INTRODUCTION Pulse-width-modulation (PWM) inverters are often utilized in motor drive system, which has motor cores made of magnetic materials. Recently, many studies have shown that iron losses in the magnetic core magnetized by PWM inverters are increased by the higher harmonic components superimposed in current and voltage waveforms [1-12]. In order to reduce iron losses of the motor core, some studies have focused on novel materials, namely, nanocrystalline magnetic materials (NMM) [13] that offer low iron losses compared to conventional non-oriented (NO) silicon steel [14, 15]. Therefore, it is important to understand iron loss properties of the NMM core under the PWM inverter excitation. However, there has been no report on iron loss properties of the NMM core excited by PWM inverters with different semiconductors. Power semiconductor is a main component of inverter circuit. Recently, next-generation semiconductors such as Silicon Carbide (SiC) or Gallium Nitride (GaN) have been studied. Such new material semiconductors allow us to have advantages of high-voltage and high-temperature operation, low on-resistance and fast switching. Recently, we have shown that there are influences of power semiconductor characteristics on iron loss properties of NO materials [16]. Therefore, the next phase is to correctly understand the influence of PWM inverters with conventional and next generation semiconductors in NMM core. This study focuses on an evaluation of iron losses of NMM excited by different PWM inverters using conventional and next generation semiconductors. To do this, we examine the iron loss characteristics as a function of carrier frequency of the NMM ring excited by two PWM inverters using Si-insulated gate bipolar transistor (IGBT) and GaN-field effect transistor (FET). RING CORE AND ITS MEASURMENT SYSTEM In this study, we examine iron loss properties of a ring specimen made of NMM under a single phase PWM inverter. Fig. 1 shows a schematic of the ring specimen and its measurement setup. This ring specimen is excited by two kinds of full bridge inverters; The first inverter is constructed with four GaN-FETs (DGF6010, Sanken Electric Corporation) and the second inverter consists of four Si-IGBTs (PM75RSA060, Mitsubishi Electric Semiconductor). The first (second) inverter is called GaN-FET inverter (Si-IGBT inverter) from here on. The ring specimen made of NMM is impregnated with acrylic resin. The stacking factor of the NMM core is 0.91. The iron losses of the ring specimen W can be calculated by $W = f_0\int H dB/\rho$, where ρ is the density of the magnetic sheet, $H = N_1I/L$ is the magnetic field intensity, and $B = \int V\, dt \,/\, N_2S$ is the magnetic flux density. Here I is the current through core, N_1 (= 264) is the number of turns of the exciting coil, L (= 0.36 m) is the average magnetic path length, V is the B-coil voltage, N_2 (= 264) is the number of turns of B-coils, and S (= 87.5 mm^2) is the cross-sectional area of the core. In the following experiments, a fundamental frequency f_0, a modulation index, and a switching dead time are set to 50 Hz, 0.5, and 3500 ns, respectively. The maximum magnetic flux density B_m of the ring is adjusted by tuning the applied voltage V_{dc} and set to 1.0 T. The ring tests are performed at carrier frequencies f_c of 1, 4, 8, 12, 16, and 20 kHz. See Ref. 5 for details of the ring measurements. RESULTS AND DISCUSSION Fig. 2 (a) shows the iron loss properties with respect to the carrier frequency of the Si-IGBTand GaN-FET-inverter-excited NMM ring. The iron losses under Si-IGBT inverter excitation are almost a constant value. The NMM ring tests under GaN-FET inverter excitation at high carrier frequency (*e.g.* f_c = 20 kHz) show drastically large iron loss compared with that excited by Si-IGBT inverter. The iron loss properties of NMM ring under Si-IGBT and GaN-FET inverter excitations have the different tendency. Figs. 2(b) and (c) show the *B-H* curves of the NMM ring under Si-IGBT and GaN-FET inverter excitations at f_c = 1 kHz. In the NMM ring under GaN-FET inverter excitation, ringing noises of the magnetic field intensity occur due to the high speed switching of GaN-FET. It is thought that the iron losses in the GaN-FET-inverter-fed ring rise with increasing carrier frequency because the number of times of ringing increases. In other words, the iron loss properties of NMM ring depend strongly on power semiconductor characteristics. CONCLUSIONS We for the first time examined iron loss properties of the NMM core excited by the PWM inverter with different semiconductors. The iron losses of the NMM ring under GaN-FET inverter excitation increased with increasing carrier frequency owing to the ringing noises. However, the iron losses based on the Si-IGBT-inverter-fed NMM ring test were an almost constant value. The iron loss properties of NMM ring depended strongly on power semiconductor characteristics. These results open the way to further research in low loss reduction in magnetic material core based on semiconductor characteristics.

FT-06. Analysis of Vibration of a Dual-stator Hybrid Excitation Permanent Magnet Motor for Electric Vehicles.

Y. Fan[1], Z. Wu[1] and C. Tan[1]
1. School of Electrical Engineering, Southeast University, Nanjing, China

INTRODUCTION The Permanent magnet synchronous motor (PMSM) has been broadly applied in electric vehicles due to its high efficiency, high power/torque density, low cogging torque and the ability of fault tolerance[1]. However, both in the integral-slot and fractional-slot motors, the electromagnetic vibration and noise issue, as one of the parasitic effects, has been paid much attention in low noise applications[2]. Furthermore, the vibration and noise levels have been the indexes to evaluate the performance of PMSM for electric vehicles. The conventional permanent magnet motor has the disadvantage that the excitation magnetic field can't be adjusted. Generally, the field weakening operation can be achieved by applying a flux-weakening current in the d-axis. While, the capacity of flux-weakening is limited and there is a risk of demagnetization of permanent magnets. Thus, a dual-stator hybrid excitation permanent magnet (DSHEPM) motor is proposed to realize the field regulation. The vibration of motor is attributed to the electromagnetic forces acting upon the stator and rotor, which are induced by the air-gap magnetic field[3]. Compared with the conventional permanent magnet motor, the DSHEPM motor can operate in a variety of working states, such as increasing magnetization, weakening magnetization and no excitation. Therefore, the air gap magnetic field is relatively complex. Both the electromagnetic force generated under different working states and the electromagnetic vibration characteristics caused by the electromagnetic force are different. Thus, it is necessary to analyze the vibration characteristics produced by the motor, which can provide guidance for the effective suppression of the vibration of the motor. AIR-GAP FLUX DENSITY ANALYSIS To obtain the air gap flux distribution under different operating modes of the motor, the finite element analysis model of the DSHEPM motor is established by the commercial finite element software Ansys. The rotor structure of the DSHEPM motor is composed of 12 permanent magnetic poles and 6 iron core poles. The rotor core pole is aligned with the d axis of the inner stator excitation magnetic field as the motor operates normally. The electromagnetic field can be adjusted by energizing the field winding, and the magnetic field can be enhanced or weakened by changing the direction of the excitation magnetic field. The air-gap flux distribution under different operating modes was shown in Fig. 1. In addition, the motor output torque can be adjusted by changing the q-axis component of the excitation magnetic field. Through the FFT analysis of air-gap flux density harmonics, the frequency domain characteristics of air-gap flux density harmonics can be obtained. ELECTROMAGNETIC FORCE ANALYSIS The electromagnetic forces are the main causes of the electromagnetic vibration in electric motors. As the vibration of motor is mainly delivered from the stator teeth to the case, and the tangential component of the electromagnetic force is very small compared with the radial component, thus the tangential electromagnetic force can be neglected. Based on the Maxwell stress tensor method, the radial electromagnetic force density can be calculated. The radial force density, which occurs from the air-gap magnetic field, is function of time and space. To accurately locate the dominant force harmonics which contribute most to the vibration and noise of the motor with the different excitation modes of the field windings. The 2D FFT is used to decompose electromagnetic force wave in the time domain and space domain. Fig. 2 shows the temporal and spatial decompositions of the radial electromagnetic force density of the motor at four different excitation modes. In Fig. 2 (a) (b) (c) the armature winding is open circuit. In Fig.2 (d) the armature winding and the excitation winding are powered, and the excitation winding is positive excitation. The electromagnetic force harmonics are influenced by the armature magnetic field and the excitation magnetic field. ELECTROMAGNETIC VIBRATION ANALYSIS A multi-physics model is established to analyze the vibration of the DSHEPM motor under different operation modes. The coupling considered in this model is the coupling of magnetic and vibrational systems, which is weak and unidirectional. Using the interpolation method, the electromagnetic force is transferred from electromagnetic mesh to structural mesh, and the vibration of case is calculated through the mode superposition method. The vibration displacement and velocity of the motor case are obtained, and the vibration peaks of motor are influenced by the electromagnetic force harmonics. CONCLUSION In this paper, the vibration level in dual-stator hybrid excitation permanent magnet motor with different operation modes are discussed based on the multi-physics model. The radial force is decomposed with 2D FFT to explain the vibration peaks induced by the dominant force harmonics. The study of this paper can be used to suppress the vibration and noise of the DSHEPM motor.

ABSTRACT This paper investigates the influence of temperature on vibrations and the acoustic field of electric machines using finite-element simulations. To predict magnetic noise, the process is multi-physical in nature. First, an electromagnetic model is simulated to calculate the magnetic pressure in the air gap as the speed and temperature of the motor changes. The magnetic forces are then loaded into the structural model to study the dynamic response of the stator. Next, this response connects to an acoustic model to translate the vibrations at the stator surface into sound. Therefore, the main contribution of this work is the inclusion of thermal effects in acoustic noise calculations. It also attempts to establish a relationship between temperature and loudness by exploring a design space of an interior permanent-magnet motor, from which new design rules may be determined.
INTRODUCTION The electric machine is one of the major contributors to noise pollution. Prolonged exposure to industrial machines without safety equipment, can pose serious health risks. Therefore, in design and operation, noise is a crucial performance index. The sources of machine noise can be grouped into four: aerodynamic, electronic, magnetic and mechanical [1]. Usually, for small and medium-sized motors (below 15kW), magnetic noise is the most essential component of the global noise [2]. Magnetic noise is caused by the presence of magnetic pressure in the air gap. The force acts on the stator tooth and cause vibratory resonances. This is what propagates in the ambient air as acoustic noise. To study acoustic noise, an understanding of the dynamic behavior of the stator is a prerequisite. This can be achieved through modal analysis. This step computes the natural frequencies of the stator and their mode shapes. Natural frequencies depend on the design parameters, material properties, DOF constraints and the fixture [3]. Heat, according to [4], is the 'biggest killer' of electric motors. Even a rise of 10 degrees C above the thermal limit of the motor can shorten its life by half [5]. Therefore, thermal effects cannot be ignored in machine performance analysis. Previous works [2], [6], [7] have extensively explored the vibro-acoustic domain of electric machines. Unfortunately, thermal effects from the acoustic perspective were not given prominence in these studies. There has been a lack of publications considering the fully coupled magneto-thermal-vibration-acoustic problem related to electrical machine design. The goal of this paper, therefore, is to consider the influence of temperature on the acoustic performance of the electric machine. Also, the variations in noise levels obtained from the simulation of a wide range of design examples for geometric variations of the motor model will be used to extract new design rules relating to the thermal-acoustic performance of the devices. In this digest, some relevant aspects of the full paper are emphasized, along with a sample case study to demonstrate the importance of the work. METHODOLOGY Infolytica's interoperable FE software MotorSolve and MagNet [8] are used to build and simulate high-fidelity electromagnetic models to extract the magnetic field solutions. Temperature-dependent BH curves are used as part of a fully coupled magnetic-thermal analysis. The radial pressure wave, P_r, at any angle,θ, along the airgap is calculated from the Maxwell stress tensor given in [2]. The magnetic forces derived a FFT decomposition of the pressure wave are mapped onto the structural mesh. The FEA solver for structural simulations NX Nastran [9] is used for modal analysis. Modal analysis is vital because it calculates the natural frequencies that resonate with the exciting forces to trigger vibrations in the stator structure. These frequencies are extracted over a range of temperatures using temperature-dependent material properties of iron and copper. This is achieved by updating the material properties at each iterative step. The vibrations are calculated by modal superposition of magnetic forces and modal parameters in the frequency domain. This is performed for several design samples of our motor model over a range of speed sweeps. Varying the rotor speed and the winding excitation frequency in a synchronous motor helps account for the electromagnetic harmonics in the vibration analysis. Finally, the vibrations data computed at the stator surface is fed into an acoustic model to estimate the sound power levels at each speed step of the sample. The Figure 1 summarizes the simulation process. PRELIMINARY RESULTS Initial results from studying one sample of a 4pole/12slot IPM motor are presented in Figure 2. In Figure 2 (a), modal analysis reveals a massive reduction in the natural frequencies at 20 degrees C and 100 degrees C. Only modes 1-6 are shown. In Figure 2 (b), the average sound pressure levels are 58.1dB and 62.8dB for 20 degrees C and 100 degrees C respectively. The variance in noise levels is substantial even though only the first 10 modes were considered, this value is expected to increase as the number of modes increases and the results will be given in the full paper. All modes within the audible frequency range (20Hz—20kHz), will be superposed in the full version. Furthermore, more design variations will be studied to extract design knowledge about the thermal effects on magnetic noise and vibrations of synchronous motors.

FT-08. Improvement of efficiency and vibration noise characteristics depending on excitation waveform of a brushless DC motor.

S. Noguchi[1]
1. Motor Drive Laboratory, Tokyo City University, Setagaya-ku, Japan

I. Introduction A structure of BLDC motor is similar to PMSM, so its characteristics are different by slot combinations [1]. Especially in 10poles-12slots BLDC motor, the back EMF waveform is pretty close to sine-wave and the cogging torque is smallest than any other slot combinations. Therefore, 10poles-12slots BLDC is superior as AC servo motor by sine-wave excitation. However, using the motor as a BLDC motor by square-wave excitation leads its efficiency, torque ripple, and noise characteristics worse than sine-wave excitation. Although, it is known that adjusting excitation angle and excitation phase can make these characteristics improvements [2]-[4]. In this paper, assumes to use the 10poles-12slots motor as a BLDC motor by square-wave excitation, we examined experimentally the changes of efficiency, vibration, and noise by adjusting excitation waveform, excitation angle, and excitation phase. II. Extension of Excitation Angle in Square-wave Excitation In order to drive a BLDC motor easily, 120 degree square-wave excitation is commonly used as simple BLDC motor driving method. However, 120 degree square-wave excitation leads the motor efficiency, torque ripple, and noise characteristics worse than sine-wave excitation. Therefore, we improved the motor efficiency by extending excitation angle in a direction of ahead and advancing current phase practically. In this experiments, we extended the excitation angles from 120 degree to 135 degree, 150 degree, and 165 degree. Then we compared the motor efficiency with each excitation angles. Also in this experiments, we use 10poles-12slots BLDC motor whose output is 30W. III. Efficiency Comparison of Each Excitation Waveform In this examination, applied voltage was fixed at constant voltage when the motor drives at 2500rpm(rated speed) and 0.12Nm load(rated). Then, we compared efficiencies with each excitation waveform. Fig.1(a),(b) shows the efficiency and loss characteristics of 120degree, 135degree, 150degree, 165degree, and sine wave excitation. From fig.1(a), the maximum efficiency is 69.0% of sine-wave excitation, but the second highest efficiency is 67.6% of 150 degree square-wave excitation, and it is increased about 3% from 120 degree square-wave excitation. Same as efficiency characteristics, from loss characteristics shown in fig.1(b), the minimum loss is 11.8W of sine-wave excitation, but the second smallest loss is 13.5W of 150 degree square-wave excitation, and it is decreased from 120 degree square-wave excitation. Therefore, as with the sine-wave excitation, it was confirmed to be able to improve the efficiency by using square-wave excitation which used hall sensors and counters. IV. Torque and Noise Comparison of Each Excitation Waveform In this examination, the motor drives at 300rpm or 600rpm and 0.12Nm load(rated). Then, we compared torque and noise characteristics with each excitation waveform. Fig.2(a), (b) shows torque characteristics of 120degree excitation and 150degree excitation, and fig.2(c), (d) shows noise characteristics of 120degree excitation and 150degree excitation. From fig.2(a), (b), 150degree excitation makes current waveform similar to sine wave compare than 120degree excitation current waveform, and torque ripple rate of 150degree excitation is decreased to 57.2% from 81.7% of 120degree excitation ripple rate. Also from fig.2(a), (b), at the range of 4kHz which clearly seen as noise easily, noise level of 150degree excitation is decreased to -72dB from -66dB of 120degree excitation noise level. Therefore, it is found that torque characteristics and noise characteristics are able to improve by extension of excitation angle. V. Conclusion In this paper, it is confirmed that using 150degree excitation leads improvement of drive characteristics like efficiency, loss, vibration and noise from characteristics of 120degree excitation for BLDC motor drive. Also, in torque characteristics, it is found that applying pseudo sine-wave excitation (improvement 150 degree excitation) can further improve the torque characteristics (will be shown in full paper). Consequently, we think the 150 degree square-wave excitation is suited for easy way to improve BLDC motor drive characteristics because 150 degree excitation is able to construct easily by using hall sensors and counters.

