Fig. 1 shows the switching probability as a function of STO position, where the position $\Delta y = 0$ nm indicates the centre of the STO was directly over the centre of the grain. Due to the chirality of the HF field acting on the grain, switching of the magnetisation (from "up" to "down") was only observed when the STO was to the left of the grain ($\Delta y \leq 0$). Similarly, switching from "down" to "up" was only possible when the STO was to the right of the grain. In a recording system it is the sharpness of the left edges of the curves in fig. 1 that will determine the minimum transition width. For a grain with K_u soft of 1×10^6 erg/cm^3 the transition from $P = 1$ to $P = 0$ took place over a width of 7 nm. Fig. 1 shows that switching probabilities of 1 (after 100 trials) were possible for a wide range of STO positions when K_u soft was between 0.5×10^6 erg/cm^3 and 1×10^6 erg/cm^3. When K_u soft was too large the switching probability began to decrease and when K_u soft was zero the areas where the switching probability was 1 became non-contiguous. Also, the optimum soft layer thickness increased as K_u soft decreased, suggesting that the magnetisation reversal process was linked to the width of the domain wall in the soft layer. Meanwhile, the optimum HF field frequency was found to increase with K_u soft. A more detailed switching probability plot for a grain with K_u soft = 0.5×10^6 erg/cm^3 is shown in fig. 2. In addition to the large region of high switching probability centred around HF field frequencies of ≈11 GHz, several other regions of high switching probability were also observed, e.g. for HF field frequencies of ≈6 GHz. The inset to fig. 2 shows the in-plane magnetisation dynamics of the soft layer when the STO frequency was 6.2 GHz, a frequency which fell within the second-largest region of high switching probability in fig. 2. To examine the state of the grain magnetisation just prior to switching the FGL M_s was reduced to 1100 emu/cm^3 and the temperature was reduced to 4.2 K. The plot in fig. 2 shows the soft layer magnetisation over a period from 50 ns to 60 ns after the application of the STO field. It was clear that although the STO oscillation frequency was 6.2 GHz the soft layer magnetisation completed two revolutions for every one rotation of the STO, doubling the soft layer oscillation frequency to 12.4 GHz. The origin of the frequency doubling was exchange coupling with the hard layer and also the strength of the field from the STO. Finally, the simulations were repeated with a full STO model and magnetostatic interactions between the grain and the STO. A current density of 1×10^{18} esu/cm^{2}s caused the FGL magnetisation to oscillate at about 12 GHz, which was sufficient to switch the magnetisation of a grain with K_u soft of 1×10^6 erg/cm^3. One issue identified from these simulations was the amount of time required for the STO oscillation to stabilise at the required frequency.

BQ-04. Columnar Structural FePt films with Good Perpendicular Anisotropy Grown on TiNZrO Intermediate Layer.

K. Dong[1], F. Jin[1], W. Mo[1] and J. Song[1]
1. School of Automation, China University of Geosciences, Wuhan, China

FePt based heat assisted magnetic recording (HAMR) medium has drawn a lot of attention because of its ability to extend the areal density to 5 Tb/in^2 in theory due to the high magnetocrystalline anisotropy of FePt. For the practical application of FePt thin film in future heat assisted magnetic recording, the FePt films should exhibit good (001) texture, large magnetocrystalline anisotropy, and small grain size with a narrow size distribution and well isolated columnar structure. In order to achieve this aim, great progresses have been made in the fabrication of columnar FePt thin films by selecting various materials to introduce into the FePt films to isolate and reduce the grain size. However, the results reported showed that the columnar structural FePt films exhibited poor perpendicular anisotropy. The objective of this work is introduced a new TiNZrO intermediate layer to improve the perpendicular anisotropy of columnar FePt-ZrO_2 films. FePt (8 nm)-ZrO_2 30 vol.% films were fabricated on TiON, TiN-ZrO_2 and TiNZrO intermediate layers by a magnetron sputtering system with a base pressure better than 2×10^{-8} Torr, respectively, and the films structure are shown in Fig.1(c). The TiNZrO intermediate layer was formed by cosputtering TiN and ZrO_2 at substrate temperature of 500°C, and the analysis of the Zr 3d spectra of the TiNZrO intermediate layer are shown in Fig.1(b). It can be seen that the FePt grains of FePt-ZrO_2 thin films grown on these three intermediate layers exhibited columnar structure (Fig.1g, h and i), and very good epitaxial growth had been observed between FePt and TiNZrO. However, with using TiON and nanogranular TiN-ZrO_2 intermediate layer, very clear FePt (200) peaks were appeared (Fig.1a) and large opening-up of in-plane M-H loops (Fig.1d and e) were obtained, suggesting the perpendicular anisotropy was poor. By introducing the TiNZrO intermediate layer, the FePt (200) peak was disappeared and the FePt film exhibited obvious perpendicular anisotropy (Fig.1f). The $H_c\perp/H_c\|$ratio of 3.27 was larger than that with using TiON (around 1.84), TiN-ZrO_2 (around 1.76). All these indicate the perpendicular anisotropy and the (001) orientations were both improved a lot with using TiNZrO intermediate layer, as compared to the common used TiON and TiN-ZrO_2 intermediate layer.

I. Introduction The shingled magnetic recording (SMR) with $L1_0$-FePt based exchange coupled composite (ECC) media is a promising way to achieve ultra-high recording density [1] [2]. With the increasing track density, shingled writing inevitably causes the adjacent tracks erasure (ATE) and corresponding erase band noise (EBN), which deteriorates the write performance and introduces more write errors. During the shingled write process, our study indicates the skew and corner angles of wide main pole affect the EBN, moreover the insensitive angular dependence of switching field of ECC media is found to play an important role in mitigating transition noise and ATE [2]. Compared to our previous digest presented in Intermag2015 [3], this paper improves the calculation method of erase band width (EBW) by considering the overwriting side in SMR, more importantly the impact of ECC media on mitigating ATE is explored with EBW and bit error rate. Furthermore, the shingled write heads with different corner angle (*CA*), tip tapered angle (*TA*) and skew angle (*SA*) are studied to reach a tradeoff between adequate write field and moderate EBW. The investigation indicated that the combination of relatively smaller *CA*, larger *TA* and smaller *SA* was beneficial for reducing the EBN, while it weakened the write field. Hence we suggested that an optimized writer design (*CA*=78°, *TA*=50°, -10°<*SA*<10° in our simulation) with ECC media $L1_0$-FePt(6nm)/$[Co/Ni]_5$(4nm) could provide adequate write field and minimize the EBN simultaneously. II. Models and Methodology A) The ECC media is modeled by Voronoi grains and each single grain consists of two-layer composite structure, shown in FIG.1(a). The thermal stability factor $\Delta E/k_BT$ is set as 60 to ensure the thermal stability for more than 10 years. The energy barrier of grain (ΔE) is given as below according to [4] $\Delta E=(K_u^h+K_u^s)(1-H/H_{sw})^\gamma$ where V is the volume of layer, H is the write field, H_{sw} is the switching field, and γ=1.5, the hard layer (index h) of $L1_0$-FePt and soft layer (index s) of $[Co/Ni]_5$ are investigated for ECC media. The magnetic parameters are given as follows according to [5]: the saturation magnetizations (M_s) are set as $M_{[Co/Ni]5}$=750emu/cc and M_{FePt}=500emu/cc. The exchange coupling constants are set as $A_{FePt}=1.2\times10^{-6}$erg/cm and $A_{[Co/Ni]5}=1.0\times10^{-6}$erg/cm. The anisotropy constant (Ku) are set as $K_{[Co/Ni]5}=2.5\times10^6$erg/cc and $K_{FePt}=1.61\times10^7$erg/cc, while the thickness of FePt and $[Co/Ni]_5$ are set as 6nm and 4nm in order to keep $\Delta E=60k_BT$. Hence, the H_{sw} of ECC media is calculated as 16.44kOe according to our simulation. B) The shingled write head is designed to provide both sufficient write field and high field gradient, as shown in FIG.1(b). The writer comprises of a single main pole, return yoke and shield. The *SA* is the angle between recording track and normal direction of trailing side; the *CA* is the angle between trailing side and flaring side from the air bearing surface view (ABS); the *TA* is the angle between the ABS and side of pole tip. The geometric and magnetic parameters of writer are similar to our previous works [3] [6]. III. Results and Discussions The shingled write head is implemented to micromagnetically write grains on ECC media to evaluate EBW and writing performance using the finite element method. The field distribution is evaluated in the center plane of recording layer (10nm below the ABS). For a write head with *CA*=80°, *TA*=40° and *SA*=0°, the effective write field (H_{eff}) and H_{sw} variations are shown in FIG.2(a). The results reveal that $P_{erasure}$ is less than 5×10^{-4} when the EBW equals to 14nm, here $P_{erasure}$ is defined as the probability that adjacent track bit is erased when writing the target bit. It is worth noting that EBW can be reduced in two ways according to FIG.2(a): 1) For the writer part, the H_{eff} decreases away from the writer corner, hence it is possible to generate the H_{eff} with an optimum magnitude (slightly larger than H_{sw}), considering excessively large H_{eff} tends to increase the fringing field and erase adjacent track more severely; 2) For the media part, the angle between the write field and easy axis of ECC media varies away from writer corner and the corresponding H_{sw} varies with the cross-track distance. Hence it is also possible to utilize the ECC media's insensitive angular dependence to reduce ATE. For a write head with *CA*=78°, *TA*=50°, the H_{eff} and EBW versus different *SA* are shown in FIG.2(b). As illustrated, the H_{eff} and EBW increase with the increase of *SA* because the skew effect stretches the field contour, hence the side-erasure field increases and the adjacent track's bits suffer more fringing field. The writer cannot provide adequate H_{eff} to reverse recording bit when *SA* is smaller than lower bound. While when the *SA* is larger than upper bound, the slope of EBW curve will increase sharply, result in a remarkable increase in the EBW and deteriorate the write performance severely. Hence the tolerable range of *SA* (-10° to 10° marked with dash line) is found by taking the tradeoff between adequate H_{eff} and small EBW. ACKNOWLEDGMENT This work was supported by the National Natural Science Foundation of China under the Grant No.61672246, No.61432007, No.51001051.

Since the early 1990's, with the arrival of the Information era, the digital data is being created exponantially every year. The need to accomodate the rapidly increasing data urges the advancement of the data storage technology by increasing the storage capacity. It hence requests for the reduction in the grain size and size distribution of heteroepitaxial recording medium. As the grain size is scaled down, the decisive factors for size limitation in a heteroepitaxial nanostructure are the strain energy brought by the lattice mismatch and the significant surface energy contribution due to high surface-to-volume ratio [1]. The misfit strain plays a particularly important role in the microstructure evolution of large lattice-mismatched systems. However, the strain effect on the size evolution of the epilayer in a heteroepitaxial system and the corresponding mechanism are still elusive. In this study, we demonstrate that the misfit strain can lead to the oscillation of size distributions in heteroepitaxial nanostructures, revealing the power of the strain in controlling the shape of the heteroepitaxial nanostructures. The samples were prepared by magnetron sputtering (AJA Orion 8) with a base pressure lower than 2×10^{8} Torr. The FePt layer with thickness of 4 nm, 6 nm, 8 nm, 10 nm was deposited on single crystal MgO (100) substrate at 400°C and at Ar working presure of 10 mTorr. The deposition rate of FePt film was fixed at 18 Å/min. 10 nm FePt thin film deposited on MgO has a maze-like pattern with <110> oriented grain boundaries as observed in the scanning electron microscopy (SEM) images as shown in Fig. 1. A statistics analysis on the feature size of the rectangular grains were carried out. The feature sizes distribution exhibits a periodical multi-peak behavior. As shown by the peak distances labelled between two neighboring peaks, the period is about 3.3 ± 0.5 nm. From the cross-sectional TEM images shown in Fig. 2, the trapezoidal shape of FePt islands indicates that the equilibrium crystal shape formed on MgO is a square truncated pyramid with top (001) and lateral (111) facets. A 12/11 domain matching epitaxy (DME) of FePt/MgO system could be observed in the inverse fast fourier transform images. With the formation of dislocations, the strain energy can be completely released in a DME system. The period of the misfit dislocations coincides well with the oscillation period of the size distributions of FePt islands, suggesting that is related to the oscillatory nature of the misfit strain energy. Based on the experimental findings, a simple model was established to investigate the correlations between the misfit strain energy and the size oscillation. The results tell us that when the FePt island size is an integer times of the misfit dislocation period, the misfit strain can be nearly cancelled by the misfit dislocations. Therefore, these discrete sizes are preferred in heteroepitaxial FePt nanostructures.

I. INTRODUCTION $L1_0$ FePt-based thin films with a (001) crystallographic texture have been largely investigated over the last two decades as potential materials for next generation ultra-high density magnetic recording media (>1Tbit/in2), due to the high magneto-crystalline anisotropy (5-10 MJ/m^3), which ensures room temperature thermal stability of grains with in-plane size down to 3 nm. Moreover, due to the moderate Curie temperature (650-750K) of the FePt-based alloys, such a material is currently the best candidate for Heat Assisted Magnetic Recording (HAMR), an emergent technology close to the commercialization, which is expected to increase the areal density in hard disk drives beyond 2 Tbit/in^2. To achieve thermally stable recording media for HAMR with an area density as large as 2 Tbit/in^2, FePt granular films consisting of columnar and well separated grains with a high microstructural uniformity and small in-plane size are required. For this purpose, single and multiple segregants such as carbon, transition metal-oxide and carbide have been extensively discussed but further work is still necessary to achieve the required morpho-structural and magnetic properties for recording densities up to 2 Tbit/in^2 and beyond. In this work a novel Mg(Ti, Ta, Zr, Nb, B)O segregant without carbon is proposed as a potential material for next generation FePt-based high density recording media. II. EXPERIMANTAL [FePt-Mg(Ti, Ta, Zr, Nb, B)O]/MgTiON/CrRu films were deposited by magnetron sputtering on glass substrates. The background pressure of sputtering system was below $5x10^{-7}$ Torr and the working pressure was set to 10^{-3} Torr. The CrRu seed layer with a (002) texture was first grown on the glass substrate to induce the formation of a (002) textured MgTiON intermediate-layer. To investigate the effect of the Mg(Ti, Ta, Zr, Nb, B)O segregant material, two different series of samples were prepared. In series (I), a Mg(Ti, Ta, Zr, Nb, B)O interlayer with a thickness *t*=0, 2, 4, 6, 13 nm was deposited under a 10 nm thick FePt layer (i.e. FePt(10nm)/Mg(Ti, Ta, Zr, Nb, B)O(*t*)/MgTiON/CrRu) in series (II), a FePt(2nm)/$[Mg(Ti, Ta, Zr, Nb, B)(t)/FePt(4nm)]_2$ (t=0, 0.5, 1, 1.5 nm) multilayer stack was deposited on top of the MgTiON intermediate-layer. In both the cases the deposition was carried out by using a $(MgO)_{70}(Ti_6Ta_6Zr_6Nb_6B_6)$ target and at a deposition temperature of 470^{o}C to favor the formation of the $L1_0$-FePt phase and the diffusion of the segregant material in the FePt layer. The crystal structure of the samples was identified using a standard X-ray diffraction (XRD) technique (BRUKER, D8 Discover). In-plane and out-of-plane field-dependent magnetization loops were measured at room temperature by using superconducting quantum interference device (SQUID) magnetometer. The film microstructure was studied by using transmission electron microscopy (TEM, JEOL JEM-2010). III. RESULTS AND DISCUSSIONS XRD spectra of series (I) are reported in Figure 1(a). Besides the (002) reflection peaks of the CrRu seed layer and the MgTiON intermediate layer, the (001) superlattice diffraction peak and the (002) fundamental reflection of the $L1_0$ FePt are present suggesting that the $L1_0$ FePt film has a (001) preferred orientation. However, the disordered FePt (200) peak is also present thus indicating that the Mg(Ti, Ta, Zr, Nb, B) interlayer has deteriorated the epitaxial growth of the FePt film. In series (II), only the (001) and (002) FePt peaks are present in the XRD spectra (Fig 1b), thus suggesting that such a deposition process does not affect the epitaxial growth of the FePt film. The out-of-plane and in-plane field dependent magnetization loops of representative samples of series I(a) and II(b) measured at room temperature are reported. In both the series, the FePt films present a preferential perpendicular anisotropy, samples from series (I) showing a larger in-plane loops area, which origins from the contribution of disordered FePt regions as evidenced by XRD results. Overall, samples of series (I) present a larger out-of-plane coercivity (H_c, up to 14.4 kOe for t= 2 nm) with respect to samples of series (II) (H_c= 10.7kOe for t=1 nm) as a consequence of a different microstructure as discussed below. Figure 2 shows the cross-sectional TEM images of FePt(2nm)/[Mg(Ti, Ta, Zr, Nb, B)O(*t*)/FePt $(4nm)]_2$ (t= 0.5, 1, 1.5 nm) multilayers (series II). The FePt film was more continuous with Mg(Ti, Ta, Zr, Nb, B)O(*t*=0, 0.5nm) interlayer for two pairs shown in Fig. 2(a-b) and the FePt grains with dark contrast were appeared in the large island and the coercivity is 8.6kOe. In Fig. 2(c-d), the FePt grains were more separated when the thickness of Mg(Ti, Ta, Zr, Nb, B)O interlayer increased to 1 nm and 1.5 nm for two pairs and the FePt films show higher coercivity(10.7kOe). The FePt grains morphology were in the dorm shape with almost perpendicular grains contact. In sample series I, the separation of FePt grains were much better than series II and illustrated much higher coercivity(14.4kOe). In summary, when a Mg(Ti, Ta, Zr, Nb, B)O interlayer is deposited under FePt layer, the FePt (001) orientation is deteriorated but the grains separation is enhanced and the films show higher coercivity but also a larger in-plane magnetization. In sample series (II), where the Mg(Ti, Ta, Zr, Nb, B)O is inserted between FePt layers, the [001] orientation was improved but the FePt grains separation is weaker, thus leading to a lower coercivity.

BQ-08. First order reversal curves and intrinsic parameter determination for magnetic materials: limitations of hysteron-based approaches in correlated systems.