I. INTRODUCTION In recent years, the silicon carbide (SiC) power semiconductors have been evaluated and proven to provide the superior overall performance for power-electronic converters and electric vehicles as compared to the silicon (Si) power semiconductors [1-4]. According to [2], the SiC-MOSFET switching device was assessed to offer the better efficiency and power density for a DC-AC inverter and DC-DC converter than the Si-IGBT switching device. Most of those studies focused on evaluation of losses in inverter and power-electronic converters. However, inverter and its power devices need to be also evaluated in the core loss of interior permanent magnet synchronous motor (IPMSM), because inverters are reported to have influence on the iron core loss characteristics [5,6]. Authors in [5] showed that an inverter with low on-voltage power semiconductors has about 10-20% smaller iron loss than the one with high on-voltage power semiconductors. In our previous work [6], we carefully considered iron loss characteristics of electrical steel sheet with the Si-IGBT and SiC-MOSFET inverter excitations. The SiC-MOSFET inverter with low on-voltage has smaller iron loss than the Si-IGBT inverter with high on-voltage; this is a material evaluation of magnetic body. So as the next step, motor core loss should be carefully assesses by three-phase inverters using the Si-IGBT and SiC-MOSFET power devices. This paper investigates core loss characteristics of the IPMSM with the Si-IGBT and SiC-MOSFET inverter excitations. Models of two three-phase inverters are developed to excite the motor, where its parameters are referred from an experimental IPMSM in our laboratory. The first inverter uses the Si-IGBT devices, and the second inverter uses the SiC-MOSFET devices. The two inverters are controlled by PWM method with a low carrier frequency of 1 kHz and a fixed DC-link voltage; the motor is operated with a low rotational speed of 750 rpm and in load operational case. In computational analysis, motor core losses with the two inverters are compared and evaluated on both time and frequency domains; waveforms of stator phase voltage of the motor with the two inverters are also examined to demonstrate efficacy of the two inverters. In addition, the magnetic flux density and distribution contours of motor core losses are analyzed. II. STRUCTURES OF Si-IGBT AND SiC-MOSFET INVERTER EXCITATIONS FOR IPMSM In this research, structures of the Si-IGBT and SiC-MOSFET inverter excitations for the IPMSM are presented in Fig. 1 panels (a) and (b), respectively. Moreover, the voltage-current characteristics of the Si-IGBT, SiC-MOSFET power devices and their built-in diodes are described in Fig. 1 panel (c). In this subfigure, where the current is smaller than 100 A, the drop voltages of the SiC-MOSFET devices are noticeably smaller than the one of the Si-IGBT device. III. COMPUTATIONAL METHOD IN SIMULATION The total core loss of the IPMSM can be calculated as expressed in (1). $P_{core} = P_{3\Phi} - R_s(I_u^2 + I_v^2 + I_w^2) - P_f - \omega T$ (1) Where P_{core} : total core loss of IPMSM, $P_{3\Phi}$: total input active electrical power, R_s : phase resistance (measured in DC condition), 0.6 Ω, I_u, I_v, I_w : phase currents in rms, P_f : IPMSM and encoder mechanical losses, 0.628 W, ω : rotational speed of IPMSM, 750 rpm, T : output torque. The stator and rotor are made of a non-oriented material, named as 35H300, and the permanent magnet in the rotor is sintered NdFeB. The nominal power of the motor is 400 W. The analysis software used for simulation is JMAG. The operational parameters for the PWM inverter are as follows; the fixed DC-link voltage is V_{dc} = 100 V, the fundamental frequency is f_0 = 50 Hz, the carrier frequency is f_C = 1 kHz, the dead-time of inverter is 3500 ns, and the torque in the load test case is fixed as T = 1 Nm. IV. COMPUTATIONAL RESULTS The total core losses of IPMSM with the Si-IGBT and SiC-MOSFET inverter excitations are P_{core} = 4.1 W and 3.99 W, respectively; the reduction value of motor core loss is about 2.76%. The waveforms of phase voltage V_{un} with the two excitations are presented in Fig. 2 panel (a); and the expanded waveforms around the value of 0 V are depicted in Fig. 2 panel (b). From the time t = 0.002 s to 0.008 s, the phase voltage with Si-IGBT inverter has the bias value of -1 V to -0.7 V; meanwhile, the phase voltage with SiC-MOSFET inverter has the much smaller bias value of -0.3 V to 0.3 V, which is symmetric around the value of 0 V. This helps the SiC-MOSFET inverter can mitigate the total core loss of IPMSM. V. CONCLUSION This study has presented analysis and evaluation on total core loss of the IPMSM with the Si-IGBT and SiC-MOSFET inverter excitations. Numerical simulation results demonstrated that the SiC-MOSFET inverter excitation is slightly better in reducing the motor core loss as compared to the Si-IGBT inverter excitation. The FFT analysis of motor core loss in frequency domain also confirmed the advantages of the SiC-MOSFET inverter excitation. In future work, we are going to soon develop a testbed for evaluating the core loss of an experimental IPMSM with the SiC-MOSFET inverter. Detailed comparison between experimental results and the computational analysis in simulation will be conducted and shown in the full version of this abstract.

FT-10. Modeling Magnetic Holding Forces of Permanent Magnet Wheels.

M.D. Noh[1], J. Kim[1] and Y. Park[1]
1. Mechatronics Engineering, Chungnam Natl Univ, Daejeon, The Republic of Korea

Wall-climbing robots have been developed for many applications such as reactor-vessel inspection robot [1], welding robot [2], or pipe inspection robot [3]. To maintain the robot position on inclined surfaces, two mechanisms are typically used: pneumatic suction or magnetic wheel. For irregular ferromagnetic surfaces, magnetic wheel is the only option. The first step in designing a magnetic wheel is to determine the size of the wheel and the magnetic source. Past efforts to design a magnetic wheel include a rule-of-thumb approach [4] and finite-element analyses (FEA) [1-2]. In most cases, the rule-of-thumb method results in a bulky design due to safety factors. Finite-element calculations take very long time for design iterations or optimizations especially for the inherently three-dimensional wheel geometry. Therefore, a simple yet accurate model to estimate the holding force of a magnetic wheel would greatly expedite the design process. If necessary, complicated three-dimensional FEA can be performed at the final stage of design validations. This paper presents a model for magnetic holding forces of permanent magnet wheels. The paper also shows how to use 2D FEA for approximating the 3D analysis. Figure 1(a) shows the schematic of a magnetic wheel. It consists of two ferromagnetic disks joined by a permanent magnet (PM). To increase traction force, a ring-shaped flexible tire surrounds the PM. To model the holding force of the wheel, it is necessary to estimate the reluctances seen by PM and the magnetic flux density along the surface of the wheel. If the disk and the surface is highly permeable, it is reasonable to assume that the flux lines are perpendicular to the surfaces. Then, the shortest path from the perimeter of the disk to the holding surface would follow a circular pattern, as evident from the results of FEA shown in Figure 1(b). If the coordinate system and the parameters are defined as in Figure 1(c), the center of this circular path is on the x-axis. From the geometric relationships, the radius of the path can be expressed as $\rho=\{R(1-\cos\theta)+d\}/\sin\theta$. Thus, the differential permeance at the angle θ is (1) $dP_g = \mu_0\, w\, R\, d\theta / r\theta$ where w is the axial width of the disk. The total permeance can be obtained by integrating this differential permeance as (2) $P_g = 2 \int \mu_0\, w \sin\theta\, d\theta / \theta\, (1-\cos\theta+d/R)$ The integration is from 0 to θ_m, the angle limit where the flux density falls off below a negligible value. Once the air gap perneance is estimated, the air gap reluctance, R_g is simply its inverse. The MMF applied to the air gap between the disk and the holding surface can then be obtained as (3) $F_m = H_c\, l_m\, R_g / (R_m+R_g)$ where R_m is the PM reluctance, H_c the coercivity of PM and l_m is the axial length of PM. Using the Ampere's law, the magnetic flux density at the angle θ can be expressed as (4) $B_g = \mu_0\, F_m / r\theta$ Using the Maxwell stress tensor, the holding force can be expressed as (5) $Fy = (1/\mu_0) \int B_g^2 \cos\theta\, w\, R\, d\theta$ The integration is again from 0 to θ_m. The validation of the force model may require a 3D FEA at much computational cost. In this paper, we propose an equivalent 2D FEA that can greatly reduce the analysis time. Shown in Figure 2(a) is the 2D rendering of the magnetic wheel. The size of PM is adjusted so that it produces the same MMF. Since the ferromagnetic material (pure iron in our case) has very high permeability, it contributes little in determining the magnetic field. As long as the flux lines with respect to the holding surface are similar, the 2D FEA would produce approximately the same forces as the 3D FEA of the magnetic wheel. Figure 2(b) shows the comparison between the results of FEA and the force model proposed in this paper. The parameters of magnetic wheel are as follows: wheel radius R = 30 mm, wheel thickness w = 10 mm, PM axial length l_m = 10 mm, The coercivity of PM, H_c is 8800 kA/m (NdFeB32), PM radius is 8 mm. The integration limit in eq. (2) and (5) is 60 deg. The results display the usefulness and limitations of the force model. First, the model predicts about the same force range that FEA calculates. If needed, the material properties of core can be adjusted so that the the predictions by the model matches better with the FEA calculations. Even the current results are very useful for the initial design of the wheel, where we need to determine the size of the wheel and PM. The actual wheel would produce higher holding forces that the design predicts. Using the force model, a design optimization can be carried out, size the force variation predicted by the model matches well with FEA. The limitations of the model is that since it assumes essentially infinite permeability of core, the predictions will be erroneous when magnetic saturation occurs. Even in that case, the model can be useful, since it is possible to determine whether the wheel is saturated or not. It would help the designers to avoid highly saturated designs such as [1-2]. Edu., Chungnam National University, Daejeon, The Republic of Korea; 3. Dept. of Fire Safety Engineering, Chungnam Provincial Cheongyang College, Chungnam, The Republic of Korea

Recently, tubular linear synchronous machines (TLSMs) are increasingly being employed in industries ranging from transportation, manufacturing, and office automation to material processing, health care, and generation systems owing to their high force density, high bandwidth, virtually zero attraction force, and the absence of end windings [1]. An axially magnetized permanent magnet (AMPM) topology can be produced at lower costs because its PMs are easily magnetized [2]. Therefore, an AMPM topology is suitable for TLSM and this paper deals with TLSM with AMPMs, as shown in Fig. 1. As is well known that the detailed knowledge of the magnetic field distribution in air gap is vitally important for design and optimization of permanent magnet machines, especially for TLSM with AMPMs. Although numerical tools, such as finite element method (FEM), are able to offer precisely field prediction, they can provide neither closed-form solution nor physical insight. Analytical methods are useful for the first evaluation of machine performances and for design optimization since continuous derivatives, which are issued from the analytical solutions, are required during most optimization methods. However, it is difficult to gain insight into the influence of the design parameters on the machine performance of TLSMs with AMPMs through analytical solutions due to magnetically complex outer PM mover structures. Therefore, this paper presents an analytical modeling and experimental study for electromagnetic analysis of a TLSM with AMPMs, accounting for the flux passing iron pole. As shown in Fig. 1(a), the analytical field domains are divided into five regions: air (I, III, V), slotless winding (II), and PMs (i) regions. The analytical model provides a description of the magnetic flux density distribution and accounts for flux passing iron pole. The governing equation in all subdomains can be solved, and the field distribution can be obtained by applying the boundary conditions on the interfaces between the subdomains [3]. The magnetic field and the electromagnetic performance obtained by the analytical method were compared with those obtained by FEM and experimental measurement of prototype (as shown in Fig. 1(b)); the comparison validates the analytical methods presented in this paper. The analytical results for the magnetic field are in good agreement with the FE analysis results, as shown in Fig. 2(a) and 2(b). For slotless coil subdomain, the computation of the flux linkage using the method of winding function theory is not suitable. Instead, the method based on the Stokes theorem using the vector potential in the slotless coil region is used. The back-EMF is calculated by the derivative of the flux linkage with respect to time. Based on analytical solution, equivalent circuit parameters, such as the back-EMF and inductance can be obtained analytically. The generating characteristics are derived with the equivalent circuit method. As shown in Fig. 2(c) ~ 2(f), the analytical predictions are compared with the measured data in order to confirm the validity of the methods proposed in this paper. The analytical solutions allow the prediction of the back-EMF, the inductance, and generating characteristics in closed forms. In turn, these facilitate the characterization of the machines and provide a basis for comparative studies, design optimization, system dynamic modeling and simulations, and control development. The analytical modeling, analysis results, discussions, and measurements of the TLSM with AMPMs will be presented in more detail in the final paper. Abstract: The paper addresses the issue of the working point migration in non-linear permanent magnets (PM). Starting from the considerations of energy, a novel working-point migration model (WPM) is proposed which can be incorporated into a magnetic equivalent circuit (MEC). The static characteristic of a bistable polarized magnetic system (BPMS), as used in actuators, is calculated using the magnetic circuit method based on the WPM, while a finite element model (FEM) is also derived. The WPM based MEC model yields reasonable results, compared with FEM, of the latching force but with much faster calculation speeds. Furthermore, the working-point state of the PM is clearly illustrated. The test system of the BPMS prototype is established. It is shown that the WPM model provides accurate prediction of static characteristics of an electromagnetic system. I. The Model Magnets such as AlNiCo are widely used in polarized magnetic systems due to their stable structure, high Curie point, simple manufacturing and low cost. However, they suffer from what is known as the working point migration (WPM) phenomenon. Even under special conditions (e.g. coil overcurrent) a reverse magnetization will occur. The phenomenon is quite complex and there exist no reliable simulation methods. An inverse hysteresis model based on spline approximation [1] achieves good accuracy but the calculation is cumbersome. A linear approximate hysteresis model of AlNiCo [2] allowed transient calculation of a PM motor, but the model is somewhat inflexible. A hysteresis model [3] based on a support vector machine (SVM) approach used statistical learning theory and structural risk minimization principle. In this paper, a non-linear WPM model based on affine transformation is established, relying on the demagnetization curve model, the recoil line model and affine transformation hysteresis loop model. Shown in Fig. 1a, the initial working point is located at Q_0, and the working point migration can be calculated by the demagnetization curve model, depicted by the black line. If after demagnetizing the working point migrates to $Q_{1,}$ then a new working point when magnetized will follow the recoil line shown by the green line. However, assume the PM is demagnetized further to reach Q_2 below the H-axis, implying reverse magnetization. Now the working point migrates along a minor hysteresis loop, shown in blue. This migration can be calculated using an affine transformation model, where a minor hysteresis loop can be transformed from the major loop as a new demagnetization curve. By combining the demagnetization curve model and the recoil line model in the minor hysteresis loop, the resultant working point can be established. II. Application of the WPM Model to a Polarized Magnetic System The structure of the system is shown in Fig. 1b, where the top PM is AlNiCo5 and the lower is NdFeB. Soft magnetic components are made of DT4E. The working principle is described graphically with the black and red dashed lines depicting the magnetic flux of the magnets and the electromagnet, respectively. With the coil excited for forward movement, in the lower air gap the fluxes due to the PM and the electromagnet are in opposition, resulting in a decrease of the downward magnetic force. In the upper air gap, on the other hand, the two fluxes act in the same direction resulting in an increase of the upward force. Consequently, the armature is pulled up by the upward net force. Conversely, with a reverse coil current, the armature is pulled down by the downward net force. Applying the WPM model results in the equivalent magnetic circuit of Fig. 1c. Using the WPM model and previous (or initial) working point, the temporary PM working point is calculated. Then the force and branch fluxes are calculated using the equivalent magnetic circuit. Next, the temporary PM working point is fixed according to the WPM model and the branch magnetic flux. The calculating process is repeated iteratively until the final working point and the force can be calculated. A prototype was built and measurements taken. Results of the calculations and experiments are shown in Fig. 2. III. Conclusion It has been demonstrated that the magnetic circuit model based on the proposed working-point migration model enables accurate and very fast calculations of the performance – in particular the magnetic force – of a polarized magnetic system. Thanks to reasonable accuracy and short computing times, this model can be used for robust design optimization.

FT-13. Analysis of Multi-phase and Multi-layer Factional-Slot Concentrated-Winding on PM Eddy Current Loss Considering Axial Segmentation and Load Operation.

Q. Chen[1], D. Liang[1], S. Jia[1] and X. Wan[1]
1. Xi'an Jiaotong University, Xi'an, China

1. Abstract: The PMs eddy-current loss of the 12-slot 10-pole machine with multiphase and multilayer windings are mainly investigated using the 3-D finite element analysis (FEA) in this paper. PMs eddy-current losses considering axial segmentation of PM is also analyzed. It is demonstrated that dual-three-phase four-layer (DTP-FL) winding layout has minimum value of the PM eddy current loss with segmentation number N=4. DTP-FL winding layout has smaller magnitude of high-order MMF harmonics. PMs eddy-current paths are divided into smaller loops, which increase the effective resistance. Finally, the average torque and torque ripple changing with multiphase, multilayer and axial segmentation are obtained.2. Introduction: Surface-mounted permanent magnet synchronous machine (SPMSM) with fractional-slot concentrated-winding (FSCW) has many attractive advantages, which can reduce the magnitude of the high-order harmonic potential, tooth harmonic potential and pulsating magnetic field. However, FSCW of SPMSM includes a large amounts of the magnetomotive force (MMF) high-order harmonics, which induce the eddy-current losses in the permanent magnets (PMs). Therefore, it is necessary for high frequency applications to investigate the multiphase and multilayer winding in order to analyse their harmonic distribution and decrease the eddy current losses in the PMs to avoid its demagnetization. A. Masmoudi et al [1] considered the impact of the axial and circumferential segmentation of the surface mounted 12-slot 10pole PM ma-chine on PM eddy current loss by 3-D finite element analysis. A comparative studies are made considering the results yielded by 2-D and 3-D FEA and their analytical model with and without considering the end effect. G. Choi et al [2] presented a new method by introducing flux barriers into the rotor back in order to reduce the rotor eddy current losses for the FSCW of PMSM with single layer layout. C.F.Wang et al [3] comparatively analysed sur-face mounted PM (SPM) and interior PM (IPM) rotor eddy current loss. The influence of the ro-tor protecting sleeve material and thickness, axi-al segmental sleeves, and short circuit rings around each magnet are particularly investigated. W. Jara et al [4] presented a novel interior axial flux PMSM by introducing steel lamination and PM circumferential segmentation. PM eddy cur-rent losses reduce obviously with steel lamination thickness and segmentation number in circumferential direction.3. Target Models Stator winding layout of SPMSM are general-ly classified into several categories as shown in Fig.1 stator (a) three-phase single-layer (TP-SL) winding layout ; stator (b) three-phase double-layer (TP-DL) winding layout ; stator (c) dual-three-phase double-layer (DTP-DL) winding layout; stator (d) three-phase four-layer (TP-FL) winding layout; stator (e) dual-three-phase double-layer (DTP-DL) winding layout. Rotor adopts surface-mounted structure, and axial segmentation of PM is shown in Fig.1.rotor (a, b, c, d). The stator outer diameter is 186 mm, the stator inner diameter is 130mm and the stack lengths in axial direction is 124 mm for the SPMSM. The remanence, relative permeability and conductivity of PM are 1.25T, 1.05 and 6.67e5 (Simens/m) respectively. 4. Results Eddy current loss in PMs for different segments number in axial direction and winding layout are different under load condition. It because that different winding layout have different winding coefficient and harmonic MMF, which is significantly affect PM eddy current loss. The loss in PMs can be calculated from the eddy current density integral by considering the effects of eddy currents in the 3-D transient magnetic field analysis as shown in Fig.2 (a, b, c, d). Winding MMF harmonic amplitude of five winding layout for 12-slot 10-pole is shown in Fig.2.(e). For example, PM eddy current losses of the DTP-FL winding layout is obtained in two electric cycle, in Fig.2 (f). A general trend of the PM eddy current loss reduce obviously with axial segmentation number increasing based on the analysis above mentioned five winding layout in Fig.2(g). However, PM eddy current loss of two segments is greater than that of the unsegmented PM from TP-SL to TP-FL winding layout. Eddy current density of two segments PM are also greater than that of unsegmented PM. Therefore, PM segmentation should avoid this segment number. PM eddy current loss have downward trend for the specified segmentation number from TP-SL to DTP-FL in sequence, similarly, PM losses reduce with segmentation number increasing, which are shown in Fig.13. 5. Conclusion The paper established a 3-D SPMSM model that takes the multiphase winding, multilayer winding and PM axial segmentation into ac-count dedicated to the analysis of the eddy cur-rent loss in PMs using the 3-D FEA. It has been found that DTP-FL winding layout has mini-mum value of the PM eddy current loss for the specified segmentation number. When axial segmentation number is four, PM eddy current loss is reduced to 74.2W. Finally, the average torque and torque ripple changing with multiphase, multi-layer and axial segmentation are analyzed. Although DTP-FL has small PM losses, a part of average torque is sacrificed compared with other winding layout.

FT-14. A study on the analytical methods for demagnetization characteristics of FEM-based permanent magnet synchronous motor.

G. Jeong[1], *D. Jung*[1], H. Kim[1] and W. Kim[2]
1. Electrical Engineering, Hanyang university, Seoul, The Republic of Korea; 2. Gachon University, Seognam-si, The Republic of Korea

1.Introduction Interior permanent magnet synchronous motor, used in this study is a high-capacity traction motor for railway veicles and has a totally-enclosed structure to prevent dust, foreign materials, etc during operation as it is placed at the bottom of railway vehicles [1]. This totally-enclosed structure is vulnerable to temperature because the cycle of heat is not good. The high-capacity traction motor for railway vehicles requires a high weight to output ratio and to increase the weight to output ratio, rare-earth neodymium permanent magnet with high energy density should be used, but are characterized by high-temperature demagnetization [2]. Also, high current may flow due to failure in power converter and it may produce a big reverse magnetic field and be demagnetized by the reverse magnetic field. Demagnetization characteristics caused by such high- temperature demagnetization and reverse magnetization are characterized by permanent demagnetization as a new demagnetization curve called as recoil line is generated. Therefore, the purpose of this study is to propose a demagnetization analytical methods considering recoil line based on FEM. It sets up an analysis scenario to drive motor based on demagnetization characteristics by considering recoil line and predicts the demagnetization of permanent magnet. And it examines the effects of output based on predicted demagnetization characteristics. Through the performance test, the proposed analytical methods is proved. 2.IPMSM for traction railway vehicles a.IPMSM design model Fig. 1 shows the IPMSM designed to the design point and winding is selected as distributed winding by considering sinusoidal gap flux density, and the numb of slot per pole/phase is selected as 3 by considering the effects of harmonic wave and then finally the combination of 6 poles and 54 slots is selected. 3.Analytical methods for demagnetization characteristics of FEM-based a.Demagnetization characteristics analysis considering recoil line Fig. 2 shows analysis scenario. Analysis was performed per cycle (for three cycles in total). Section T1 was for no-load driving, section T2 for 100% or 200% load, and section T3 for counter electromotive force demagnetized during no-load. 200% load is a condition for reverse magnetic field. Temperature is a totally-enclosed condition vulnerable to heat and 180°c is set as the worst condition for insulation design. Fig. 3 is a result of demagnetization analysis of N38UH, and the peak value is reduced by approx. 2.7% in case of 100% load and by approx. 53% in case of 200% load. In conclusion, much of permanent magnet was demagnetized at the temperature of 180°c in case of 200% load. The result was obtained that N38UH has a big influence on the performance of electric motor due to high temperature and reverse magnetic field. Therefore, materials are changed to obtain the reliability of rotor prior to reanalysis. Material is selected as Sm2Co17 that is lower than residual magnetic flux density of N38UH, but strong in high temperature. Fig. 4 is an analysis result, and the peak value was reduced by approx. 0.4% in case of 100% load and by approx. 1.3% in case of 200% load. Therefore, the reliability of rotor was obtained because the peak value of the demagnetized counter electromotive force was reduced by approx. 1.3% max. 4.Final prototype model a.Test product and performance test As speed-specific test, performance test was conducted up to 3,200 rpm within the allowable range because high-velocity section test is inevitable due to lack of IGBT switch capacity of power converter that is held and it can be seen in Fig. 5. Fig. 5 compares speed-torque characteristics between performance test and analysis result of IPMSM and the errors are 0.22% min. and 5.75% max. The reason why such an error occurs is that error factor increases because in case of analysis using the electromagnetic field finite element method, it does not consider machine loss and stray load loss and in case of performance test, machine losses such as frictional loss and wind loss gradually increases with the increasing speed. 5.Conclusion This study examined the study of analytical methods for demagnetization characteristics of FEM-based permanent magnet synchronous motor. The high-capacity interior permanent magnet synchronous motor for traction railway vehicles required the weight to output ratio greatly and used neodymium permanent magnet with high energy density. However, it had a disadvantage in that it was vulnerable to high temperature and might cause reverse magnetic field because high current might flow due to failure in power converter. In this case, neodymium permanent magnet may be permanently demagnetized by high temperature and reverse magnetic field. Therefore, this study proposes how to analyze the demagnetization characteristics by considering recoil line FEM-based, carries out an analysis, and conducts design to obtain the reliability of rotor. By using this proposed method, the reliability of rotor was obtained, test prototype was manufactured, and the validity of this study was verified through performance test.

FT-15. Determination of Solenoid Coil Size for Resonance-Based Magnetically Coupled Wireless Power Transfer with Rated Distance.

H. Song[1] and Q. Xu[1]

1. Key Laboratory of Image Processing and Intelligent Control of Education Ministry, Department of Control Science and Engineering, Huazhong University of Science and Technology, Wuhan, China

ABSTRACT In this paper, the relationship between the distance with the best efficiency and the size of the coil for WiTricity system has been investigated. An equation with the coil radius and transmission distance is derived by lumped circuit theory and empirical parameter formulas. It shows a good agreement among our numeric results, finite element simulations, and experimental data. INTRODUCTION Recently, several wireless power transfer (WPT) techniques have been investigated. Microwave power transfer systems are able to transmit power with an efficiency of over 90%. But they are limited by the need for high alignment. Inductive coupling techniques are extensively used in the near-field applications. Though many novel smartphones have already featured inductive charging, these products still suffer from the distance restrictions. In 2007, MIT researchers proposed a new WPT technique called 'WiTricity' using strongly coupled magnetic resonances [1]. Coupled-mode theory and lumped circuit theory are the most popular methods used by researchers to analyze the system and optimize the designs [1, 2]. It has been proved that these two theories can be consistent with each other [3]. Many efforts have been made to optimize the coil design and to determine the relations between system efficiency and different variables [4]-[7]. However, the relation between transmission distance and the smallest coil size with the best power transfer is still unclear. Using lumped circuit theory and empirical formulas, this paper answers this question and the results are in agreement with simulations and experiments. METHODOLOGY In this paper, the system is modeled by lumped circuit theory. Firstly, each part of the circuit can be modeled as a combination of resistance, inductance, and capacitance. Secondly, the mutual inductions between the coils need to be considered. Since the couplings between any two distant coils are too weak to have an effect on the circuit, we considered only three pairs of coils. The coupling coefficients between drive loop, Tx coil, Rx coil and load loop are represented as k_{12}, k_{23}, and k_{34} respectively. Thirdly, four equations can be obtained by Kirchhoff's voltage law. This WiTricity system can be considered as a two-port network (that one port fed by the source as the input, and the other feeding the load as the output). The power transfer can be represented in terms of linear magnitude scattering parameters ($|S_{21}|$). These four equations can be solved simultaneously for the voltage across the load resistance that can be used to compute the equivalent S_{21} scattering parameter when the resistance of the load and the source are well matched [8, 9]. When we plot S_{21} magnitude as the function of frequency and the transmitter-to-receiver coupling coefficient k_{23}, frequency splitting can be clearly observed as the value of k_{23} is increased. Frequency splitting occurs when the system works in the over coupled regime and the two coils are strongly coupled. The two frequencies will converge at f_0 which is the self-resonant frequency of the coil when the system works at the "critically coupled" state corresponding to a critical coupling coefficient k_{cr}. In practical situations, the working frequency of a system is usually fixed so that the self-resonant frequency f_0 is often chosen to be the frequency of the source. Therefore, the distance between Tx coil and Rx coil corresponding to the critical coupling coefficient is the most suitable transmission distance for a given system. It is worth noting that only parameter k_{23} is related to the distance d between transmitter and receiver coils. Other parameters including resistance, inductance, and capacitance are related to the material and the structure of coil. To determine the relation between the transmission distance and the radius of the coil, the parameters a and N are treated as constants. Using empirical formulas [10, 11], the circuit parameters can be evaluated by the coil's radius and then be substituted into the equations. An equation with d and r can be obtained from the simultaneous equations, wherefore the optimal coil size can be computed with rated distance. SIMULATION AND EXPERIMENT The High Frequency Structure Simulator (HFSS) software (ANSYS Corporation, Canonsburg, PA, USA) is used to simulate the S_{21} parameter for different coil radius and at different distances. The critical transmission distance was measured for different coil sizes. In Fig. 1, it shows that the experimental results well meet the numerical solution from the derived equation. DISCUSSION This paper investigates the key question for coil designing that what is the smallest coil size with the best efficiency when the working distance is given. Lumped circuit theory and empirical formulas are used to establish a relation between the transmission distance and the critical coil radius. This result shows great agreement among numeric solutions, finite element simulations, and experimental data. Though our work only investigates the helix structure coils, the method using lumped circuit theory and empirical formulas likely extends to coils with other structures such as planar spiral coils. Meanwhile, more experiments remain to be done.

Motivation: Fractional slot concentrated windings (FSCW) permanent magnet synchronous machines (PMSM) have high content of space harmonics in the magnetomotive force (MMF) due to which the harmonic inductance is much larger than the magnetizing inductance [1]. These inductance harmonics lead to high torque ripple and low power factor. In case of FSCW, the coils are full pitched and cannot be chorded like in distributed windings to reduce inductance harmonics and also a suitable rotor structure have small impact on reduction of these harmonics. However, the space harmonic content in the FSCW PMSM vary significantly with the choice of slot-pole combination. Thus, the inductance harmonics can be modeled and minimized using an optimal choice of machine phases (m), stator slot numbers (S) and rotor poles (P). *State of the art*: [2] has presented the selection of slot, pole and phase numbers for reducing harmonic leakage inductance specifically for single layer CW PMSM. In [3], a detailed procedure for slot-pole selection based on inductances for single and double layer windings are provided. However, these are restricted for odd phase numbers and the selection process is time consuming. In this paper, the impact of winding layers, phase belt, slots, poles, and phase numbers on inductance harmonics has been studied. Further, an Adapative gradient (Adagrad) algorithm based approach is implemented to optimally select these parameters with little prior knowledge about the structural data. *Methodology*: MMF for a FSCW PMSM can be analyzed using stator slot star approach [3] or winding function theory [4]. In this paper, winding function method has been adapted to calculate the harmonic winding factors in the MMF and using this, the inductance harmonics are computed. Adagrad algorithm shown in Fig. 1(a) is implemented for optimally selecting slot, pole and phase numbers. This algorithm is a stochastic gradient descent with varying learning rate for every parameter unlike the standard algorithms that gives one global learning rate. Learning rate determines the size of steps the algorithm takes to reach a local minimum [5]. Adagrad algorithm performs larger updates for infrequent data sets and smaller updates for frequent parameters. This feature is well suited for sparse data such as large set of varying slot, pole and phase numbers. Initially, input data sets for slot, pole and phase numbers are provided as shown in step 1 for i number of iterations. Based on denominator of slot per pole per phase (spp), a space harmonic range (h) is defined for calculating the winding factor harmonics as in step 2. The phase belt (α) for a particular spp is calculated as in step 3. Further, using the values of phase belt and space harmonic range, the harmonic winding factors for single layer and double layer winding configurations are calculated using (1) and (2) respectively. The objective function (f) in step 4, which is to be minimized, is described in terms of inductance harmonic coefficient (ϕ) and harmonic winding factors for single and double layer configurations. In order to comprehensively obtain the slot-pole combination, it has been assumed that the inner stator diameter (D_{in}), air-gap length (l_g), stack length (L_{st}) and number of turns per coil (N_c) are one per unit for all the FSCW PMSM. *Results*: The best solution sets obtained from adagrad algorithm for all the phase numbers are shown in Fig 1(b) for double layer winding configuration. A sample solution set for three and six-phase FSCW PMSM with double layer winding configuration having least inductance harmonic coefficients is chosen from the solution sets and is presented in Fig. 2(a). Electromagnetic models for these solution sets are developed and the self-inductance harmonics obtained from FEA for 3- and 6-phase configurations are shown in Figs. 2(b) and (c) respectively. It has been observed that the self-inductance harmonic trend obtained from FEA and the proposed algorithm are in close agreement. Detailed modelling of self and mutual inductance harmonics, validation of best solution sets obtained for all the phase numbers with single layer and double layer winding configurations and analysis of MMF harmonics for these solutions will be provided in full paper.