S. Ruta[1], O. Hovorka[2], K. Wang[3], P. Huang[3], G. Ju[3] and R.W. Chantrell[1]
1. Physics, University of York, York, United Kingdom; 2. Faculty of Engineering and the Environment, University of Southampton, Southampton, United Kingdom; 3. Seagate Technology, Fremont, CA, United States

I) Introduction The intrinsic switching field distribution (SFD) is a fundamental characteristic of granular magnetic materials and it determines the quality of recording media used in hard disk drives. Being able to evaluate the thermal SFD of a system of coupled grains dominated by thermally activated hysteresis behaviour remains a challenge and is an essential practical step for developing and optimising the present-day and future magnetic recording technology. SFD is defined as a distribution of irreversible switching events of magnetic grains in the absence of inter-granular interactions. If there are no reversible components of magnetization the SFD corresponds directly to the differentiated hysteresis loop. If thermal relaxation is absent, then the SFD provides direct information about the distributions of intrinsic material properties of grains, such as anisotropy and volume. This relatively simple physical picture becomes complicated 1) by the presence of thermal relaxation, when the SFD also includes a component from thermal activation and becomes non-linearly dependent on the sweep rate of external field applied during the hysteresis loop measurement, and 2) by inter-particle interactions leading to correlated switching of magnetic grains, when the intrinsic switching thresholds of individual grains can no longer be resolved. In this work we have investigated the range of validity of first order reversal curves (FORC) technique, as is widely used for the applications mentioned above. II) Methods and Results First Order Reversal curve (FORC) method is extensively applied as a tool to qualitatively capture the general aspects of a magnetic system: mixed magnetic phases, cluster/long-range ferromagnetic state, magnetic characterization of geological mixtures minerals and different magnetization reversal mechanisms[1]. The method is also used as a quantitative approach for determination of thermal intrinsic switching field distributions (SFD), and interaction field distribution (IFD) in magnetic systems with hysteresis, such as in recording media. The attractiveness of the FORC method is in its simplicity and its straightforward applications to a wide range of systems displaying hysteresis. The correct SFD identification of the FORC based techniques originate in the work of Mayergoyz [2]. He mathematically proved that for any hysteresis system (magnetic or non-magnetic) that satisfies the Preisach model condition, the input SFD (or the equivalent quantity for non-magnetic system) can be accurately re-obtained using the FORC method. As a benchmark for validating the methods we consider a kinetic Monte-Carlo (kMC) model of exchange and magnetostatic interacting Stoner-Wohlfarth grains, including self-consistently the volume and anisotropy distributions, and thermal activation. Using kinetic Monte-Carlo framework we developed a model of increasing layers of complexity to describe realistic devices, from non-interacting system, to mean-field approximation and to grain-grain interaction, where intercalation are calculated taking into account the grain geometry (shape, size, position). Our results show that the reliability of the FORC technique is critically affected by the presence of interaction (magnetostatic and exchange), when there is correlated behaviour of magnetic entities. The nature of correlations are irrelevant, as we show with a 'toy model' in which the correlations are artificially induced. This toy model, gives the possibility to explore the effects of correlation in a general system, as the interaction strength is always the same and just the degree of correlation is systematically varied [3]. This is a fundamental limitation of the FORC method, independent of the benchmark model. We quantify the limiting model parameter range (in terms of magnetostatic and exchange interaction) of the FORC methods for a perpendicular magnetic recording system (Fig. 1). Figure (1a) shows the dependence of the maximum value of the correlation function in absolute value as function of the exchange and magnetostatic field magnitudes. The results show that the parameter space having the best determination of the SFD from the Preisach-based FORC analysis corresponds to that having weak spatial correlation of the magnetization structure. In these work we demonstrate that FORC methods can be applied only when interaction induced correlations are negligible (Fig. 1).

BQ-09. Magnetization Reversal of antiferromagnetically coupled (Co/ Ni) and (Co/ Pt) Multilayers.

A.Y. AlSubhi[1]
1. Physics, Sultan Qaboos University, Muscat, Oman

The antiferromagnetic coupling (AF) between two ferromagnetic layers separated by nonmagnetic spacer has been investigated due to its importance in magnetic recording and spintronic devices. For instance, in magnetic tunnel junction with perpendicular anisotropy, the stray field from reference layer could reach large values which could affect the stability of the free layer. The AF structure is a good way to minimize the magnetostatic field. In this study, the AF coupling between a soft $(Co_{0.3}/ Ni_{0.6})_{xN}$ multilayers and a hard $(Co_{0.3}/ Pt_{0.8})_{12}$ multilayer is investigated. The number of repeats of the soft multilayer is varied from 4 to 8 while it is fixed to 12 for the hard one. The AF coupling is induced by a thin Ru of 0.8 nm between the two multilayers. Fig 1 shows the major and minor loops of the coupled structure for N = 4 at room temperature. In this case a clear two steps switching is observed. The coercivity of the $(Co/Ni)_4$ soft layer H_{C1} and $(Co/Pt)_{12}$ hard layer H_{C2} were measured for both single and exchange coupled cases. The antiferromagnetic exchange coupling H_{ex} measured from the shift of the minor hysteresis loops. In the inset of Fig 1 $J_{ex} = H_{ex} M_{S\times}t_f$ is plotted as a function of temperature where M_S and t_f are the saturation magnetization and thickness of the soft layer respectively. This behavior is different from the case of two AF coupled (Co/ Pd) multilayers [1]. The maximum exchange coupling is observed at around 150 K. For low temperature, a gradual increase of J_{ex} following an Arrhenius law was revealed. The non-monotonous dependence of J_{ex} with temperature is unusual in such films. Recently Xiao et al reported a similar behavior in antiferromagnetically coupled $[Pt/CoFeB]_{N1}/Ru/[CoFeB/Pt]_{N2}$. Where N_1 and N_2 are the number of repetetions [2] For large (Co/Ni) with 8 bilayers, the two steps magnetization reversal disappears and a rotation of the magnetization of the soft layer from out-of plane to in-plane is observed as can be seen in Fig 2. This hysteresis loop is characterized by cooperative reversal of all the layers instead of layer-by-layer switching. This type of the hysteresis is seen for different temperatures ranging from 4 K to 300 K. For an understanding of the magnetization reversal of AF structure, magnetic force microscopy and micromagnetic simulation will be presented.

INTRODUCTION CoPt-oxide granular films have been widely used for perpendicular magnetic recording media. To further increase recording density of the media, enhancement of magnetocrystalline anisotropy (K_u) to overcome the thermal stability issue and reduction of media noise to increase signal-to-noise-ratio are essential. The requirements can be realized through the promotion of columnar growth of magnetic grains which are phase separated with oxide boundary material and intergranular exchange decoupling[1)], respectively. Generally, for the grain boundary materials of the granular media, oxides with amorphous phase which do not dissolve into CoPt metal have been utilized. The oxide is expected to segregate into the trench of Ru underlayer so that CoPt grains can grow heteroepitaxially on the bump of Ru underlayer. Many authors have proposed various kinds of oxide materials to be segregated into the grain boundaries, like SiO_2[2)], TiO_2[3)], Ta_2O_5[3)], Nb_2O_5[4)], WO_3[4)], MgO[5)], Cr_2O_3[5)], and Y_2O_3[5)]. Previously, we had found that a granular medium with high magnetocrystalline anisotropy (K_u) was successfully realized when B_2O_3 was applied for the grain boundary material[6)]. However, the separation between magnetic grains at the initial growth region in the Ru trench by low melting point oxide such as B_2O_3 is not sufficient[7)]. Therefore, we have carried out an investigation on the deposition of a buffer layer (BL) with non-ferromagnetic metal and oxides of various melting points (T_m) on the Ru underlayer to grow the non-ferromagnetic metal and oxide on the Ru bump and trench, respectively, aiming to intergranular exchange decouple the magnetic grains. In this paper, we will discuss about the effect of utilizing BL with oxide of various T_m on the intergranular exchange decoupling of CoPt-B_2O_3 granular media in relation with magnetic properties. RESULT AND DISCUSSION Samples structure used in this study: Sub./ Ta (5 nm)/ $Ni_{90}W_{10}$ (6 nm)/ Ru (0.6 Pa, 10 nm)/ Ru (8.0 Pa, 10 nm)/ BL/ $Co_{80}Pt_{20}$-30vol%B_2O_3 (16 nm)/ C (7 nm). $Ru_{50}Co_{25}Cr_{25}$-30vol%TiO_2 (0-4 nm) was used for the BL. Here for the BL, a non-ferromagnetic Ru alloy which consists of the metal element of underlayer (Ru) and granular media (Co) was adopted for the metal material to maintain hetero-epitaxial growth of CoPt alloy on Ru. While TiO_2 was chosen as a typical material used for the grain boundaries in the granular media. Fig. 1 shows dependence of H_c on the BL thickness (d_{BL}). When d_{BL} is increased from 0 to 1.5 nm, a large increase of H_c around 20%, from 7.5 to 9.0 kOe can be observed. Further increase of d_{BL} to 4.0 nm will decrease H_c from 9.0 to 8.7 kOe. This indicates that the employment of the BL is quite effective to increase H_c of the medium. To find out the origin of H_c variation according to various BL thickness, anisotropy field (H_k), thermal stability and degree of intergranular exchange coupling were investigated. Here, thermal stability and degree of intergranular exchange coupling are determined from $v_{act}K_u^{grain}/kT$ and a, where v_{act} is the activation volume measured from time dependence of remanence coercivity[8)] and K_u^{grain} is evaluated from K_u of the granular media when 30vol% B_2O_3 is excluded. Fig. 2 shows dependence of (a) H_k and K_u, (b) $v_{act}K_u^{grain}/kT$ and (c) a on d_{BL}. When d_{BL} is varied from 0 to 4.0 nm, H_k and K_u remain constant at around 18.5 kOe and 8.0×10^6 erg/cm^3, respectively. On the other hand, $v_{act}K_u^{grain}/kT$ and a decrease from 160 to 140 and from 1.7 to 1.2, respectively, when d_{BL} is increased from 0 to 1.5 nm. This reveals that the granular medium is thermally stable and the intergranular exchange decoupling is promoted. This result suggests that the decrease of degree of intergranular exchange coupling when d_{BL} is increased from 0 to 1.5 nm induces larger H_c. From these results, the introduction of RuCoCr-TiO_2 BL underneath the high K_u CoPt-B_2O_3 granular media is quite effective to increase H_c through reduction of intergranular exchange coupling. In the conference, the effect of melting point of the oxide for RuCoCr-oxide BL on magnetic properties and microstructure of CoPt-B_2O_3 granular media will be reported.