Diaz-Aviles, "Large-scale learning with Adagrad on Spark," *IEEE International Conference on Big Data,* Santa Clara, CA, pp. 2828-2830, 2015.

ALGORITHM:

Step 1: Define training set for 1<*i*<*n*
$w_i \in \{m_i, S_i, P_i\} \in R^d$
$m_i = \{3,4,5,6,9\}$
$S_i, P_i \in 2k, k = 1,2,\ldots 25$

Step 2: Generate harmonic range for winding factor
$spp = S_i / P_i m_i = a/b$
$\left.\begin{array}{l} b: odd \\ h = \pm P_i/b\,(2m_i k+1) \\ b: even \\ h = \pm P_i/b\,(2m_i k+2) \end{array}\right\} k = 0,1,2,\ldots$

Step 3: Calculate phase belt
$if\ S_i = (2k \pm 1)m_i : k = 0,1,2..$
$\alpha_i = 360/m_i$
$else$
$\alpha_i = 180/m_i$

Step 4: Define objective function
$\varphi = 1.52e-06\left(N_c^2 D_{in} L_{st} / g_0 P_i\right)$

$$\left.\begin{array}{l} f_1(w_i) = \varphi/i \sum_{i=1}^{n} K_{wh\_SL}(w_i) \\ K_{wh\_SL}(w_i) = \sum_{h=1}^{\infty} \dfrac{\sinh \alpha_i}{2spp\,\sin\left(h\alpha_i / 2spp\right)} \end{array}\right\} (1)$$

$$\left.\begin{array}{l} f_2(w_i) = \varphi/i \sum_{i=1}^{n} K_{wh\_DL}(w_i) \\ K_{wh\_DL}(w_i) = K_{wh\_SL}(w_i) \sum_{h=1}^{\infty} \cos\left(h\alpha_i / 2P_i spp\right) \end{array}\right\} (2)$$

Step 5: Initialize learning rate >0, weights w_{ij}=0 for iterations i
Step 6: Compute, aggregate and update gradient, $g_{t,i}^2 = \sum_{t'=1}^{t} g_{t',i}^2$
Step 7: Update weights,
$w_{t+1,i} = w_{t,i} - \dfrac{\eta_0}{\beta + \sqrt{\sum_{i=1}^{t} g_{t,i}^2}} g_{t,i}$
Step 8: Repeat Step 5-7 for 1<t<*i*+1;
Step 9: Return *w*

FU-01. Performance Analysis of Squirrel Cage Induction Motors under Broken Rotor Bar and Stator Interturn Fault Conditions Using Analytical Modeling.

M. Ojaghi[1], M. Sabouri[1] and J. Faiz[2]

1. Electrical Engineering, University of Zanjan, Zanjan, The Islamic Republic of Iran; 2. University of Tehran, Tehran, The Islamic Republic of Iran

I.INTRODUCTION Three phase squirrel cage induction motors (SCIMs) have found wide applications in industry. Condition monitoring for early detection of the faults in the SCIMs can involve many advantages including: - Preventing the motor from major damages and the related costly and long-term repairs. - Avoiding unexpected stop of the production line. - Reducing wasted products. Alerting the incipient fault type and extent can increase the benefits attained from using the condition monitoring systems. Among the SCIM faults are the stator winding interturn (SWI) short-circuit fault and the broken rotor bar (BRB) fault. These faults have various effects on the motor performance and may be rooted in each other, so, they may be present at the same time in a SCIM [1]. This paper applies multiple coupled circuit modeling (MCCM) along with the modified winding function theory to achieve an analytic model for the SCIMs under the SWI and BRB faults presenting simultaneously or individually with variable degrees. The magnetic saturation effect is included in the model by applying appropriate air gap function. Simulation results show that the well-known indices for the BRB fault in the stator current spectrum are also produced by the SWI fault. Analytical study approves the simulation results. This fact may cause the condition monitoring systems alarming presence of BRB fault instead of SWI fault or vice-versa. How to discriminate between the faults is the other aim of this paper. II.SCIM Model with SWI and BRB Faults MCCM can be applied to model SCIMs under the SWI faults. For this purpose, the shorted turns of the faulty phase in the stator are considered as the 4-th winding of the stator whose terminals have been shorted. Differential voltage equation is written for the 4-th winding, too, and added to the set of differential equations governing MCCM of the SCIM [2]. Assuming the shorted turns to be in the same coil of the stator winding, the model can be made flexible to encounter variable number of shorted turns, i.e. the SWI fault severity. By the event of breaking any bar of the rotor, its current diminishes to zero. To model this faulty condition, the resistance of the broken bar can be increased sufficiently in the model. This way, the faulty condition is introduced to the model without changing the number of the rotor meshes, and this approach facilitates flexible modeling with variable number of the broken rotor bars. The proposed SWI fault and BRB fault modeling techniques can be applied at the same time to achieve a flexible model for the mixed fault condition. When simulation, the faults severities, i.e. the number of the broken rotor bars and the number of the shorted stator turns, should be introduced to the model, first. Individual faults are simulated by entering zero for the severity of the other fault and the healthy condition is simulated by entering zero for the severities of both the faults. III.Inductances Calculation by Including Magnetic Saturation Effect Modified winding function theory yields the following expression for calculating the SCIM various self-/mutual-inductances at different rotor and air gap flux positions [3]: $L_{yx} = \mu_0 rl \int g^{-1} n_x N_y \, d\phi$ (1) The integration should be performed from 0 to 2π, where x and y are representing any stator phase or rotor mesh, L_{yx} is the mutual inductance between the x and y circuits, n_x and N_y are the turn function and the modified winding function of the x and y circuits, μ_0 is the air magnetic permeability, r is the air gap mean radius, l is the stack length, ϕ is the angle in the stator reference and g^{-1} is the inverse of the fictitious air gap function under magnetic saturation effect [4], which is defined as follows [3]: $g = g'[1-\rho\cos(2P(\phi - \phi_f))]$ (2) where ϕ_f is the angular position of a zero-crossing point of the air gap flux density, P is the pole pairs and g' and ρ are defined by the following expressions: $g' = 3k_s g_0 / (k_s+2)$ (3) $\rho = 2(k_s-1) / 3k_s$ (4) where k_s is the saturation factor [4]. IV.Simulation Results Using the proposed modeling technique, an industrial 1.1kW, 380V, 50Hz, 4-ploe SCIM is simulated under mixed and individual SWI and BRB faults as well as the healthy conditions. Fig. 1 show the stator current spectra obtained by simulation under various conditions. As seen, the BRB fault causes sideband harmonics around fundamental current whose frequencies are determined using (5) with k=1. $f_{BRB} = \left|(1\pm 2ks)\, f_s\right|$ (5) where s is the slip, f_s is the fundamental frequency and k=1,2,3,…. These sidebands are the well-known indices for diagnosing the BRB faults. However, the same sideband harmonics are also present in the spectrum corresponding to the SWI fault condition. The SWI fault can produce harmonic components in the stator currents whose frequencies are determined by following expression [5]: $f_{SWI} = \left|[m \pm n(1-s)/P]\, f_s\right|$ (6) where n=1,2,3,…, m=1,3,5,…. Putting n=4 and m=1 and 3 in (6), yields the same harmonic frequencies as (5) yields with k=1. In addition, the spectrum corresponding to the SWI fault shows the harmonics whose frequencies are obtained using (5) with k=2 and 3. In fact, these frequencies are attained from (6) by proper setting of the n and m values. This study shows that the stator current harmonics, which have been known as the main indices for the BRB faults, are also produced by the SWI faults. This fact was noticed when both the faulty conditions studied at the same time. The authors will offer a technique for discriminating the faults in the full paper.

FU-02. Hybrid analytical modeling of saturated electromagnetic devices: Integration of Fourier modeling and magnetic equivalent circuits.

J. Bao[1], B. Gysen[1] and E. Lomonova[1]
1. Eindhoven University of Technology, Eindhoven, Netherlands

Modeling of the electromagnetic field distribution is vitally important in the design and optimization process of electromagnetic devices. In recent years, several advanced methods are being researched, e.g. Fourier modeling, charge modeling, Schwarz–Christoffel conformal mapping, boundary element method, etc [1]. Among these, Fourier modeling is particularly interesting for structures with periodicity, however, the drawback is the unavailability of including geometric details (regions smaller than the full periodicity) made of high-permeable material, e.g. slot shapes [2]-[3]. In [3], a hybrid analytical modeling (HAM) technique that integrates Fourier modeling and meshed magnetic equivalent circuit (MEC) is introduced to model complex structures in Cartesian coordinate system. It provides promising results under the assumption of linear material properties, however, such assumption is not often sufficient during the design of electromagnetic devices. Therefore, this paper further investigates the HAM technique to include nonlinear materials for saturated electromagnetic devices. To present the diverse applicability of the proposed method, it is applied to two electromagnetic examples, one in Cartesian coordinate system with permanent magnet excitation (geometry shown in Fig. 1(a)), and the other one in polar coordinate system with current excitation (geometry shown in Fig. 1(b)). Only 2D solutions are discussed in this paper, however, it could be extended to 3D modeling [4]. In the examples, periodicities are respectively applied in x- or θ-directions, while regions are divided in y- or r-directions. Only the airgap and outer air regions are modeled using Fourier expressions since Fourier modeling divides the geometry in periodical regions with homogeneous permeability and does not allow to model local saturation. The meshed MEC, on the other hand, is used for regions with nonlinear permeability (such as stator and rotor), since each mesh element has its unique permeability and hence, is able to take saturation into account. Inside Fourier and MEC regions, the expression of magnetic field is derived by solving the magnetostatic Maxwell equations. Each mesh-based element in MEC regions contains the information of dimension, permeability and magnetic source as presented in Fig. 1(c). In elements that represent soft magnetic materials, the permeability and magnetic source are defined by a locally linearized B-H characteristic in terms of differential permeability and remanent magnetic flux density, and are updated by an iterative approach [1]. The elements representing permanent magnets and coils have magnetomotive (MMF) sources related to magnetization and current. Particularly, the distribution of current-related MMF sources has to fulfill the Ampere's law [5]. Between Fourier and MEC regions, boundary conditions are given such that continuity of magnetic field is ensured, i.e., consistent normal flux density and tangential magnetic intensity in both spatial frequency and space domains [3]. Details of model formulations, iterative algorithm and field solutions will be discussed in the full paper. The results calculated by this modeling technique are validated by finite element analysis (FEA). Excellent agreement is achieved in both examples as can be observed in the flux density waveforms in Fig. 2(a) and Fig. 2(b), respectively. Additionally, the flux density waveforms when a linear B-H curve would be applied for the iron materials are shown as reference. The HAM technique has several advantages with respect to FEA. It has the potential to be faster than FEA since Fourier regions are not meshed, while for the airgap, a high mesh density is required in FEA to obtain an accurate flux density distribution. Additionally, since the expression of the magnetic field in the airgap is obtained analytically, force and torque calculations are straightforward and fast since the Maxwell stress tensor can be solved analytically. Furthermore, it offers the advantage of fast dimension and topology sweeping without redrawing geometries, therefore is able to simplify and accelerate the design and optimization procedures for saturated electromagnetic devices, resulting in a new computational and design framework. Future research will focus on implementation for different motor topologies, improvement of meshing and iterative algorithms to reduce computation time, and derivation of inductance and iron losses, etc.

FU-03. Convergence Analysis of SEM and FEM to an analytical field distribution in the airgap.

M. Curti[1], J. Jansen[1] and E. Lomonova[1]
1. Electrical Engineering, Eindhoven University of Technology, Eindhoven, Netherlands

1. Introduction The optimisation routines and the validation models for the Electrical Machines (EM) are often based on Finite Element Method (FEM) models. However, their computation time is manifestly high, and are often replaced by semi-analytical models, which approximate the essential performance of EM with reduced computational cost. Therefore, the trade-off between the model accuracy and the size of the problem leads to the appropriate choice of the modelling technique [1]. Recently, Spectral Element Method (SEM) which uses higher order mesh elements compared to FEM, has been implemented for EM [2]. The latter benefits from higher convergence rate, resulting in a smaller size of the problem. Therefore, SEM is considered a potential option for building low-cost EM models. However, complex EM geometries are challenging for any technique, limiting their accuracy by the high aspect ratio and shapes with sharp corners. Consequently, the performance analysis must be thoroughly checked before making the choice. In this paper, the performance analysis of both SEM and FEM is discussed. An analytical solution for the magnetic field is used for the reference which is generated by the Harmonic Model (HM) [3] using a finite number of harmonics. 2. Analytical Model of the airgap field In the Fig. 1. an equivalent EM geometry is presented. Where only the airgap field is modelled, the sources from the rotor and the stator slots are mapped in the current sheets. This technique is commonly used to simplify EM models [4]. In this paper, the later is used to obtain an analytical solution for the EM. Following the transformations, the geometry has two boundary conditions: $H_t\,|_{rs}=j_s$ *(1)* $H_t\,|_{rr}=j_r$ *(2)* where, H_t is the tangential component of the magnetic field strength, j is the current density distribution on the interfaces and r_r and r_s are the outer radius of the rotor and inner radius of the stator, respectively. Given that, the current sheets are approximated by a finite number of harmonics. The solution for the Laplace equation in polar coordinate systems for the magnetic vector potential is: $A_z=\Sigma_n^{Q}(a_{z1n}sin(\omega_n\theta) + a_{z2n}cos(\omega_n\theta))$ *(3)* where $a_{z1n}=c_{1n}(r/r_p)^{\omega_n}+c_{2n}(r/r_p)^{-\omega_n}$ and $a_{z2n}=c_{3n}(r/r_p)^{\omega_n}+c_{4n}(r/r_p)^{-\omega_n}$ with the spatial harmonics ω_n, scaling constant r_p, unknowns $c_{1\text{-}4n}$, and number of harmonics Q. The close form of H_t is obtained from eq. (3) and is used to force the Neumann boundary conditions on the rotor and the stator sides of the airgap. Following [3], the unknowns can be solved for each harmonic separately, $c_{1n}=((r_p/r_r)^{\omega+1}a_{ns}-(r_p/r_s)^{\omega_n+1}a_{ns})/\delta_n$ *(4)* $c_{2n}=((r_r/r_p)^{\omega-1}a_{ns}-(r_s/r_p)^{\omega_n-1}a_{ns})/\delta_n$ *(5)* $c_{3n}=((r_p/r_r)^{\omega+1}b_{ns}-(r_p/r_s)^{\omega_n+1}b_{ns})/\delta_n$ *(6)* $c_{4n}=((r_r/r_p)^{\omega-1}b_{ns}-(r_s/r_p)^{\omega_n-1}b_{ns})/\delta_n$ *(7)* where, $\delta_n=\omega_n(-(r_r/r_p)^{\omega-1}(r_s/r_p)^{-\omega_n-1}+(r_s/r_p)^{\omega-1}(r_r/r_p)^{-\omega_n-1})$, *(8)* a_n and b_n are the Fourier coefficients of the current density distribution along the interfaces. 3. Numerical approximation To generate an analytical solution from section 2, it is considered that a limited number of harmonics Q equal to 60 are enough to get the distribution of the current sheets. The same amount of source harmonics are injected in the boundary conditions of SEM and FEM models. By increasing the accuracy of the methods, the convergence is evaluated with the respect to their degrees of freedom (dof). 3.A. Finite element method The numerical approximation by FEM is implemented in FLUX2D [5], where, the second order triangular mesh elements are used. The mesh density is generated by homogeneously enforcing the number of line elements on the rotor and stator lines. No relaxation is applied in the airgap region, so that a homogeneous mesh distribution is obtained, which is important to capture the field in the airgap, containing most of the energy in a rotating EM. 3.B.Spectral element method The major difference of SEM with the respect to FEM is the distinctive features of the mesh elements used to discretize the geometry. Unlike FEM, SEM implementation from this paper uses quadrilateral mesh elements where the solution is approximated with high order Legendre polynomials giving the possibility to choose between fewer high order elements (p refinement), or more elements with a lower degree of polynomials (h and r refinement) [6]. It should be noted that quadrilateral elements can have curved boundaries, which allow a more precise approximation of the geometrical features of the model. Moreover, the arrangement of the orthogonal Legendre basis offers a fast convergence of the error giving a more stable approximation and fewer dof for similar accuracy compared to FEM [7]. 4. Results In the Fig. 2. the overlap of SEM, FEM and analytical solution of the tangential and radial component of the magnetic field in the middle of the airgap is shown. The convergence plot from the Fig. 2c. shows that, for an increased accuracy, SEM approximation gives a better performance compared to FEM. Reaching 3500 dof, SEM reaches round off errors while FEM has a limited accuracy. 5. Conclusion In this paper, the FEM and SEM model is compared with an analytical solution in the airgap of an EM. It can be seen that the solution approximated by SEM gives higher accuracy, as a consequence, SEM becomes an efficient technique for modelling EM. In the full paper, detailed performance analysis of SEM and FEM will be presented.