BQ-12. Ion beam patterning of ultrathin $L1_0$-MnGa (001) film grown on CoGa buffer layer.

Y. Horie[1], D. Oshima[1], T. Kato[1] and S. Iwata[1]
1. Nagoya University, Nagoya-shi, Japan

Bit patterned media (BPM) are considered to extend the areal density of magnetic recording to more than 5 Tbit/in^2 by combining it with heat or microwave assisted magnetic recording. One of the major issues for the practical use of BPM is the development of a low-cost and high-yield fabrication process. We reported that magnetism of MnGa was altered from ferromagnetic to paramagnetic associated with the phase change from $L1_0$ ordered to A1 disordered phase by 30 keV Kr^+ ion irradiation and that bit patterned media with a pitch size down to 80 nm were realized by the ion beam patterning [1]. For further high-density patterning, thinner resist masks and incident ions with lower kinetic energy should be used. In order to pattern using low energy Kr^+ ions, e.g., < 10 keV, the growth of ultrathin $L1_0$-MnGa layer is necessary. Recently, an ultra-thin MnGa film was reported to be grown successfully on a nonmagnetic CoGa buffer layer [2]. In this report, we also used the CoGa buffer layer to grow the ultrathin MnGa layer and fabricated bit patterned MnGa with a pitch size less than 80 nm by using 10 keV Kr^+ ion irradiation. The MnGa film with a stack of Cr (2) / MnGa (5) / CoGa (30) / Cr (20) / MgO(001) (thickness in nm) was prepared by rf magnetron sputtering. The Cr buffer layer was deposited at a temperature at 400 °C, and post-annealed at 600 °C for 60 min. After cooling down to 400 °C, the CoGa layer was deposited and post-annealed at 600 °C for 30 min. The MnGa layer was deposited by co-sputtering of $Mn_{40}Ga_{60}$ and $Mn_{60}Ga_{40}$ targets at 300 °C, and post-annealed at 400 °C for 60 min. The composition of the MnGa was tuned to $Mn_{50}Ga_{50}$ by controlling the sputtering power of the two targets. Ion-beam bit-patterned film was fabricated by e-beam lithography and an ion implantation system. Anisole-diluted ZEP520A resist with a thickness of 40 nm was used as a mask for patterning. The energy of the Kr^+ ion irradiation was set to be 10 keV. Figure 1 (a) shows the *M-H* out of plane loop of the CoGa-buffered MnGa film. *M* represents the magnetization per unit volume of the MnGa layer. It is expected that there are two components in the *M-H* loop; one is square hysteresis with H_c = 2 kOe and another is superparamagnetic hysteresis with zero coercivity and remanence. From the surface-sensitive Kerr loop measurements, 5-nm thick MnGa was confirmed to have square hysteresis, indicating a large perpendicular anisotropy and smooth wall propagation in spite of the ultrathin thickness of the MnGa. The superparamagnetic component is considered to come from the CoGa buffer layer. The saturation magnetization of the ultrathin MnGa film can be estimated to be 320 emu/cc by excluding the contribution of CoGa in the *M-H* loop. Figure 1 (b) shows the dependence of the saturation magnetization M_s on the dose of 10 keV Kr^+ ion irradiation. The M_s gradually decreased with the dose and became a constant at the dose of 1×10^{14} ions/cm^2 or more. The residual magnetization is considered to come from the contribution of the CoGa buffer layer as discussed in Fig. 1 (a), and the ferromagnetism of the MnGa layer disappeared by the 10 keV Kr^+ ion dose of 1×10^{14} ions/cm^2 just as our previous report [1]. Figure 2 shows the MFM images of the bit patterned MnGa film with pitch sizes of (a) 100 nm and (b) 60 nm. As shown in Fig. 2 (a) and (b), bright and dark signals were observed in non-irradiated regions indicating the existence of the perpendicularly magnetized $L1_0$-MnGa. On the other hand, no magnetic signal was seen in the irradiated regions. Thus, magnetically patterning with a pitch size of 60 nm was successfully realized by using ultrathin MnGa, and 10 keV Kr^+ ion irradiation.

A single femto-second optical pulse can fully reverse the magnetization of a film within picoseconds [1]. Such fast operation hugely increases the range of application of magnetic devices. However, so far, this type of ultrafast switching has been restricted to ferri-magnetic GdFeCo films and, in contrast, ferro-magnetic films require multiple pulses [2], thereby being slower and less energy efficient. Here, we demonstrate magnetization switching induced by a single laser pulse in various ferromagnetic Co/Pt multilayers grown on GdFeCo, by exploiting the exchange coupling between the two magnetic films. We have shown that, despite using thick (up to 5 nm) metallic Pt spacers to separate a Co/Pt multilayer from a GdFeCo layer, we can still achieve single-shot AOS of the ferromagnetic layer by exploiting the exchange interaction [3]. Moreover, we demonstrated a 7 ps switching time on a sample with a 1.5 nm Pt spacer. This rather general method can be extended to other ferromagnets, ferrimagnets and even antiferromagnets. We believe that this approach will greatly expand the range of materials and applications for ultrafast magnetic switching.

BQ-14. Thermodiffusion and the replenishment phenomena of PFPEs for the application of heat-assisted magnetic recording.

P. Chung[1]
1. Energy Engineering, Inje University, Gimhae-si, The Republic of Korea

New design and component materials of head-disk interface are required to satisfy stringent operating conditions including heating and cooling cycles that occur within the order of nanosecond to achieve the necessary data rates and to generate a large thermal gradient for sharp bit edge for heat assisted magnetic recording (HAMR). During the HAMR operation, the locally heated lubricant experiences evaporation as well as thermal flow-out. The stumbling block in HAMR technology is to fully understand the system behavior under large thermal gradient in addition to elevated temperature. We introduce the Soret effect for the first time in HAMR research to rigorously analyze diffusional flux in continuum level. The temperature gradient can cause mass flux via process known as thermodiffusion or Soret effect. At the same time the concentration gradient can also contribute heat transfer via Dufour effect and these effects modifies temperature and concentration profile (Fig 1a). We examine these two effects using molecular dynamics (MD) by hybridizing aforementioned continuum model using PFPE replenishment phenomena as benchmark example. Marchon and Saito examined local thermal diffusion phenomena of nonfunctional PFPE lubricant by studying the lubricant removal at the center and the formation of a rim at the edge of hot spot using MD as well as computational fluid dynamics [1]. Dahl and Bogy investigated the recovery of the depleted lubricants for functional PFPEs have been investigated as functions of temperature and the hot spot size using continuum based Reynold's equation [2]. Although there exists previous attempt, the thermodiffusion mechanism at the rim, where the drastic temperature gradient exists, and this phenomena has not been fully understood. We examine replenishment phenomena for various PFPEs controlled by the temperature gradient at the rim (Fig.1b). Specifically, chemical functionalities covering linear functional PFPEs (*e.g.*, Zdol and Ztetraol) as well as other chemically complex PFPEs (*e.g.*, ZTMD, TA30, and QA40) will be examined using coarse-grained MD. The local heating and cooling in molecular scale were simulated by propagating the kinetic energy of PFPE molecules adjacent to the heat source. We also investigated the reflow process of the lubricant film by analyzing time-dependent evolution of the thin lubricant film profile and correlated to the thermodiffusion coefficient via hybridizing continuum model including Soret coefficientMolecular weight dependence is also examined in addition to the functionality effect to demonstrate the significance of the thermodiffusion contribution. In-depth analysis on the lubricant behavior with heating and cooling cycle with large temperature gradient will provide better molecular design criteria of HAMR lubricants.

Faculty of Engineering, King Mongkut's Institute of Technology Ladkrabang (KMITL), Bangkok, Thailand

Abstract: In this work, we propose the nonlinear generalized partial response (GPR) targets for the perpendicular heat-assisted magnetic recording (HAMR) channels with Volterra model (VM). We consider the trellis of nonlinear values for BCJR based detector, which is used to estimate the probability of the data bits. The bit error rate (BER) simulation is based on various parameters of the perpendicular HAMR system in linear and nonlinear channels at the areal density of 5 Tb/inch^2. The simulation results show the BER performance of the BCJR based detector with nonlinear GPR target better than the nonlinear PR1 target. Heat-assisted magnetic recording (HAMR) system requirements achieve high areal densities about to 1 Tb/inch^2. The medium of HAMR system is temporarily heated during the recording process [1]. However, as grain sizes are reduced, thermal fluctuations can reverse spontaneously the grain magnetization direction. As an alternative to the Bahl-Cocke-Jelinek-Raviv (BCJR) algorithm [2] method, a trellis based detector is proposed for the HAMR channels. In this research, we apply the nonlinear generalized partial response (GPR) targets for the state trellis diagram of BCJR based detector [3] on perpendicular HAMR system with Volterra model (VM) [4] for the readback signal, as shown in Figure 1. We modify the PR1 target to nonlinear PR1 target for the 1st VM kernel. After that, the nonlinear GPR target of channel has been adjusted by the designed 2nd VM, in which the readback signal is the VM actual waveform signal. We improve the branch values of trellis from linear GPR target to nonlinear GPR targets. The received signal y_i and the readback signal r_i with AWGN signal n_i can be expressed as $r_i = y_i + n_i = a_i * h_i + n_i$ The received signal y_i is updated by paper [4], which is modify the linear target to nonlinear target for the trellis diagram, as shown in Figure 2. We can define the equations of a state branch in the trellis for BCJR detection as $g_i(a,q) = 1/\mathrm{sqrt}(2\pi\sigma^2)\times\exp(-(r_i - y_i\ (a,q))^2/2\sigma^2)$ $g_i(b,q) = 1/\mathrm{sqrt}(2\pi\sigma^2)\times\exp(-(r_i - y_i\ (b,q))^2/2\sigma^2)$ Forward in trellis, calculate each branch values in equation $a_q = a_{a-1}(Q) \times g_i(a,q) + a_{b-1}(Q) \times g_i(b,q)$ $a_Q = a_q/\mathrm{SUM}(a_q)$ In addition, calculate each branch values in backward of trellis are as follows: $b_q = b_a \times g_{i-1}(q,a) + b_b \times g_{i-1}(q,b)$ $b_Q = b_Q/\mathrm{SUM}(b_q)$ After that, we calculate the sum of the probability values between forward and backword to update the soft information as $\Pr[u_i=1|r_i] = a_Q \times g_i(a,q) \times b_Q + a_Q \times g_i(b,q) \times b_Q$ In the simulation, we consider the HAMR system at the areal density of 5 Tb/inch^2, which the parameters are described previously by P. Tueku, et al, [5]. The parameters of VM kernel determine the constant coefficients $K_1 = 1$ and $K_2 = 0.3$. The jitter noise is 20 percents. The additive white Gaussian noise (AWGN) has zero mean and variance $\sigma^2 = 0.5\times10^{-(SNR/10)}$. We define the range of signal-to-noise ratio (SNR) is 15 to 25 dB. In Figure 3, we compare the improved BCJR based detection with nonlinear GPR target and PR1 target. The BCJR based detection with nonlinear GPR target achieves the gain of 0.1 dB over the BCJR based detection with nonlinear PR1 target based detector at the BER of 10^{-5}. Conclusions We propose the method to improve the branch values of trellis by using linear GPR target to nonlinear GPR target for BCJR detector on HAMR system with VM kernel. In the simulation results, we found the BER performance of the BCJR detector with nonlinear GPR target is better than the BCJR detector with nonlinear PR1 target.

Exchange bias (EB), as an internal magnetic bias induced by a ferromagnetic-antiferromagnetic exchange coupling, is extremely important in many magnetic applications such as memories, sensors and other devices. [1, 2] Voltage control of exchange bias in multiferroics provides an energy-efficient way to achieve a rapidly 180° deterministic switching of magnetization, which has been considered as a key challenge in realizing next generation of fast, compact and ultra-low power magnetoelectric memories and sensors. [3] Although there are some researches related to the voltage controlled EB, [4-6] few of them focus on the regulation of perpendicular EB which is of great technological relevance for high-density spintronics. In this study, we demonstrated E-field control of perpendicular EB based on Pt 4nm/IrMn 4nm/Co 0.7 nm/(Co 0.7nm/Pt 0.95 nm)$_2$/Ta 3nm/PMN-PT (011) multiferroic heterostructure at room temperature. Angular dependences of EB with different applied voltage were studied through vibrating sample measurements (VSM) and ferromagnetic resonance (FMR) measurements respectively. For each method, maximal E-field induced exchange field change of ΔH_{eb} = 47 Oe and 95 Oe were obtained at θ=0° and 10° while under the compressive stress. Since VSM and FMR have different measurement principle, the difference of ΔH_{eb} is predictable.[7] We related this phenomenon to the strain induced lattice distortion, which can influence the Co 3d - Pt 5d interfacial hybridization [8, 9] and then the change of interlayer exchange bias. This voltage manipulation of perpendicular EB should offer new possibilities towards novel magnetic devices and memories with great energy-efficiency and ultra-high densities.

One of the central challenges in realizing multiferroics based magnetoelectric memories is the ability to non-volatilely switch magnetization between the in-plane and out-of-plane directions with a control voltage.[1] This switching often requires overcoming a large demagnetization field, which is hardly achieved by a relatively small voltage-induced magnetic anisotropy in conventional multiferroic laminates.[2,3] However, in ultra-thin ferromagnetic/ferroelectric heterostructures, given the effect of spin reorientation transition, voltage induced-lattice strain can tip the balance between the surface anisotropy and demagnetization field, leading to a deterministic switching of magnetization between the in-plane and out-of-plane directions.[4] In this work, we demonstrate a voltage switching of perpendicular magnetic anisotropy in $(Co/Pt)_3$/(011) PZN-PT multiferroic heterostructures at room temperature. Electric field control of magnetic anisotropy was quantitatively studied by ferromagnetic resonance (FIG. 1a) Taking the advantage of large electric field induced strain during phase change in PZN-PT piezoelectric single crystalline substrates, a large electric field-induced effective magnetic field up to 670 Oe was observed(FIG. 1b), leading to a switching of magnetization easy axis rotation from out-of-plane to in-plane that demonstrated by angular dependence of ferromagnetic resonance fields (FIG. 1c and 1d). In addition, it was also confirmed by the magnetic hysteresis loops(FIG. 1e and 1f). The strong magnetoelectric coupling in $(Co/Pt)_3$/PZN-PT at room temperature provides a new platform for realization of voltage control of perpendicular magnetic anisotropy that will enable power efficient multiferroic memories.

BW-03. High isotropic Terfenol-D/PZT magnetoelectric sensor based on ring nested structure.

X. Wu[1], J. Ouyang[1], W. Wang[1], Y. Ren[1], S. Chen[1] and X. Yang[1]
1. School of Optical and Electronic Information,Huazhong University of Science and Technology, WuHan, China

Magnetoelectric sensors with high sensitivity and the easy preparation of structure, etc, have broad application prospects in the weak magnetic signal detection and other fields. In recent years, scholars [1-4] studied the dependence of the magnetoelectric effect on the magnetic field direction. The results show that the output of the magnetoelectric composites change with the angle of the magnetic field, and the ratio of the maximum value to the minimum value of the output signal is recorded as K. When K is very large, the magnetoelectric composites have high anisotropy, which means they are very sensitive to magnetic field in a particular direction and are therefore suitable for vector magnetic field measurements; in contrast, when K is very small, the magnetoelectric composites are highly isotropic, which means their outputs are less affected by the direction of magnetic field and thus are suitable for the scalar field measurement. Dong et al [1] and our team [2] made highly anisotropic magnetoelectric sensors (K values between 100 and 1000), and it was found that K values were related to the shape anisotropy of piezoelectric materials and magnetostrictive materials. But so far, high isotropic magnetoelectric sensors have not been reported yet. In this respect, Terfenol-D/PZT magnetoelectric sensor based on ring nested structure is studied in this paper, both of which have shape isotropy, as shown in Fig 1(a). We tested the relationship between the voltage (V) output of the structure and the DC bias magnetic field (Fig 1(b)). The structure was placed in the horizontal AC magnetic field generated by the coil, and the electromagnet provided a DC bias magnetic field in the horizontal direction. When the AC magnetic field (H_{AC}) is 1Oe at 10kHz, and DC bias magnetic (H_{DC}) field increases from 280Oe to 10920Oe, the output curve of the structure (Fig 1(c)) shows that the rapid increase before 2520Oe of H_{DC}, and then decreased slowly. The voltage reaches a maximum of 364.055mV when H_{DC} is 2520Oe. In order to miniaturize the sensor probe, we changed the electromagnet to a small cylindrical magnet with a diameter of 10 mm and a height of 10 mm, making it a sensor as shown in Fig 2(a). It consists of Terfenol-D/PZT structure, two magnets with the same polar direction and a frame. In order to study the output linearity of the sensor, we use the instruments shown in Fig 2(b) to test the relationship between V and H_{AC}, by adjusting the distance between magnets and material, the probe response reaches its maximum. At this time, the output voltage of the sensor, which in the magnetic shield barrel, increases linearly with the increasing AC magnetic field at 10kHz, which generated by the coil, as shown in Fig 2(c). In order to study the magnetoelectronic isotropy of the sensor, keeping the H_{AC}=1Oe at 10kHz, each time the sensor is rotated by 30°, the relationship between V and the rotation angle shown in Fig 2(d) is obtained and fitted by our proposed finite element model, and it can be calculated that K equals 1.99. According to the results of finite element method, we found the test values were in agreement with the theoretical values, which proved experimentally and simulatively the ring nested structure sensor was highly isotropy. And it was also found that magnetoelectronic isotropy could be affected by the shape isotropy of the piezoelectric and magnetostrictive materials, as well as the direction of the bias magnetic field by the finite element method.