FU-04. Reduction of Stator Core Loss in Interior PM Machines for Electric Vehicle Applications.

Y. Hu[1] and *S. Zhu*[1]
1. Nanjing University of Aeronautics and Astronautics, Nanjing, China

I. Introduction Interior permanent magnet (IPM) machines are very attractive for the electric vehicle (EV) traction applications due to its excellent performance such as high torque density, high power density, and wide constant power speed range [1]. Stator core losses are the main component of power loss in the Interior permanent magnet (IPM) machines under high speed operation. They depend essentially on the flux-density waveform of stator core which are influenced by the rotor magnetomotive force [2]. Therefore, reduce the harmonics of air-gap density is an important issue of IPM machine design. II. Main Body Fig. 1 shows magnet configurations and there air-gap flux density of four IPM machines, where ap1-ap3 are the pole-arc to pole-pitch ratio of PMs. The single layered IPM machine is model I, the single-layered IPM machine with shaping is model II, the two-layered IPM machine is model III, and the three-layered IPM machine is model IV. It can be seen that the air-gap field distribution of model IV is closer to sinusoidal waveform. The rated power of the machines is 48 kW, the continuous rated current (rated load) is 200 A, the maximum speed of the machines is 12000 r/min. A prototype IPM machine with model IV is manufactured to verify the effects of core loss. Fig. 2(a) shows the photographs of the stator and rotor. The FEA predicted core losses density distributions of four IPM machines on 12000 r/min are analyzed and compared. In order to clear show the flux-density waveform and its harmonics of stator core and rotor core, the flux-density waveform and its harmonics of stator teeth are added. Fig. 2(b) shows the spectral components of stator teeth flux density and core loss. It can be seen that, the 3th, 5th, 7th harmonics of model I are significantly higher than the other machines. The 9th harmonics of model III are higher than the other machines. The 13th, 15th harmonics of model IV are higher than the other machines, and the model IV has the lowest stator teeth flux density and core loss. The simulated and measured total iron loss of the prototype machine are shown in Fig. 2(c). In general, good agreement of FEA and experimental results. III. Conclusion This paper has analyzed and compared the core loss of four Interior PM machines for electric vehicle applications. The major conclusions derived from the results of analysis and experiments are summarized as follows. [1] The shaping of single-layered IPM machine can reduce the stator core loss due to the harmonics of air-gap density can be reduced. [2] Increase the rotor magnet layer number of IPM can effectively reduce the stator core loss but also increase the manufacturability compared with the single-layered machines.

FU-05. Vector Magnetic Characteristic Analysis of Induction Motor Considering Harmonic Wave by Slip Motion.

M. Enokizono[1] and N. Kunihiro[2]
1. Vector Magnetic Characteristic Technical Laboratory, Usa-city, Japan;
2. Oita University, Oita, Japan

Induction motors are widely used in houses and factories. Furthermore, it is noticed as a motor for EV. Improvement of their efficiency of even one percentage would result in a great energy savings. On the other hand, it is well known that the magnetic field intensity *H* is not parallel to the magnetic flux density *B* in soft magnetic materials under two-directional excitation. This property is called the two-dimensional vector magnetic property. We have proposed the dynamic E & S modeling for numerical simulation, which is able to express precisely the two-dimensional vector magnetic property and enabled the analysis taking account of the magnetic anisotropy and non-linearity [1, 2]. In this paper, results of magnetic characteristic analysis of an induction motor core by using the finite element method taking account of the two-dimensional vector magnetic properties are reported. In this method we can obtain directly the iron loss distributions in the stator core with the direct calculation from hysteresis loops obtained at each finite element. In the analysis, we propose a new method to consider harmonic components based on slip motion. The load characteristics depending on slip under harmonic magnetic field are made clear by vector magnetic characteristic analysis considering vector magnetic characteristics. Analytical Results and Discussion Generally, the waveforms of the magnetic flux density and the magnetic field intensity in the stator yoke of the induction motors include secondly slot harmonic components. Figure.1. shows the loci of *B* at each point as an example. As shown in Fig.1. loci of *B* had distortion, and the distortion was very large at the tooth top. The influence of the secondly slot harmonic was very small at the core back part. From these results, it was shown that not only the magnetic flux density but also the magnetic field intensity was distorted. Moreover, it can be concluded that the magnetic flux and field intensity waveforms include about 20% of the harmonic components in the maximum at the tooth top parts near the air gap. Then, it was understood that the largest number of harmonic was changed depending on slip. The tendency is well known as a slot ripple depending on the number of secondly slot and relative velocity. Inclusion of number of harmonic is similar, however the amplitudes are little different. As results, it can be said that the relationship between *B* and *H* should be understood as a vector property. Figure.2. shows BH loops in x-direction when slip = 0.5 at point A indicated in the Fig. 1. Induction motor has three kinds of coordinate system, which are static coordinate, rotational exciting coordinate and slip coordinate. Therefore the hysteresis loop is not closed in the period. Firstly, it is understood that BH loops close within few periods according to slip as shown in Fig. 2, though this is a only characteristic of an induction motor (have a slip). In a word, when the iron loss of the induction motor is evaluated, it is necessary to know the lowest common multiple of the rotating magnetic field and the rotor rotation to obtain the closed. The core loss of induction motor can be obtained by equation (this equation will be shown on full paper). Where, N is the order of considering component, T_{LCM} is period of exciting waveform of the lowest common multiple, ρ is core material density. When slip is 0.5, T_{LCM} is 2.

FU-06. Elimination of Unipolar Leakage Flux in Consequent-Pole PM Machines by Employing Novel Pole Sequence.

J. Li[1], *K. Wang*[1] and C. Liu[1]
1. Electrical Engineering, Nanjing University of Aeronautics and Astronautics, Nanjing, China

I. Introduction Many permanent magnet (PM) machines have employed rare-earth magnets such as NdFeB as magnetic potential source owing to its high energy density, which can obtain high efficiency and high torque density [1]. However, the one of their drawbacks is the high production cost, which results from the shortage and unstable supply of rare-earth materials around the world [2]. In order to improve the PM utilization ratio, the consequent-pole PM (CPM) machine is proposed and investigated in recent years. These reported literature indicates that consequent-pole structure in both rotor-PM machines [3] and stator-PM machines [4] has a great potential to reduce the cost. However, due to the magnetic unbalance, the unipolar leakage flux exists in the end region of the CPM machine. It can lead to the magnetization of the mechanical components such as the shaft, bearing and screws, and even poses threats to the reliability and safety of the machine system. In this paper, a novel CPM machine with N-iron-N-iron-N-S-iron-S-iron-S sequences is proposed to eliminate the unipolar leakage flux. Besides, the tangential magnetized PMs are embedded to the rotor of the novel CPM machine, i.e., hybrid-pole PM (HPM) machine, further improving the PM utilization ratio and output torque. Both finite element (FE) analyses and experiment are used to investigate these machines. II. Machine Topologies The 9-slot/10-pole PM machine with double-layer non-overlapping winding is employed to investigate the electromagnetic performance of the conventional and proposed machines. Fig. 1 (a) shows the conventional CPM (CPM1) machine, whilst Figs. 1 (b) and (c) show the proposed CPM (CPM2) machine and HPM machine, respectively. Fig. 1 (d) shows the prototyped HPM rotor. All these machines have the same stator, stack length and airgap length. The PM-arc ratio α_p ($\alpha_p = \theta_m p/2p$, where θ_m is the PM arc and p is the number of pole-pair) of the CPM1 machine is optimized for maximizing the output torque, and it equals to 0.65. The N-S in the pole-sequences of the proposed machines is adjoining, and thus the PM-arc ratio α_p is fixed by 0.5. In addition, the thickness of the tangential magnetized PM in the HPM machine is optimized and equals to 2mm. It should be noted that the magnetized direction of all the PMs in the CPM1 machine is uniform, whilst the PMs of the proposed CPM2 and HPM machines have opposite magnetized direction, which is preferred for the elimination of the unipolar leakage flux, as will be shown later. III. Elimination of Unipolar Leakage Flux Figs. 2 and 3 show the 3D FE predicted flux density distributions at the surface of the end shaft for all the investigated machines. It is up to 0.008T within the axial length of 10mm for the CPM1 machine. However, the peak flux density is 0.002T within the axial length of 10mm for the CPM2 machine, which is much lower than that for the CPM1 machine. Apparently, the HPM machine has higher flux density of the end shaft than the CPM2 machine due to the assisted flux provided by the tangential magnetized PMs. It should be noted that the polarity of the leakage flux in the end shaft of the CPM2 machine is opposite to that in the HPM machine. This is due to the fact that the tangential magnetized PMs in the HPM machine can be regarded as the flux barriers, which changes the leakage flux path, as shown in Fig. 2 (c). More importantly, the leakage flux in the end of the CPM1 machine is unipolar, as shown in Fig. 3 (a). However, in the proposed CPM2 and HPM machines, the unipolar leakage flux does not exists and replaced by the bipolar one, as shown in Figs. 3 (b) and (c). Therefore, the magnetization of the mechanical components in the end of the proposed machines can be effectively reduced. Fig. 4 shows the measured flux density at 30 mm of the end shaft of the HPM machine, which agrees with FE predicted one. The detailed analysis and experimental results will be presented in the full paper.

FU-07. Indirect Analytical Method for Electromagnetic Performances Analysis of V-shaped Interior Permanent Magnet Synchronous Machine.

L. Xu[2] and M. Lin[1]
1. Southeast University, Nanjing, China; 2. School of Electrical and Information Engineering, Jiangsu University, Zhenjiang, China

In this paper, an indirect analytical method is presented to analysis and optimize the electromagnetic performances, such as air-gap flux density, back EMF, cogging torque, and torque, of the V-shaped Interior permanent magnet (PM) synchronous Machine (IPMSM). The new method provides an indirect calculation model of the V-shaped IPMSM, by transferring the rotor into an equivalent linear one in the Cartesian coordinate system. Based on a proposed magnetic field curvature factor, the magnetic field distribution of the motor is initially analyzed using the magnetic scalar potential. The Maxwell stress tensor method with Schwarz–Christoffel (SC) transformation is subsequently utilized to analyze the magnetic field in detail and predict the torque performances of the V-shaped IPMSM accurately. The magnetic field and torque performances obtained by the analytical method are compared with those obtained from finite element analysis (FEA). The analytical predictions are compared with the measured results in order to confirm the validity of the methods. II. Electromagnetic Analysis of the V-shaped IPMSM A.V-shaped IPMSM Configuration A 9-slot-6-pole motor with V-shaped interior PMs is instanced, and this motor adopts concentrated windings. The parameters of the IPMSM is shown in Table I. The model of the motor is shown in Fig. 1(a). B.Analysis Model For establishing the analytical model, the motor shown in Fig. 1(a) is cut along the axial and flattened as shown in Fig. 1(b). The rotor is divided into three parts which named Region II, Region III-1, and Region III-2 respectively. Region II is the PM region. The Region III-1 and Region III-2 are the rotor iron core region. In order to further simplify the analytical model, the model shown in Fig. 1(b) can be equivalent to the one as shown in Fig. 2. Region I is the stator region, and Region IV is the armature current sheet. Thus, the V-shaped PMs are equivalent to two parts, and the air-gap flux can be calculated separately. Based on the some assumptions, the air-gap flux density in open circuit can be deduced by solving the Maxwell and Laplace's equations in the two parts, and the SC transformation is utilized to calculate the slot effects. The Matlab SC Toolbox is used to draw the real slot shape. Moreover, considering the armature winding current effect, the Laplace's equation is solved again, and the fractional slot windings are assumed as thin wires. In terms of the Maxwell stress tensor method, the rotary cogging torque and torque can be indicated. C.Curvature Factor The curvature factor k_q, which has been proposed as a modifying function in [1], is defined as the ratio of the analytical flux densities in 2-D parallel magnetization PM array to in 2-D radial magnetization linear PM array by $k_q = B_{rq} / B_l$ III. Results and Discussion Based on the analysis in Section II, the electromagnetic performances including air-gap flux density, back-EMF, cogging torque, and torque are given, and they are compared with that obtained by FEM in this section. The air-gap flux density is shown in Fig. 3. Furthermore, the prototype of the V-shaped IPMSM is constructed as shown in Fig. 4, and the experiments are done. IV. Conclusion Based on the equivalent model, the analytical method with curvature factor is presented for the electromagnetic performances investigation of the V-shaped IPMSM in this paper. Both of the FEM and experimental results verified the correctness of the analytical method.

FU-08. Improved E&S Model for Core Loss Calculation of Brushless Doubly Fed Machine with Hybrid Rotor.

F. Zhang[1], Y. Wang[1] and S. Yu[1]
1. School of Electrical Engineering, Shenyang University of Technology, Shenyang, China

Brushless doubly fed machine (BDFM), is a new type of machine with special structure, shows promising features for the field of variable frequency speed regulation and wind power generation due to its inherent characteristics, which has the advantages of reliable operation, adjustable power factor, lower operation and maintenance costs as well as requiring a smaller capacity converter [1]-[2]. Since core loss has an important effect on efficiency and temperature distribution, it is vital to accurately calculate such component in an optimal design procedure. Furthermore, rotor core loss is also a significant factor which can affect the performance characteristics of BDFM due to the complex magnetic field distribution and relatively high value of slip. Specifically, a novel hybrid rotor structure which is combined with magnetic barrier and assisted cage has better coupling ability than the commonly used rotor structures such as cage rotor and reluctance rotor is presented but it also increases the difficulty of core loss calculation. E&S model is a vector magnetic hysteresis property model [3]-[4], in which H (magnetic field intensity) is dependent not only on B (magnetic flux density) but also on time derivative of B. Increase of core loss when the phase difference between B and H occurs, is well expressed in this method, while the conventional analysis was not able to consider the phase difference between B and H. Furthermore, the total core loss including both alternating and rotational losses can be directly calculated from the fundamental terms of obtained B_x, B_y, H_x and H_y without other fitting data, which can improve the core loss computation accuracy of BDFM with hybrid rotor in contrast with conventional core models. In this paper, an improved E&S model based on a 2-D rotational magnetic property analysis for core loss of BDFM with hybrid rotor is proposed by considering the high-order harmonic magnetic field. The finite element analysis model of BDFM with hybrid rotor is established. The core loss calculation results are compared with the simulation results to verify the correctness and feasibility of the proposed E&S model. Fig. 1 shows the finite element model, hybrid rotor of prototype and special points distribution diagram of BDFM with hybrid rotor. As shown in Fig. 1 (a)-(b), the cage bars are added on the non-magnetic layer of the radial magnetic barrier rotor, and the cage bars are respectively divided into concentric cage bar and common cage bar. There are two kinds of rotating magnetic fields with different poles and frequencies in the air-gap of BDFM, which renders that the air-gap magnetic density harmonic contents are rich and the magnetic properties of each part of core are different. According to the basic principle, structure characteristics and magnetic field distribution of BDFM with hybrid rotor, some special points of stator and rotor are analyzed and calculated. The relationship between B vector and H vector, and the relationship between the waveform of B_x, B_y and the waveform of H_x, H_y, obtained by the combination of the improved E&S model and finite element analysis, is shown in Fig. 1 (c), which is seen that the phase between B and H is different. The improved E&S model can consider higher order harmonic magnetic field than the conventional E&S model. As shown in Fig. 2 (a), the stator and rotor core loss calculation process of BDFM with hybrid rotor is described by the flow diagram. The datum of B_x, B_y, H_x, H_y are obtained by the combination of the improved E&S model and finite element method, and all order harmonic of B_x, B_y, H_x, H_y are computed by fourier series expansion. Therefore, the total core loss of BDFM with hybrid rotor can be calculated by the formula in the flow diagram, where, ρ is the magnetic material density, T is the period, m is the amount of the special points, n is the harmonic order, and M_i is the mass. In addition, in order to verify the accuracy of the core loss calculation, the 2-D finite element model of BDFM with hybrid rotor is established, and the simulation results are shown in Fig. 2 (b). The validity and feasibility of the improved E&S model is verified by comparing with the simulation results. In addition, the full paper will present the detailed calculation procedure and analysis.

FU-09. About Accuracy and Influence of the Pole Coverage for Eddy Current Losses within Permanent Magnets of Electrical Machines.

E. Schmidt[1] and M. Kaltenbacher[2]
1. Institute of Energy Systems and Electrical Drives, Vienna University of Technology, Vienna, Austria; 2. Institute of Mechanics and Mechatronics, Vienna University of Technology, Vienna, Austria

Abstract In particular with surface mounted permanent magnets, eddy current losses within the magnets are one of the most significant portion of losses in permanent magnet exited synchronous machines. These losses are generated by asynchronous components of the air-gap field caused by either higher harmonic waves or higher time harmonics. On one hand, there is no interaction of the various harmonics with regard to these losses. On the other hand, the pole coverage shows a significant impact on these losses. Thus, detailed numerical analyses with various higher order formulations are carried out in order to show aspects of the accuracy of these eddy current losses, too. Introduction The precalculation of eddy current losses arising in surface mounted permanent magnets caused by sub- and superharmonics harmonics of the air-gap field is a matter of particular interest with the design process of permanent magnet excited electrical machines. On one hand by using very fast evaluation methods for the standard design procedures, on the other hand by using highly accurate calculation methods for reference purposes \cite{Wang09,Etem12}. These eddy current losses may always lead to an excessive partial heating and subsequently can cause the magnets to get partially or even fully demagnetised \cite{Elre10,Wang10,Okit12}. As shown with the full paper, both planar and cylindrical arrangements are described with only few parameters, such as air-gap, ratio of pole pitch and air-gap, ratio of magnet height and air-gap as well as the pole coverage as ratio of magnet width and pole pitch. In order to compare the various approximation orders of the finite element analyses and their influence on the accuracy of the numerically obtained results, an analytical calculation will be used for the reference results. In addition, various pole coverages with their effects on the eddy current losses are discussed by these numerical analyses. A surface current sheet in axial direction K_z(x,t) at the inner stator boundary perpendicular to the cross section of the conducting region as K_z(x,t) = \hat{K}_z \Re (exp{j om t} exp{-j nu pi x/tau_p}) can cover for any harmonics generated from either the stator currents, the slotting as well as the saturation. Therein, om = 2 pi f denotes the exciting circular frequency with respect to the moving region, nu the harmonic order and -1 <= x/tau_p <= 1 being the region of two pole pitches along the circumferential direction, respectively. Referring to the total eddy current losses, there is no interaction between waves with different harmonic orders as well as different frequencies. General numerical results All analyses carried out with different high order approximation functions utilise an identical discretisation with the minimum skin depth as approximately the half of the mesh size in radial direction and the mininum wave length as approximately 7.5 times the mesh size in circumferential direction. Obviously and as included with the full paper, the total eddy current losses are quite similar between both arrangements with a deviation in the range +-5% only. With a ratio of wave length to skin depth <<1, the power losses versus frequency increase with a power of 2. On the other hand with a ratio of wave length to skin depth >>1, the power losses versus frequency increase with a power of 0.5 only. However with very low ordinal numbers, there is a transitional region where the power losses are rather constant. Accuracy of the numerical results The relative error eps = Power_{FEA} / Power_{Ana} - 1 between the power losses of finite element and analytical analyses with different approximation orders is shown in Fig.1 and Fig.2. Thus, the usage of 3rd or even higher order elements is strongly suggested for evaluating such eddy current losses. In particular with 3D meshes, the possibility of generating a relatively coarse mesh within the conducting regions shows explicit advantages against a dense mesh with 2nd order elements. Influence of the pole coverage The finite element calculations very easily allow to encounter for the influence of various pole coverages on the eddy current losses, too. With regard to a practical point of view with planar and cylindrical arrangements, the pole coverages as of 5/6, 3/4 and 2/3 are concerned in more detail. Obviously and as shown with the full paper, the pole coverage only affects the power losses of the lower harmonics while the power losses of the higher harmonics are directly proportional to the value of the pole coverage. Conclusion The paper discusses the numerical evaluation of eddy current losses in surface mounted permanent magnets of electrical machines. Planar and cylindrical arrangements are compared against their results by using identical geometry parameters and various pole coverages. Additionally, the finite element analyses utilise different approximation orders with hierarchic shape functions in order to validate the accuracy of the eddy current losses.

FU-10. Non-conforming finite element method to simulate eddy currents due to motion using the T,Φ-Φ formulation.

G. Wallinger[1] and O. Biro[1]
1. Institute of Fundamentals and Theory in Electrical Engineering, Graz University of Technology, Graz, Austria

Abstract: The non-conforming meshing approach, which is based on interpolation techniques, is used to carry out a time transient simulation of a two pole asynchronous machine with a squirrel cage rotor at constant rated speed. This newly revisited approach uses 2nd order node-based hexahedral elements and represents an alternative to computational demanding methods like the use of Lagrange multipliers and mortaring methods. 1. Introduction The analysis of electromagnetic devices, especially electrical machines is an expensive task starting with finite element (FE) modeling of the machine and ending with time consuming computations. These tasks get even more costly, if a three dimensional model is taken into account. In terms of classical finite element modeling, the procedure of discretization and time transient computation to take rotor movement into account is even more demanding. To overcome this problem of exhaustive pre-processing and enormous computational costs, it is favorable to allow two meshes of separable domains to become non-conforming with hanging nodes on a defined sliding surface. This enables modeling of two independent FE meshes, one for the fixed and another one for the moving domain, respectively. The most popular and successfully implemented methods are the use of Lagrange multipliers as well as the mortaring method with both techniques imposing the essential interface conditions weakly at the sliding surface. The resulting system matrix in case of the latter method is symmetric and positive definite, whereas the use of Lagrange multipliers introduces additional degrees of freedom which leads to an ill-conditioned and non-positive definite matrix [1]-[6]. Furthermore, most current computational tools introduce a magnetic vector potential to describe the fields. This leads to high computational costs, since it results in a large number of degrees of freedom and the use of edge elements is mandatory. When analyzing electrical machines, the sliding surface can be naturally selected in the air gap of the machine. Hence, using a magnetic scalar potential in non-conducting regions e.g. the air gap and a current vector potential in conducting regions enables the sliding interface to connect scalar potential degrees of freedom. This also reduces the number of unknowns and thus computational costs will decrease. We have shown earlier [7]-[9] that the non-conforming meshing method based on interpolation techniques can be used to take account of the relative motion between a fixed domain and a moving domain by coupling the scalar potential associated with nodes of the moving domain with those of the fixed domain applying a master slave principle. This paper presents the analysis of a standard two pole asynchronous machine with a squirrel cage rotor [10] with eddy currents due to motion taken into account. In a first step, a time transient analysis of the machine driven by voltage sources is performed at constant rated speed of the rotor. 2. Numerical method The current vector potential T is used in the conductors carrying eddy currents and a reduced magnetic scalar potential F in the non-conducting domain. The description of the voltage excitation results in additional equations. The governing equations are obtained by applying Galerkin techniques as well as the interpolation method of [7]-[9] to Faraday's law and the Gaussian law of magnetism. 3. Finite Element Model The finite element model consists of two independent meshes of the fixed stator domain and the moving rotor domain, respectively. These meshes lead to an overall mesh with about *60 000,* 2nd order node-based hexahedral elements. As a starting point, the computations are performed using a quasi 2D model, i. e. a 3D geometrical model of the machine consisting of only one mesh layer in axial direction. The model consists of *48* stator teeth and *40* rotor teeth and linear material properties are assumed. Figure 1 shows the model, stator winding as well as the rotor bars, and provides a detailed view of the mesh in the air gap region. 4. Preliminary Results The results are obtained for voltage driven sources with the winding of the phases in a star-connection. The time resolution chosen is 15 time steps per electrical period at a frequency *f=50* Hz. Figure 2 shows the computed eddy current density of the stator winding and rotor bars at a certain time instant. Comparisons with results obtained by mortar techniques will also be provided. 5. Conclusion The proposed non-conforming meshing approach is found to be an adequate alternative method to the use of Lagrange multipliers or mortaring techniques. It will be shown in the final version that the method leads to adequate results when simulating the startup of the investigated asynchronous machine.

I. Introduction The conventional methods for reducing the cogging torque of single-phase BLDC motors include the length change of the air-gap, PM asymmetry arrangement, skew of the stator or rotor and shape change of the stator teeth. Some papers reported reduction in the cogging torque for single-phase BLDC motors by varying the air-gap profile, considering the tapered teeth [1-4]. We reduced the cogging torque by applying method to variation of air gap, considering manufacturing and cost aspects[5]. The most accurate style among the other techniques for analyzing the cogging torque is to use finite element analysis(FEA), however this method has the disadvantage in which modeling is actually executed by user also the analysis takes a long period of time [6]. Therefore, it is important to understand trends in the initial design of BLDC motors. Analytical method can be used to obtain proper accuracy and quick analysis results. These studies are being conducted to improve the accuracy and algorithm simplification of shape [7]. This paper presents an analytical method when applied tapered air-gap with notches for cogging torque analysis for single-phase BLDC motor. In order to calculate the magnetic flux density, the asymmetric slot function was applied to express the tapered air gap and was tested for the analysis of the cogging torque. We proposed analytical method technique with asymmetric slot function in stator and analysis about cogging torque in motor with notches. Finally, the proposed analytical method technique was confirmed by cogging torque characteristic of 2D FEA. II. Cogging Torque of Single-phase BLDC Motor This paper used the 120[W] class single-phase BLDC motor with an eight-pole/eight-slot structure. Because in the case of a single phase, the ratio of the number of poles to the number of slots should be 1:1. In consideration of securing the winding space and effectiveness must be in the accordance with the design requirements. Also, the outer diameter was 94 [mm], and stator teeth has designed asymmetric that length of both ends as g1 and g2 of figure1 and it applied two notches on stator teeth. III. Cogging Torque Calculation Cogging torque is occurred inevitably, due to the torque interaction between the permanent magnets of the rotor and the stator slots of a permanent magnet machine. Also, that is one of the causes of noise and vibration, so that the more precision motor should be designed considering cogging torque. In order to establish analytical solutions for the field distributions, the following assumptions are made: - the permeability of iron is infinite - the slot openings have rectangular shape and are infinitely deep - the relative permeability of the permanent magnet is unity The cogging torque is the amount of energy variation according to the amount of rotor rotation that can be expressed the following: $T_{cog} = -(\Delta W(\alpha)/\Delta\alpha)$ ------------ (1) where W is the magnetic energy of the machine and α is the rotational angle of the rotor. For surface permanent magnet type of BLDC, most of the energy change occurs in the air-gap portion. Therefore, the energy in the air-gap must be considered when calculating the cogging torque. For surface permanent magnet type of BLDC, most of the energy change occurs in the air-gap portion. The air-gap energy for the external rotor motor of cogging torque can be expressed as (3) by differentiating the air-gap energy gained from (1) according to (2) with the rotation angle of the rotor. $W(\alpha) = (L_s/4\mu_0)(R_m^2-R_s^2)\{\int_0^{2\pi}\sum B_{nNL}G_{nNL}\cos({}_nN_L(\theta+\alpha))\cos({}_nN_L\theta)d\theta)\} = (L_s/4\mu_0)(R_m^2-R_s^2)\sum B_{nNL}G_{nNL}\cos({}_nN_L\alpha)$ ------------ (2) $T(\alpha) = (L_s\pi/4\mu_0)(R_m^2-R_s^2)\sum B_{nNL}G_{nNL}\sin({}_nN_L\alpha)$ ------------ (3) where B, G, R_m and R_s are the flux density, relative air-gap permeance function, inner radius of the rotor and inner radius of the stator, respectively. Also, where N_p is the number of rotor poles, N_s is the number of stator slots, B_{nNL} is the Fourier coefficients of the flux density function, and G_{nNs} is the Fourier coefficients of the relative air-gap permeance function. L_s is the stack height and N_L is the least common multiple(LCM) of N_p and N_s. According to (3), the cogging torque can be reduced by changing B_{nNL}, G_{nNL}, and N_L. Thus, Cogging torque can be reduced through effectual applied notches. The analytical field solution is found by combining the field solution in the slot less air gap developed by Zhu et al[8, 9]. This paper is calculated by combining the stator teeth function $B(\theta,\alpha)$ for eq(4) and figure2. $\int Rs(\theta)d\theta=Rs-\{g1+((g2/a)\int a(\theta)d\theta)\}$ ------------ (4) that shows magnetic flux density is calculated by applying the stator function according to [9]. When $np \neq 1$ and External Rotor, $Rr = Rs + g + hm$ and hm is radial thickness. Fig.2 comparison cogging torque between the analytical method of Equation (2), FEM and experiment for model applied asymmetric air-gap. The period and magnitude of the cogging torque of analytical method were similar to the results of FEA and experiment. IV. Conclusion The properties of the proposed cogging torque analytical method were verified experiment. The cogging torque meter with a 0.001% RPM accuracy was made by SUGAWARA in Japan. The period and magnitude of the cogging torque were similar to the results of FEA and experiment. More details on additional results will be presented in the INTERMAG2018.

FU-12. Two-Level Surrogate-Assisted Differential Evolution Multi-objective Optimization of Electric Machines Using 3D Finite Element Analysis (FEA).