BW-04. Preparation and Characterization of Permalloy and Cobalt Doped $BiFeO_3$ Hybrid Core-shell nanostructures.

K. Javed[1,2], N. Ahmad[3], M. Shahzad[1] and S. Shah[1]
1. Physics, Forman Christian College, Lahore, Pakistan; 2. Institute of Physics, Chinese Academy of Sciences, Beijing, China; 3. Department of Physics, FBAS, International Islamic University, Islamabad, Pakistan

Nanowires and Nanotubes have got considerable attention because of their novel potential applications in ultrahigh magnetic recording media, ultrasmall magnetic sensors, drug delivery etc.[1] The properties of nanostructures are highly dependent on their size, which makes them very attractive for industrial applications[2] Hybrid coreshell nanostructures have attracted ever-increasing interest due to its potential for applications as multifunctional devices[3-4]. Hybrid interfaces comprising ferromagnetic metals and ferroelectric/multiferroic oxides are of particular interest for the next generation magnetoelectric memories, in which magnetism can be tuned electrically via strain-/spin-mediated couplings across the interfaces[5]. Hybrid one-dimensional core-shell nanowires and coreshell nanotubes consisting of Permalloy core and Cobalt doped $BiFeO_3$ multiferroic shell were synthesized using a two-step method (Sol-gel and DC electrodeposition). Doping effect has been studied by structural and magnetic characterization. The results have shown a significant exchange bias and coercivity, particularly for hybrid coreshell nanotubes. This may be attributed to effective reduction of domain size between coreshell adjacent layers. SEM and TEM showed excellent surface morphology for both coreshell nanowires and coreshell nanotubes, with shell thickness ~20nm. At low temperature, super-paramagnetic contribution plays an important role to control magnetic behavior. Easy magnetization axis aligned parallel to axis of coreshell nanowires due to dominant shape anisotropy. The results have shown that by site engineering method the properties of multiferroic composition can be improved. This multipurpose method can be used to blend several hybrid one dimensional core-shell nanowires as well as for coreshell nanotubes.

BW-05. Large Magnetoelectric coupling in a Y-type hexaferrite.

Y. Yang[1,2], K. Jiang[1], J. Li[1], C. Duan[2], X. Wang[1] and H. Ge[1]
1. College of Materials Science and Engineering, Zhejiang Province Key Laboratory of Magnetism, China Jiliang University, Hangzhou, Hangzhou, China; 2. Key Laboratory of Polar Materials and Devices, Ministry of Education, East China Normal University, Shanghai, Shanghai, China

We report the multiferroicity and large magnetoelectric coupling in a Y-type hexaferrite, $Ba_{0.5}Sr_{1.5}Zn_2(In_{0.08}Fe_{0.92})_{12}O_{22}$.By applying an electric field, the magnetization, planar helix transition temperature, coercivity and magnetization reversal of $Ba_{0.5}Sr_{1.5}Zn_2(In_{0.08}Fe_{0.92})_{12}O_{22}$ are effectively modified. As shown in Figure.1, two peaks are observed at 315 and 337 K, corresponding to T_S and T_N, respectively. The inset shows the temperature dependence of magnetization (M-T) for In-BSZFO measured at 50 Oe. The sample undergoes an AFM phase transition at T_N = 337 K followed by a PH transition around T_S = 315 K, agreeing well with the DSC results. Remarkable electrical controlling of magnetism is observed at 315 K. According to the M-T curves for In-BSZFO at 2 kOe with or without DC electric field (E_{dc}) shown in Figure. 2(a), it is clear that M is almost unchanged below 280 K, but decreases distinctly with E_{dc} in the vicinity of T_S, suggesting that E_{dc} can affect M more easily around the PH to AFM phase transition region. As a result, T_S shifts toward the lower temperature about 7 K, which can be seen from the inset of Fig. 2(a). Interestingly, cross-control of magnetism and ferroelectricity is simultaneously realized in this magnetoelectric hexaferrite[Fig.2(b)]. Large direct and converse magnetoelectric effects in In-BSZFO give a valuable contribution to the study of magnetoelectric effect, which is of great importance in promising its practical applications in the future.

1. Introduction The demand for high speed, high storage density, and low power consumption nonvolatile memory technology has stimulated extensive research into new functional materials. Resistive switching has been reported in multiferroic bismuth ferrite (BFO), in which the resistance can be switched between a high resistance state (HRS) and a low resistance state (LRS) [1-2]. These two resistance states can stand for binary 0 and 1 in resistive-switch memory. In general, the metal/BFO/metal cell shows bipolar resistive switching that the set to a LRS occurs at one voltage polarity and the reset to the HRS appears at reversal voltage polarity. It has been widely recognized that this so-called bipolar resistive switching is usually connected with a voltage-driven oxygen vacancy movement.However, BFO films exhibit p-type conduction as a result of Bi loss[3], and a Schottky junction or a p-n junction may be formed at the metal/BFO interface and can be modulated by the ferroelectric polarization, which induces blocking or non-blocking interfaces for the transport of carriers and consequent the resistive switching behavior [4-5]. Here, we prepared Pt/BFO/$SrRuO_3$/$SrTiO_3$ resistive device units and observed a repeatable and switchable resistive effect of BFO films with a tunable HRS/LRS ratios and a low resistance switching voltage of ±1.5 V, apart from the high forming voltage. 2. Experiments The BFO films of 25 nm were deposited on $SrTiO_3$ (001) substrates with 40 nm $SrRuO_3$ buffered layer via RF magnetron sputtering. The substrate heating temperature and the working pressure of oxygen gas were maintained at degree centigrade and 1 Pa, respectively. To fabricate a metal/insulator/metal cell, top electrodes of Pt (100 nm) with diameters of 100μm, 200μm and 300μm were sputtered onto the as-deposited BFO films through a shadow mask shown as Fig1. The I–V curves of the devices were measured by an Agilent B1500 source meter and the maximum current is limited by a compliance current to avoid permanent hard breakdown while unipolar HRS switches to LRS. 3. Results and Discussion Fig 1 shows the I–V measurements by sweeping the bias voltage from 0 to -2V, back to +2 V and returning to 0, repeatedly. The large hysteresis in I–V curves is clearly observed and the Pt/BFO/SRO cell changes from low conducting state (OFF) to high conducting state (ON) at about -1.5 V. Moreover, when sweeping bias voltage transforms from negative value to positive value, we find that the Pt/BFO/SRO cell changes from ON to OFF at about ±1.5 V. Furthermore, I-V curves exhibit good repeatability within nine testing cycles and the resistance switching does not need the forming process, which indicates that resistive switching does not origin from a voltage-driven oxygen vacancy movement, but is possibly correlated with the change of the potential barrier height in the interface between BFO and SRO [3]. Fig 2 presents the OFF/ON resistance ratio at different testing cycles and stimulated voltage range. It is easily seen that the ON resistance almost keeps the same value, but the OFF/ON resistance ratio significantly depends on the maximum value of negative voltage. The OFF/ON resistance ratios reach about 100, 30 and 10, when the negative voltages are -2V, -1.8V and -1.6V, respectively, probably due to the different degree of ferroelectric polarization in the BFO films[4]. More research details for the ferroelectric polarization induced resistive switching will be bring out in the conference. 4. Conclusion We demonstrated a significant resistive switching at a low operating voltage of ±1.5V with ON/OFF ratios as high as 100 in Pt/BFO/SRO/STO (001) heterostructures, and can successfully tune ON/OFF ratios from 10 to 100 by applying different negative voltages. By further optimizing its cell structure, BFO film based device may become a promising candidate for non-volatile memories due to the advantages of low power consumption, multi-value storage and high stability. ACKNOWLEDGMENTS This work was supported by the National Natural Science Foundation of China (Grant Nos. 61432007 and 61474050) and the Fundamental Research Funds for the Central Universities, HUST (Grant No.2016YXMS204).