N. Taran[1], D. Ionel[1] and *D.G. Dorrell*[2]

1. Electrical and Computer Engineering, University of Kentucky, Lexington, KY, United States; 2. Discipline of Electrical, Electronics and Computer Engineering, University of KwaZulu-Natal, Durban, South Africa

Introduction Many parameters are considered in electric machine design and an optimization algorithm can be used. These usually need thousands of design evaluations before meeting the termination criterion. Time consuming 3D finite element analyses (FEAs) are not tenable although machines with 3D flux paths, such as axial flux and transverse flux, cannot be accurately evaluated with 2D models. One solution is to use surrogate models rather than 3D FEA; however, the accuracy of surrogate models reduces for a large and nonlinear search space. Another solution can utilize algorithms that find the global optima with a minimum number of design evaluations. A combination of these two solutions is proposed here. *Optimization Algorithm* The proposed approach has an exterior level evolutionary algorithm, replacing the mutation with an interior level complete differential evolution (DE) optimization. The exterior loop uses expensive FEAs while interior loop uses cheap surrogate models. The first generation of exterior loop parent designs are estimated Pareto and, in fact, very close to the actual Pareto front (non-dominated designs). The two-level evaluation of Pareto designs results in an efficient exploration and exploitation approach so that the global optima can be located within the first few generations, depending on the surrogate model accuracy. The surrogate model is a Gaussian process prediction, known as universal kriging in geostatistics [1]. The algorithm does not solely rely on estimated values; it has a dynamic sample pool that stops increasing in size once the estimation error is sufficiently small and gradually improves the kriging model resolution only around the Pareto designs. This achieves accurate final results with self-adjustment of the sample pool for different problems, avoiding unnecessary expensive evaluations and faster convergence. Multi-objective optimization sets a maximum number of function evaluations or maximum number of generations as the termination criterion. For algorithms that quickly converge to the optima, this criterion can produce many dispensable generations; it is vital to avoid this for more expensive functions. Here, a hybrid stopping criterion is used. Negligible improvement in the tips and middle point of the Pareto front for a few consecutive generations will satisfy the third stopping criterion. Meeting any of these criteria stops the algorithm. Fig 1 gives a flowchart for the algorithm. *Algorithm Validation and Machine Design Examples* The new optimization algorithm was implemented and validated using the test function DTLZ2 [2]. This is capable of assessing the algorithm for problems with different complexity levels, i.e., number of optimization variables and objectives. Tests with one to three objective functions, each with four to twelve variables, were studied. The results show that even for high numbers of variables, the proposed two-level algorithm outperforms the conventional method. For complex problems with more than 3 objectives and 12 variables, the sample pool construction needs almost as many function calls as the total number of evaluations in the conventional DE algorithm. Hence, their performance is comparable. Two practical implementations of the optimization algorithm are developed here. These are for an axial flux permanent magnet (AFPM) machine. Two different arrangements are considered: a multi-disc coreless machine with two stators and a commercially available motor with a single-rotor single-stator topology [3]. The objectives are to minimize the total loss and active mass under rated operational conditions. The number of variables are four for the coreless machine and six for the conventional machine. The Pareto front obtained from conventional multi-objective DE (MODE) and two-level surrogate assisted algorithm (SAMODE) are presented. *Discussion and Conclusions* A two-level surrogate assisted DE based optimization is proposed for electric machine design with 3D FEA. The results (Fig 2) show that the algorithm outperforms conventional methods with less than half the number of design evaluations. If the kriging model is sufficiently accurate, the number of generations of the exterior loop remains low. Comparing the Pareto fronts for the different examples, the conventional algorithm terminates prematurely and needs a tighter stopping criterion. This is because the total number of function calls in two-level optimization is the sum of interior loop (cheap) and exterior loop (expensive) function evaluations which will be orders of magnitude more than that of the conventional algorithm. Increased number of evaluated designs means a wider search for each generation, hence faster convergence towards optimum designs. It can be noted is that the two-level algorithm constructs a high-quality kriging model for designs close to Pareto. Therefore, the gap between designs in the Pareto can be easily filled using the kriging model. For the conventional algorithm, the only way to have a fuller Pareto front is to increase the population of each generation, which requires even more expensive FEA simulations be run.

FU-13. Comparison of Various Constraints in 3-D Adaptive Degrees-of-Freedom Finite Element Method.

Y. Zhang[1], S. Ho[1] and W. Fu[1]
1. Department of Electrical Engineering, The Hong Kong Polytechnic University, Hong Kong, Hong Kong

In this paper, the 3-D application of a novel adaptive degrees-of-freedom (DoFs) finite element method (FEM) is presented with different categories of constraints. Performance of this novel method is compared with the conventional h-refinement adaptive finite element (AFEM). Moreover, various constraints are investigated to balance the efficiency and the accuracy. A preliminary study on the constraint constructed with shape function of polyhedron is conducted. I. Introduction Adaptive finite element methods (AFEMs) have been widely applied in electromagnetic device design and analysis. The major purpose of AFEMs is to obtain solutions, which have a uniform error distribution over the entire domain, for practical problems. There are two key technologies used in the adaptive method, the error estimator and the mesh adaptive method [1]. According to the mesh adaptive method, the AFEMs are classified into three categories: h-refinement method, p-refinement method and r-refinement method. The h-refinement method [2, 3], which changes the number and size of elements, is a popular one and is adopted in many commercial and opensource software packages [4, 5]. Recently, adaptive degrees-of-freedom (DoFs) FEM is proposed as a novel AFEM [6, 7]. Through this method, explicit elimination of nodes is replaced by imposing constraints on DoFs of these nodes. The symmetry characteristic of the stiffness matrix is maintained, while the size of the global equations is reduced. In [6, 7], a formulation of two master DoFs is employed for 2-D problems, which is validated with several examples. In this paper, this method is extended to 3-D application. Meanwhile, constraints of different number of master DoFs are investigated to find a balance between efficiency and accuracy. Further estimation on the performance of the adaptive DoFs FEM is conducted through comparisons with the conventional AFEM. II. Methodology Constraints are linear or nonlinear formulations involving one or several DoFs, which are classified into slave DoFs and master DoFs. These formulations are used to eliminate and recover variables in the preprocessor and postprocessor. The stiffness equations are modified before global assembly in the form given by $Ku=f$ *to* $T^{T}KTu'=T^{T}f$ Although the dimensions of these three matrixes are increased in the element level, the size of global stiffness equations is reduced by the number of constraints. The sparseness of the stiffness matrix is decreased, which requires more memory space. The increment of nonzero entries of stiffness matrix is determined by the number of master DoFs used in constraints. New correlations between DoFs are introduced to the mesh mathematically and corresponding geometric links may not exist. However, more master DoFs could increase the accuracy of the constraints. The gradients of field along different directions are unknown, then it may be difficult to find two master DoFs to represent one slave DoF accurately. The extreme scheme is regard all the nodes, which share edges with the slave node, as master nodes. And shape function of the polyhedron [8] involving all the master nodes is employed as the constraint. For this scheme, the number of master DoFs in one constraint is uncertain and is larger than ten under some circumstances. A simple scheme is to employ two master DoFs in a liner manner. Because of the insufficient knowledge of field distribution, the choice of master DoFs is blindness to some extent. Then choosing the most adjacent nodes to the slave node is reasonable and easily implemented. Despite of the number of master DoFs, the mesh is not coarsened, i.e. the quality of mesh is maintained. For traditional AFEM, slave nodes are eliminated explicitly. The performance of this novel method can be evaluated through comparison with that of the traditional method in terms of memory requirement, computation time and accuracy. III. Numerical Results A preliminary study of the constraints is conducted on a cylinder shape domain, which is meshed with tetrahedron element. Then several nodes are randomly chosen and regarded as slave nodes. The number of their master nodes ranges from nine to seventeen. Based on the shape function of polyhedron and the coordinates of slave nodes, linear constraints for each slave node is conducted. The sum of the coefficients of each constraint formulation equals to one. Detailed information of two slave nodes with fewest and most master nodes are shown in Fig. 1 with the master node Id and corresponding coefficient. It can be found that the correlations between slave node and master nodes are roughly uniform. Reducing the number of master nodes may result in large sacrifice on accuracy. IV. Conclusion The application of a novel ADoF FEM in 3-D problems is investigated in this paper, and the performance of this method is compared with that of the traditional AFEM. One type of constraint is tested in the preliminary study. Detailed information about the evaluation of different categories of constraints will be reported in the full paper.

FU-14. Finite-element Method with Topological Data Structure Mesh for Optimization of Electrical Device.

X. Liu[1] and *W. Fu*[1]
1. Electrical Engineering, The Hong Kong Polytechnic University, Hong Kong, Hong Kong

Abstract–This work applied the finite-element method (FEM) with topological data structures to the optimization of electrical devices. A generic modifiable graph data structure is built according to the graph-theoretic foundation for these data structures. The employed topological FEM avoids rebuilding of the mesh in traditional FEM method while geometrical variations happen. The effectiveness of the algorithm which can save computer storage and working time when applied to successive optimization is verified by numerical example. Comparison of the topological FEM with traditional FEM on storage load and working time is shown in this work. I. Introduction The commonly used node element mesh contains a set of elements which corresponds with a set of node impact. Since this data structure lacks of topological information, it is not enough in an adaptive analysis environment [1]. Abstract topological entities on which relay a type of model can be manifested by topological data structures. For 2D models, a face of an element in a 2D mesh usually corresponds to face, edge and vertex. In order to consider a topological representation sufficiently, the data structure must contain enough information which retrieve all adjacency relationships among its topological entities and it should capable of preventing errors or ambiguities [2]. In computational science, one problem is to develope methods for the problems on domains which contain one or several objects which may have time-dependent geometry structure [3]. In this case, the regeneration of mesh at each time step will cost dramatic amount of computing time and storage. One of the approaches for this type of problems is to employ a novel mesh structure which can make the regeneration much efficient and economical. In this paper, modifiable array data structures for topology FEM mesh is employed, and it is applied in the optimization of electrical device which contains geometrical deformation. Numerical test is executed to prove the methodology is practical. II. Conforming of FEM mesh Finite element mesh is consisted by *m*-entities whose closures are one of the following types: (1) point (d=0); (2) line (d=1); (3) triangle (d=2); (4) tetrahedron (d=3). The fields of the FEM are defined as piecewise functions composed of basis functions. They are controlled by a finite set of degrees of freedom which are attached to mesh entities. Therefore, a mechanism is required for connecting degrees of freedom with mesh entities. The graph structure is developed as in Fig. 1(a) and it is used to represent a mesh topology graph, and the example of graph structure layout is shown as Fig. 1(b). While vertices point to one adjacent element, implementations of elements and vertices are represented with three adjacency relations: elements point, adjacent elements and vertices. A modifiable structure is the GRUMMP system which is developed by [4]. This structure clearly explains the vertices, sides and elements. The adjacencies which are from elements to sides, sides to vertices, and vertices to sides are always stored. III. Structure of Arrays for Geometrical Deformation Problem In the process of optimization, the geometrical position of an object may be modified. This process can be decomposed to two steps: removing and adding. Removing an object can create a hole at some arbitrary index. If the indices cannot be changed, then the holes must be remained. These holes will be tracked by using a free list, or list of available space and this means new variable array along with those of the objects will be created. To remove an object, the resulting hole will be simply added as the first hole in the free list. Adding an object first needs to check whether there are holes in the free list. If hole exist then the first hole is used as space for the object, and it will be removed from the free list. Otherwise the object should be added at the end and a geometric growth of all arrays may be triggered at the same time. A helpful layout diagram of modifiable object arrays is shown as Fig. 1(c). IV. Optimization procedure Sizing and shape optimization of the optimal design problems is of paramount importance. In the process of optimization, FEM for field computation is widely used in order to get parameters, including design parameters that can be computed by static field analysis and transient field analysis. In this paper, genetic algorithm (GA) is employed for the optimal design problem. V. Numerical Examples An optimal shape design problem is solved using the topological FEM with the graph structure mesh and the GA. The direct current (DC) magnet device is shown in Fig. 2(a). The pole shape AB is to be optimized. It is to generate a magnetic flux density as uniform as possible in the observation line CD. For this problem, the design variables are taken to be $\{x_0, y_0, r_0\}$ as shown in Fig. 2(a). The constraint conditions are shown as Fig. 2(b). The optimization result is shown as Fig. 2(c). And the comparison of the topological FEM with traditional FEM is shown as Fig. 2(d). VI. Conclusion The validation shows that it is capable of the proposed method to reach an accurate result. The numerical example shows that the algorithm the working load of the optimization with topological FEM is significantly reduced compare to the optimization with traditional FEM. The computing time of FEM simulations is shortened and the optimization process is accelerated while the accuracy of it is still ensured.

1.Introduction Soft magnetic composite (SMC) materials and SMC electromagnetic devices have attracted strong research interest in the past decades due to its unique properties, such as isotropic magnetic and thermal properties and low eddy current loss[1-2]. Compared to the laminated steels commonly used in electrical machines, SMC ones have core losses comparable to the copper losses[3]. Therefore, effective and accurate prediction of core losses is crucial for design and optimization of high-performance motors, especially for those with new materials and nonconventional topology and complex structures and three-dimensional (3D) magnetic fluxes. As shown in figure1, the three phases of the motor are stacked axially with an angular shift of 120^o electrical from each other. Each stator phase has a single coil (not shown in the figure for clarity) around an SMC core, which is molded in two halves. The outer rotor comprises a tube of mild steel with an array of magnets for each phase mounted on the inner surface. Mild steel is used for the rotor because the flux density in the yoke is almost constant. 2.Modelling of core losses Core losses is crucial for high-speed motor because the core losses is the dominant component of power loss due to high operating frequency[4]. The local flux density patterns within a claw pole permanent magnet motor are quite complex, with flux density locus at one position can be alternating (1D), two dimensional (2D) or even 3D rotating with purely circular or elliptical patterns[5]. For alternating core loss modelling, a standard practice is to separate the loss into three components: hysteresis, eddy current and anomalous losses, i.e. $P_a=C_{ha}fB^h+C_{ea}(fB)^2+C_{aa}(fB)^{1.5}$, where B is the peak value of flux density, f the frequency, and C_{ha}, h, C_{ea}, and C_{aa} are the loss coefficients. Similarly, the specific core loss with a circular rotating flux vector B can also be separated into three components as $P_r=P_{hr}+C_{er}(fB)^2+C_{ar}(fB)^{1.5}$, where C_{er} and C_{ar} are coefficients for the rotational eddy current and anomalous loss components, and P_{hr} is the rotational hysteresis loss and it was proposed by a formulation: $P_{hr}/f=a_1[1/s/(a_2+1/s)^2+a_3^2-(1/(2-s)/(a_2+1/(2-s))^2+a_3^2)]$ where $s=1-B/Bs*sqrt(1-1/(a_2^2+a_3^2))$ More generally, the flux density loci in 3D flux machines may be elliptical, characterised by major and minor axes B_{maj} and B_{min}, with ratio $R_B=B_{min}/B_{maj}$, with alternating ($R_B=0$) and circular ($R_B=1$) patterns as limiting cases. The core loss with an elliptical rotating flux density can be predicted from the alternating and purely circular formulations as: $P_t=R_BP_r+(1-R_B)^2P_a$, where P_r and P_a are the core losses with a circular B and an alternating B with $B_{maj}=B_p$, respectively, and B_p the peak value of the alternating B[6-7]. 3.Equivalent circuit for predicting core losses in steady-state conditions The motor is assumed to operate in the optimum brushless DC mode. When running in synchronous mode, the claw pole motor's steady-state performance including core losses can be predicted by the equivalent circuit model as shown in Fig. 2. Where E_1 is the root-mean-squared(RMS) value of induced back EMF, R_1 is the stator winding resistance, ω_1 is the angular frequency, $L_{1\sigma}$ is the leakage inductance of the phase winding, and L_1 is the synchronous inductance of the phase winding, which equals the self inductance of a phase winding plus half the mutual inductance between two phase windings. All these parameters have been obtained in the electromagnetic design. Particularly, R_{c1} is the core loss resistance, and it can be expressed by: $R_{c1}=V_1^2/P_t$ 4.Experimental validation To measure the core loss of the claw pole PM machine, a calibrated dc motor is used as a prime mover. At no-load and connected to the tested machine, the power fed into the dc motor is measured. The difference gives the sum of the core loss and mechanical loss of the tested machine. The mechanical loss of the PM machine is measured by replacing the SMC stator with a wood tube (to imitate the windage) and then repeating the previous procedure. The core loss is obtained by subtracting the mechanical loss from the sum of the core loss and mechanical loss. 5.Conclusion The comparison between the calculated core loss using equivalent core-loss resistance and measured core loss in a claw pole permanent magnet SMC machine shows that the proposed equivalent circuit model and calculation method are practical.

FU-16. Finite-element models for foil windings with an improved resolution of the electric field distribution.