Magnetoelectrics offer the ability to electrically control magnetic material and device properties. This feature has the potential to provide numerous benefits to electronic systems and motivate the integration of magnetic devices into mainstream electronics [1-3]. Most work on magnetoelectrics thus far, however, has involved either specialized crystalline multiferroic materials [1,4-6] or bulk piezoelectric/magnetic composite layers [7-13]. Here, we attempt to bridge the gap between magnetoelectricity and silicon-integrated electronics by producing the first fully-integrated thin-film magnetoelectric resonant waveguides for tunable radio frequency (RF) systems [14]. Tunability of these devices is achieved through electric field control of magnetic permeability in order to change the phase velocity and resonance frequency of coplanar waveguides. The devices were fabricated on a conventional silicon substrate and incorporate thin-film magnetoelectric composites, made up of both magnetic and piezoelectric material layers for strain-control of magnetic anisotropy. The fabricated devices achieved reversible tunability of the resonance frequency with a large converse magnetoelectric coupling coefficient of up to 24 mG-cm/V using just thin films. The tunable waveguide device, shown in Fig. 1, was designed as an RF quarter-wavelength resonator, whose resonance is based on the total effective permeability and permittivity of the material stack. To provide the capability of tuning the resonance frequency, a thin-film magnetoelectric composite was created using a magnetostrictive ferromagnetic layer on top of a piezoelectric/electrodes combined layer, with the silicon substrate on the bottom. A coplanar waveguide on the surface of the structure carries the wave such that its propagation is influenced by the properties of the underlying magnetoelectric stack. Electric field control of piezoelectric strain couples to the magnetic layer for strain control of magnetization and permeability, therefore influencing the propagating phase velocity and resonance frequency of the waveguide. Fig. 1a illustrates the simplified integrated structure as well as the electric field lines from the interdigitated electrodes controlling the piezoelectric. Fig. 1b shows scanning electron microscope images of the cross-section of the fabricated devices, produced by focused-ion beam. Platinum interdigitated electrodes (IDE) [11] apply an approximately in-plane electric field, as shown in Fig. 1a, to the piezoelectric PNZT and take advantage of the d_{33} strains, which are typically larger than d_{31} strains. The ferromagnetic material, $Co_{43}Fe_{43}B_{14}$ (At%) [12] was selected for its high magnetostriction value of $\lambda s \sim 55 \times 10^{-6}$ and high ferromagnetic resonance frequency (~ 2 GHz for a square film). These two properties allow for a large degree of electrical control (via strain) of magnetization and a material resonance frequency well separated from that of the device resonance. In addition, the magnetic film was laminated and patterned into a narrow bar parallel to the wave propagation direction, such that the shape anisotropy contributed to aligning the magnetization uniformly along the length direction, with permeability measured along the orthogonal (width) direction. Fig. 2 presents measurement results from the magnetoelectric resonator device. The polarization measurements around the remanence point, indicate that the polarization (and related strain) is fairly linear and reversible, despite some hysteresis. The corresponding RF resonance shifts for the magnetoelectric waveguide follow a similar trend but with opposite polarity. This is due to the fact that the strain causes a rotation of the magnetization and an increase in the permeability with electric field; permeability is inversely related to the phase velocity and resonance frequency, therefore leading to a decrease in the resonance frequency with applied electric field. Neglecting contributions due to stray fields or temperature effects, we extract an effective magnetoelectric coefficient for the composite device equal to approximately 24 mG-cm/V, which is comparable with many other multiferroic and magnetoelectric composites. Acknowledgement Research for this project was conducted with government support under FA9550-11-C-0028 and awarded by the Department of Defense, Air Force Office of Scientific Research, National Defense Science and Engineering Graduate (NDSEG) Fellowship, 32 CFR 168a. Part of this work was performed using the Stanford Nanofabrication Facility (SNF) and the Stanford Nano Shared Facilities (SNSF) at Stanford University.

BW-08. Study of magneto-dielectric behaviour in Haldane spin chain Ho_2BaNiO_5.

S.K. Upadhyay[1] and E.V. Sampathkumaran[1]
1. Department of Condensed Matter Physics and Material Science, Tata Institute of Fundamental Research, Mumbai, MUMBAI, India

In search of new multiferroic materials, researchers have discovered various rare earth based multiferroic materials $RMnO_3$, $R_2Mn_2O_5$ (where, R= rare earth) in the past decade, due to its interesting physics as well as promising application in the field of memory devices[1]. During last few years, our group has explored multiferroicity in Haldane spin chain based system R_2BaNiO_5 (R=Gd, Dy, Tb, Er, Sm etc.) [2, 3]. This family of insulating oxides, crystallizing in *Immm*-type orthorhombic structure, occupy a special place in the area of magnetism. In this family, Ni^{2+} ions (spin = 1) form linear chains which are well separated by R ions. For R= Y, there is no magnetic ordering from Ni sublattice, but for magnetic rare-earth members, ordered magnetic moments appear simultaneously for R and Ni ions with a complex antiferromagnetic structure [4]. We noted that, for R= Gd, Dy and Er, onset of short-range or long-range magnetic order triggers ferroelectricity due to the distortion of Ni-O bond distances, whereas, for the Tb member, multiferroicity appears well below its Néel temperature (T_N) associated with different magnetic structure. Focussing on the Ho member, it was reported in the literature [5] that there are two meta-magnetic transitions in this compound. We have studied its magnetic, dielectric and magneto-dielectric behavior in detail, the results of which are reported here. The polycrystalline sample of Ho_2BaNiO_5 was prepared by a standard solid-state reaction route as reported in ref.[5]. The x-ray powder diffraction pattern (Cu-K_α radiation) at room temperature confirmed the single phase formation of the sample. The observed diffraction pattern was analyzed by Rietveld fitting by using Fullproof program. The lattice parameters obtained by the best fitting (a= 3.760(1) Å, b= 5.758 (4) Å and c= 11.329 (3) Å) match well with the literature [5]. Ac magnetic susceptibility (χ) and isothermal M measurements were carried out by a commercial superconducting quantum interface device (SQUID, Quantum design, USA). Agilent E4980A LCR meter with a home-made sample holder integrated with the PPMS (Quantum Design, USA) was used for the complex dielectric permittivity measurements. Isothermal dielectric constant (ε¢) as a function of magnetic field (H) was measured at some selected temperatures. Figure 1 reveals the one to one correspondences between the dielectric constant (electrical susceptibility) and magnetic susceptibility of the studied sample. A careful analysis of dielectric data as a function of temperature showed that around 12 K, there is an anomaly in dielectric data for the frequency of 100 kHz as shown in the left frame of figure 1. The first derivative of the ac-susceptibility data shows peak close to 12 K (right frame of figure.1), suggesting a new magnetic transition following anti-ferromagnetic transition around 52 K (please see the inset of figure1). In order to support the existence of a magnetic transition around 12 K, we measured isothermal magnetization at various temperatures (not all temperature shown here). We observe a distinct upturn in $M(H)$ near (H_{cr1} =) 29 kOe and (H_{cr2}=55 kOe) for T= 10 K, attributable to the existence of a field induced transition as shown in the left frame of the figure2. Further support for magnetodielectric coupling is obtained from isothermal magnetodielectric data, shown in the right frame of Fig. 2. For 10 K, ε [defined as = {ε (H) – ε (0)}/ε (0)] undergoes a sharp increase with H and achieve a maximum near H_{cr1}; there is another upturn at H_{cr2}, supporting the existence of two (broad) meta-electric transition. The field at which this upturn happens decreases with increasing temperature. No such meta-electric like feature is observed for the curves well above 12 K. Magnetic, dielectric and magneto-dielectric behaviour have been studied for the Haldane chain based system Ho_2BaNiO_5. The strange behaviour of dielectric in the presence of magnetic field is manifested by the possible field induced change in magnetic structure and due to the existence of magneto-dielectric coupling. Neutron measurements are underway for understanding the magnetic structure to relate to magneto-dielectric coupling differences above and below 12 K.

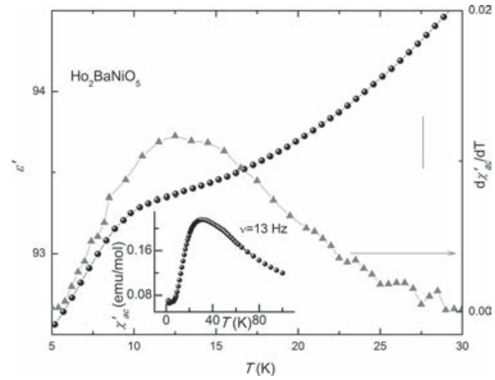

Fig. 1. Left frame presents the dielectric data in zero magnetic field with frequency of 100 kHz. Right frame shows first derivative of ac-χ data in zero field with frequency of 13 Hz. Inset shows the ac-χ data to highlight the antiferromagnetic transition around 52 K.

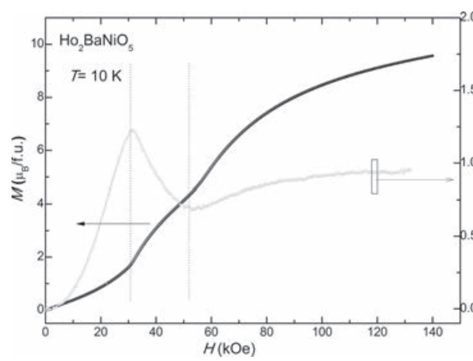

Fig. 2. Left frame presents the *M-H* data while right frame presents the magneto-dielectric data depicting the one to one correspondence.

BW-09. Prediction of Room Temperature Oxygen Vacancy-mediated Multiferroicity in a Cobalt-substituted Perovskite.

M.C. Onbasli[1]
1. Dept. of Electrical and Electronics Engineering, Koc University, Istanbul, Turkey

Multiferroic materials are a source of novel physics as well as enablers of memory and logic devices that are unattainable using conventional semiconductors. Most of the known single-phase multiferroic materials, however, are only multiferroic at low temperatures, are antiferromagnetic instead of ferro- or ferrimagnetic, or present either sinusoidal (with negligible magnetization) or screw-type magnetism with low Curie temperature. Here, we predict through density functional theory calculations that both magnetism and electric polarization can originate from the interactions between oxygen vacancies and the B-site cations in cobalt-substituted $SrTiO_3$, and we show experimentally that oxygen-deficient polycrystalline and single crystal thin films of $SrTi_{0.70}Co_{0.30}O_{3-\delta}$ can exhibit mixed Co valence states giving rise to room temperature ferromagnetism. The experimental and modeling results suggest a class of multiferroic materials with properties controlled by their oxygen stoichiometry. There has been intense interest in voltage-controlled magnetism and other magnetoelectric phenomena that can occur in multiferroic oxide thin films [1–4]. For integrated memory and logic applications, materials with significant room temperature (RT) polarization and magnetization, as well as coupling between the magnetic and ferroelectric order parameters, are desirable. Out of the wide range of multiferroic materials studied, many of them are multiferroic only at cryogenic temperatures [5–9], are antiferromagnetic at RT [10–12], or exhibit high magnetic field or voltage bias points [13]. $Bi_{0.75}Sr_{0.25}FeO_3$ [10] and $BiFeO_3$ and its derivatives [11,12] are both antiferromagnetic and strongly ferroelectric. Significant RT multiferroicity and low-field magnetoelectric coupling has been observed in $Sr_4Co_2Fe_{36}O_{60}$ [14], $Sr_3Co_2Fe_{24}O_{41}$ [15] and Y-type $BaSrCo_{2-x}Zn_xFe_{11}AlO_{22}$ ceramics [16], and RT electric control of magnetism has been achieved in $SrCo_2Ti_2Fe_8O_{19}$ [17]. $Sr_3Co_2Fe_{24}O_{41}$, a ferroelectric hexaferrite, has a spiral spin structure and is magnetoelectric at moderate fields [15]. Magnetoelectric coupling has been observed in oxygen-deficient ferroelectric domain walls in $PbTiO_3$ [18] and in PZTFT ($(PbZr_{0.53}Ti_{0.47}O_3)_{0.6}$-$(PbFe_{0.5}Ta_{0.5}O_3)_{0.4}$) [19], and Co-doped TiO_2 exhibited ferromagnetism [20] and magnetoelectric coupling [21] at RT. Despite these advances, obtaining a material which is both magnetic and ferroelectric at room temperature remains an important challenge. A path towards RT magnetoelectrics may exist by control of both magnetic substitution and defect engineering in perovskites. Substitutional doping of magnetic cations into the B sites of perovskite films has been shown to induce intrinsic RT magnetism without metallic precipitates, as in the case of $Sr(Ti,Co)O_{3-\delta}$ [22–24], (La or Ba,Sr)$(Ti,Co)O_{3-\delta}$ [25,26], and $Sr(Ti,Fe)O_{3-\delta}$ [23,27]. Perovskites can support large oxygen deficiency [28] and it is known that oxygen vacancies and other defects promoted by vacancies affect the electronic properties by introducing lattice distortion, lowering symmetry, and stabilizing mixtures of cation valence states. For example, ferroelectricity in $SrTiO_3$ (STO) is promoted by strain [29,30] and Sr-vacancy defects [31–33]; magnetism is promoted by oxygen vacancies [34–38]; and oxygen vacancies were also found to strongly affect mobility and resistivities in $SrTiO_3$. $SrMnO_3$ films exhibit strain-induced coupling of electrical polarization and defects [39]. Oxygen vacancies were found to interact with ferroelectric domain walls to cause magnetism in $PbTiO_3$ thin films [18]. Resistive switching dynamics and polarization in $BaTiO_3$ were controlled by varying oxygen vacancy concentrations [40], and polarization gradients were created across multiferroic $SrMnO_3$ films by introducing oxygen vacancy gradients [41]. The combined effects of strain and oxygen vacancies on resistivity and magnetism were also shown for $SrCoO_x$ thin films [42]. Changing oxygen partial pressure (vacancy concentrations) alter the strain by lowering the symmetry and alter the multiferroic coupling coefficient in $(BaTiO_3)_{1-x}(BiFeO_3)_x$ films [43]. Oxygen vacancies affected both ferroelectricity[44] and magnetism [45] in $YMnO_3$. One may therefore intuit that the simultaneous substitution of magnetic B-site ions, introduction of oxygen off-stoichiometry and strain in a perovskite could trigger both ferroelectricity and magnetism, and presumably coupling between them. Here, we predict through density functional theory (DFT) calculations that both magnetism and ferroelectricity can coexist in oxygen-deficient $SrTi_{1-x}Co_xO_{3-\delta}$ (STCo) with $x = 0.25$ arising from the interplay between oxygen vacancies, B-site ions and structural distortions of the material, suggesting a route to multiferroicity in a class of oxides. We experimentally support several key ideas of this prediction with measurements on $SrTi_{0.70}Co_{0.30}O_{3-\delta}$ (STCo30) deposited as single crystal films on STO or as polycrystalline films on Si and SiO_2, which demonstrate the presence of mixed-valence Co and RT magnetism, though ferroelectricity was not observed above 77 K. The DFT modeling predicts magnetic and polarization order parameters in oxygen-deficient STCo, and identifies the complex V_O interactions that lead to magnetism and polarized charge in this material. We find that both magnetism and ferroelectricity are intrinsically derived from the same structural and electronic features, i.e., the non-centrosymmetrically-distributed spin and charges around the ions. This observation presents a general feature that may be used to identify and manipulate other multiferroic systems.

The magnetostrictive/piezoelectric laminate composites consisting of Ni, Permendur, Metglas or Terfenol-D as magnetostrictive phase and PVDF, PZT or PMN-PT as piezoelectric phase demonstrate strong magnetoelectric effect due to the product property, which provide effective conversion between electric field energy and magnetic field energy. The superior performances make them potential applications in novel multifunctional devices, such as multiple-state storages, energy harvesting transducers, tunable microwave devices, magnetic field sensors, and transformers. Recently, it has been found that the magnetic permeability for magnetostrictive material directly affects its effective piezomagnetic coefficient and corresponding magnetoelectric effect. Combining traditional magnetostrictive/piezoelectric laminate composites and high permeability materials can significantly enhance the effective permeability, which produce the self-biased ME effect. However, in previous reports, most researchers have focused on the preparation method and testing composite structure consisting of specific high permeability materials, which is lack of comparisons and analysis for composites with different high permeability material. Actually for the practical applications of magnetoelectric composites, it is both physically interesting and technologically important to systematically investigate the ME composites with different high permeability materials. Hence in this study, by bonding three different high permeability materials FeCuNbSiB, FeSiB and CoNiFeSiB into Terfenol-D/PZT laminate, the FeCuNbSiB/Terfenol-D/PZT, FeSiB/Terfenol-D/PZT, and CoNiFeSiB/Terfenol-D/PZT laminate composites are prepared. The influences of the different high permeability materials on the ME characteristics of the composites have been investigated, as shown in Fig.1. On one hand, the experimental results demonstrate that the maximum zero-bias ME voltage coefficient for FeCuNbSiB/Terfenol-D/PZT achieves 1.105V/Oe due to the larger magnetic permeability of FeCuNbSiB, which is ~2 times higher than that of CoNiFeSiB/Terfenol-D/PZT and ~ 3 times higher than that of Terfenol-D/PZT. On the other hand, the maximum ME voltage coefficient for FeSiB/Terfenol-D/PZT achieves 2.108V/Oe at low bias field H_{dc}=175Oe due to the higher saturation magnetostriction of FeSiB, while the maximum ME voltage coefficients for Terfenol-D/PZT, CoNiFeSiB/Terfenol-D/PZT, FeCuNbSiB/Terfenol-D/PZT achieve 1.893V/Oe at H_{dc}=510Oe, 1.742V/Oe at H_{dc}=439Oe, 2.065V/Oe at H_{dc}=598Oe, respectively. Correspondingly, the study indicates both the saturation magnetostriction and magnetic permeability of high permeability materials have noticeable influences on the ME characteristics of the laminate composites, which should be taken into consideration when selecting the suitable material.

Abstract: To seek the approach for nonvolatile storage, the ferroelectric dependent transport properties and ferroelectric switchable photovoltaic effects have been widely studied in recent years [1-3]. However, the solutions for realizing high performance electrical writing and optical reading are still limited. As one of the most potential lead-free ferroelectric materials and the unique singular room-temperature multiferroic material, $BiFeO_3$ (BFO) has a very large remnant ferroelectric polarization [4]. Moreover, BFO is particular for its relatively narrow band gap of about 2.7 eV, which supports the photovoltaic effect in the visible range [5]. To optimize the polarization related device performance, it is essential to reach the balance between ferroelectricity and conductivity. It has been demonstrated that the 10% doping of La at the Bi site can effectively avoid the formation of Bi vacancy and improve the crystallization and stabilize the crystal structure [6]. Therefore, $La_{0.1}Bi_{0.9}FeO_3$ (LBFO) was chosen as the ferroelectric layer for its smaller leakage current and lower coercivity compared with BFO. Epitaxial LBFO films with $SrRuO_3$ bottom electrodes were fabricated on $SrTiO_3$ (001) substrates by magnetron sputtering. The LBFO thin films exhibit strong ferroelectric properties (Figure 1a). Electric field controlled nonvolatile reversible resistance switchings (Figures 1b and 1c) and switchable photovoltaic effects (Figure 2a) have been observed in Pt/LBFO/SRO heterostructures, which have been proved to be modulated by the ferroelectric reversal. With 88-nm-thick LBFO layer, the observed room temperature pulsed-read resistance switching ratio can reach 10^5 % magnitude by applying ±2.7 V pulse voltages (Figure 1d). Besides, Figure 2b shows the ferroelectric switchable photovoltaic effect in the visible wavelength range, which exhibits a large tunable open-circuit photovoltage (V_{OC}) from –75 to –330 mV. The switching mechanisms in resistance and photovoltaic effects can be attributed to the polarization reversal modulated interfacial barriers and deep trap states. Our result has demonstrated a high-performance photovoltalic readable ferroelectric nonvolatile memory, which should be helpful in designing novel multifunctional memory devices with high manipulating speed, high density and lower power assumption.