H. De Gersem[1]
1. Technische Universitaet Darmstadt, Darmstadt, Germany

Foil winding are sometimes preferred over wire windings because of their favorable electric and thermal properties. Foil windings, however, feature a very particular eddy-current effect, i.e., the current gathers at the foil tips and may there cause substantial thermal problems. As the operating frequency increases, the skin depth gets smaller and an accurate consideration of this particular eddy-current effect in an overall finite-element model of e.g. a transformer or an inductor featuring several foil windings gets cumbersome. In [1] and [2], dedicated finite-element models for foil windings have been proposed. These models avoid to resolve the individual turns of the winding in the finite-element mesh which would make the overall model prohibitively large. Instead, the electric field is modeled such that it is experiences the resistive voltage drop along the winding, the insulating voltage drop perpendicular to the foil and remains constant in the third direction by an additional set of finite-element basis functions. These models, however, turned out to be quite heavy because they necessitate an interpolation between two independent finite-element meshes and because of large dense matrix blocks in the system of equations. In this paper, the mesh interpolation problem is alleviated by a better choice of the finite-element basis functions for discretizing the electric field strength. Based on Legendre polynomials, a basis can be provided which allows an interpolation without the necessity to intersect mesh elements. The overall procedure also leads to smaller dense matrix blocks in the systems of equations. The paper illustrates the improvements by comparing the original models proposed in [1] and [2] with the new technique proposed here, according to the convergence of the finite-element discretization error and according to the computational efficiency.

Downscaling poses a number of new challenges for the implementation of magnonic devices. In particular, the traditional inductive method for spin wave excitation becomes inefficient at nanoscale due to the increasing requirements for the power density, the unavoidable limitations imposed on the wavelength of the excited waves by the geometry of the inductive antennae, and the difficulty of the impedance matching of the latter. An alternative approach to the excitation of spin waves can be based on the spin-transfer torque (STT) mechanism, which provides the ability to directly convert dc electrical currents into microwave-frequency spin waves on nanoscale. Unfortunately, the limitations of the geometry of traditional STT devices operating with spin-polarized electric currents place significant constraints on their compatibility with magnonic devices. By contrast, a significant geometric flexibility can be achieved in the STT devices operated by pure spin currents generated either by the spin Hall effect or by the nonlocal spin injection (NLSI). Indeed, excitation of propagating spin waves by pure spin currents generated by the NLSI mechanism has been recently demonstrated, providing a simple and flexible route compatible with magnonic devices. The ability of a spin-wave source to generate short wave packets is particularly important for the practical implementations of high-speed integrated magnonic circuits. The performance of the traditional inductive excitation technique is very limited in this respect, since the externally generated microwave signal has to be pulse-modulated by semiconductor switches, which are generally characterized by a relatively low power efficiency, and on-off times of at least several nanoseconds. The fastest spin-wave excitation rate demonstrated so far was achieved by utilizing ultra-short laser pulses. However, this approach requires a high-power femtosecond optical source, and therefore has significant technological limitations. Here, we use the time- and space-resolved micro-focus Brillouin light scattering spectroscopy to study the temporal characteristics of the NLSI-based mechanism for the excitation of propagating spin waves. The studied magnonic devices consist of a vertical NLSI spin valve based on a 60 nm diameter nanocontact dynamically coupled to a spin-wave waveguide formed by a 20 nm-thick and 500 nm-wide Py strip fabricated on top of the CoFe(8 nm)/Cu(20nm)/Py(5 nm) trilayer, and terminated at the distance of 150 nm from the nanocontact. Pure spin current, produced due to the spin accumulation in Cu layer above the nanocontact, flows into the active Py layer, exerting STT on its magnetization that results in the compensation of the magnetic damping. When damping is completely compensated by the spin current, the magnetization of the Py layer exhibits microwave-frequency auto-oscillations in the area above the nanocontact. These localized oscillations are then transformed into spin waves propagating in the Py waveguide. By applying the driving dc current in the form of short pulses, we show that the NLSI mechanism is sufficiently fast to enable generation of short spin-wave packets with the duration down to 2 ns, close to the best results achieved by using optical-pulse excitation. Moreover, we find that the intense spin-wave packets generated by the pure spin current experience a nonlinear compression while propagating in the magnonic nano-waveguides, which further reduces their temporal width. A similar mechanism is responsible for the formation of nonlinear spin-wave solitons. It allows one to compensate for the dispersive broadening of spin-wave packets by engineering the nonlinear characteristics of magnonic transmission lines, resulting in improved information flow capacity. Our findings clearly demonstrate the unique benefits of NLSI oscillators as nanocale sources of short spin-wave packets for the implementation of high-speed magnonic devices. We believe that our results should stimulate further developments in magnonics, and bring this area of research closer to the real-world applications.

The formation and development of concepts of magnonics, the field of research based on the use of elementary quanta of magnetic excitations (magnons) and spin waves as carriers of information signals, will allow us to develop a new generation of devices and devices for data transmission and processing operating at microwave frequencies with characteristics that could not be obtained earlier[1,2]. Finite-width microstructures based on yttrium iron garnet (YIG) films are key elements of "magnonic networks," which are widely used in planar devices for signal processing, where information is transferred by means of spin waves and logical operations are implemented according to the principles of spin-wave interference [3,4]. The variation of the working frequency range under the action of a magnetic field for magnonics devices [5] operates much slower and requires a higher energy than that under the action of an electric field. The use of piezoelectric layers in lateral topologies of magnetic microstructures makes it possible to significantly expand the functionality of these microstructures owing to the possibility of creating controlled waveguide channels [6,7]. Here we report on numerical and experimental study of the dynamics of spin waves propagating in a magnonic microwaveguide with a piezoelectric layer. Figure 1 schematically shows the structure, consisting of a magnonic waveguide formed by the CW laser patterning from a YIG film with a thickness of 7.7 μm on a gallium-gadolinium garnet substrate. The piezoelectric layer of lead zirconate-titanate (PZT) is placed on the magnonic waveguide. The structure is placed in a static magnetic field H = 1100 Oe, directed along the short axis of the magnonic waveguide for effective excitation of surface magnetostatic waves (MSSW). 150 nm thick electrodes of chromium were deposited on the surface of the piezoelectric layer (on the side where the YIG film is bonded) using a laser cutting method on this side a system of "counter pins" was formed to improve the interaction with the magnonic waveguide. Positive and negative voltage values are applied to the electrodes, as shown in Fig. 1. 250 nm thick electrodes of chromium are deposited on the top of the piezoelectric layer. We use the finite-element method (FEM) to find the strain produced in the YIG film by the PZT layer and then we compute the internal magnetic field profile in the magnetic layer. Figure 2 shows the internal magnetic field profile in the case of positive and negative electric field values. By the means of microwave vector network analyzer and Brillouin light scattering (BLS) technique (by scanning the probing light spot over the MC surface) we demonstrate the electric field induced forbidden gap formation in the SW transmission. Magnetic tuning can be performed through the variation of a bias magnetic field, while electric tuning is possible due to control of the properties of PZT layer through the variation of an applied electric field.

FV-03. Spin wave propagation in sputter-deposited YIG nanometer films.

Y. Shiota[1], S. Kasukawa[1], T. Moriyama[1] and T. Ono[1,2]

1. Institute for Chemical Research, Kyoto University, Uji, Japan; 2. Center for Spintronics Research Network, Osaka University, Toyonaka, Japan

Yttrium iron garnet ($Y_3Fe_5O_{12}$, YIG) is well-known material with an extremely small magnetic damping, $\alpha = \sim 10^{-5}$ in bulk, which is two orders of magnitude smaller than that in ferromagnetic metals. The growing demands for YIG-based spintronics have led to the development of YIG thin films with a nanometer thickness range [1, 2]. Recently, magnonics has been attracted considerable interests for the transmission, storage and processing of the information using propagating spin waves [3]. To miniaturize the magnonic devices, it is necessary to reduce the thickness of YIG films for a shorter wavelength. For high quality YIG nanometer films, it has been reported that the YIG thin films by pulsed laser deposition (PLD) show the relatively low damping constant of 2.3×10^{-4} for 20 nm thickness [1]. From the view point of a broad utility and industry, the sputtering growth is better than PLD. In this study we investigate the spin wave propagation in sputter-deposited YIG nanometer films, and characterize the YIG thickness dependence of the several parameters, such as magnetic damping constant, spin wave group velocity and nonreciprocity. The YIG thin films were grown on 0.5-mm-thick single crystal gallium gadolinium garget (GGG) substrates with (111) orientation by RF magnetron sputtering. During the deposition, the substrate was kept at room temperature, the argon pressure and sputtering power was 0.06 Pa and 150 W, respectively. The films were annealed at 900 °C for 8 h in the air. We varied YIG film thickness from 20 nm to 50 nm. Using electron-beam lithography and Ar ion-milling technique, the films were patterned into a circular shape with 10-μm-diameter for ferromagnetic resonance (FMR) measurement and a rectangular shape with 50-μm-width for the spin wave measurement. After patterning the YIG films, an insulating layer of 30 nm SiO_2 was deposited on the entire surface. Finally, microwave antennas were deposited for the FMR and spin wave measurement. First, we evaluate the magnetic damping constant α from FMR measurement using a vector network analyzer. Figure 1 (a) shows the FMR linewidth as a function of resonance frequency. α was extracted from the slope of the linear fits to the data. As shown in Fig. 1(b), the α value decreases with increasing the thickness and we obtained lowest value of $\alpha = 1.3 \times 10^{-3}$ in 50-nm-thick YIG, which is slightly larger than the reported values for sputter-deposited YIG thin films [2]. While we need further optimization of the sputtering condition and/or annealing process to reduce α, it should be noted that the obtained α in this study is significantly smaller than that of ferromagnetic metallic films with similar thickness. Second, the propagating spin wave spectroscopy was performed under the in-plane magnetic field to excite the magnetostatic surface spin wave (MSSW) mode. Figure 2(a) shows the group velocity of spin wave estimated from the oscillation period in transmission spectra. It was about 1.1 km/s in 50-nm-thick YIG waveguide under 14 mT. We found that the spin wave group velocity decreases with increasing the magnetic field and decreasing the film thickness. The group velocity v_g can be calculated from the spin wave dispersion $\omega(k)$ as defined $v_g = d\omega(k)/dk$, which nicely reproduces the experimental results. By comparing the signal intensity, the nonreciprocity defined as A_{12}/A_{21} was also estimated, where A_{12} and A_{21} denote the signal intensity of S_{12} and S_{21}, respectively. The unity value indicates the reciprocal characteristics. In our experiment, the nonreciprocity is mainly caused by x- and z-components of microwave magnetic field [4]. As shown in Fig. 2(b), the nonreciprocity increases with increasing magnetic field and we obtained the largest nonreciprocity of 0.1 at 85 mT. This This nonreciprocity is much more significant than that in ferromagnetic metals [4], which is attributed to the smaller saturation magnetization of YIG than that in ferromagnetic metals.

FV-04. Suppression of spin-wave transport in antiferromagnets.

J. Ohe[1] and N. Arakawa[1]
1. Department of Physics, Toho University, Funabashi, Japan

Manipulation of the spin-wave is an important task for the spintronics field. Especially, the unidirectional propagating spin-wave is used as a carrier of spin currents or heat currents. It is pointed out that the interference effect of the spin-wave in the Mach-Zender type magnonic circuit gives the NOR gate in the new type of spintronics logistic devices. The other interference effect has been well studied in terms of the Anderson localization that causes the suppression of the electron conductivity in the low dimensional electron gas system. The weak localization effect is occurred in the electron wave function because the time reversal symmetry is conserved. By applying the magnetic field, the time reversal symmetry is lifted and it causes the negative magneto-resistance. For magnetic systems, the time reversal symmetry is broken when the magnetization has an ordered configuration such as a ferromagnetic phase. It means that the spin wave in ferromagnetic systems has no localization effect. However, the time reversal symmetry is conserved when the system has an anti-ferromagnetic order. The localization effect on the spin-wave may affect the thermal conductivity and open a new type of spin wave transport in mesoscopic regime. In this report, we investigate theoretically the weak localization effect of the spin-wave in the disordered antiferromagnetic systems. We calculate the thermal conductivity in classical Heisenberg model by using the diagram technique and found the suppression of the spin wave transport.[1,2] We also calculate the magnetization dynamics using the micromagnetic simulation. The wave packet dynamics shows the strong coherent back scattering [3] during the propagation through antiferromagnetic systems. We prepare the initial wave packet with a certain averaged wavenumber k_0 in antiferromagnetic system. After time evolution, the intensity of the spin wave with the negative value $-k_0$ becomes large as shown in Fig.1. The peak value of the coherent back scattering is larger than that obtained by the ferromagnetic systems. The thermal transport via the spin wave is also suppressed and the possibility of the experimental set up is investigated.

FV-05. Antiferromagnetic magnonic crystals with alternating Dzyaloshinskii-Moriya interaction.

S. Lee[1] and K. Lee[1]
1. Korea Univ., Seoul, The Republic of Korea

1. Introduction The collective excitation of magnetic moments in magnetic material is named spin-wave (magnon). The spin wave logic devices have been extensively investigated in "magnon spintronics"[1-5], because spin-wave frequency can cover conventional GHz range electronic devices and also can have THz frequencies in antiferromagnet. Moreover spin-wave devices have attractive feature in energy consumption because the spin-wave devices, do not involve electron transport, can avoid Joule heating and thus it is appropriate for low power computing. The antiferromagnetic materials are regarded as proper for magnonic medium. Because the antiferromagnetic materials can have THz frequency with higher spin-wave group velocity. Furthermore, recent works showed that spin-wave devices with antiferromagnetic materials could be performed as spin wave field-effect transistor [3] and polarizer/retarder [4]. Recently, in ferromagnetic materials, magnonic crystals with alternating Dzyaloshinskii-Moriya interaction show large tunability of spin-wave band gap [5]. In this work, based on micromagnetics, we demonstrate sub-THz spin-wave band gap in antiferromagnetic magnonic crystals with alternating Dzyaloshinskii-Moriya interaction. 2. Model In our system, the magnetic free energy density W is given by $W=(1/2)[A(d_x n)^2 - D(x)e_y.(n \times d_x n) - K_u(n.e_y)^2]$ where A is the exchange stiffness constant, $n=(m_1-m_2)/2$ is the staggered order, $D(x)$ is the interfacial DMI constant as function of position x and K is the anisotropy constant. In this work, based on equation of motion for magnetic moments in antiferromagnetic materials, we obtain boundary condition at the boundary between two different DMI constant regions. With this boundary condition, we can obtain reflectance and transmittance of spin-wave and establish dispersion relations in this system with Bloch's theorem. Also to verifying our analytic solution, we performed micromagnetic simulation in 1-D antiferromagnetic system with 1) DMI step and 2) magnonic crystals with alternating DMI constant. In this simulation we use following parameters: the atomic lattice parameter is 0.3 nm, the exchange stiffness constant A is -1×10^{-6} erg/cm, the anisotropy constant K_u is 1×10^6 erg/cm^3, the magnetic moments is 800 emu/cm^3, the Gilbert damping parameter α is 0.001 and we fixed DMI constant in region 1. D_1 as 0 erg/cm^2 and varying D_2 with -2~2 erg/cm^2. 3. Result and Discussion Figure 1 a) shows spin-wave transmittance as a function of DMI constant in region 2 (D_2). The lines are obtained from the analytic solution with boundary condition and symbols are obtained from the micromagnetic simulations. The circle symbols correspond to circular polarized spin-wave and star symbols correspond to linear polarized spin-wave. Here we find that the spin-wave transmittance could be larger than 1 and results from both cases have reasonable agreements regardless of spin-wave polarization. Figure 1 b) shows constructed bands in antiferromagnetic magnonic crystals with alternating DMI constant. Here we plot spin-wave forbidden gap(black) and allow bands(white) as DMI constant in region 2 (D_2). The black(white) regions are calculated from analytical dispersion relation in magnonic crystals. The Symbols are obtain from micromagnetic simulations. Likewise results for spin wave transmittance (Fig. 1. a)), the analytical solution and numerical results are well matched and the spin-wave polarization does not affect to the results. From Fig. 1. b), we find that for D_2= 2 erg/cm^2 the spin-wave band gap opens up to 0.1 THz. 4. Summary We propose antiferromagnetic magnonic crystal with alternating DMI and investigate its property based on micromagnetic simulation. Also, compared with ferromagnetic materials, the large band gap can opens in this system. Moreover, since the DMI constant can be modulated by external electric field, the spin-wave band gap also has tunability with electric fields. Thus these results show that the antiferromagnetic magnonic crystal also can be one of candidates for magnon transistor like modulating electron transport in semiconductor transistors by electric field.

FV-06. Motion of a skyrmionium driven by spin wave.

M. Shen[1], Y. zhang[1], J. Ouyang[1], X. Yang[1] and L. You[1]
1. School of Optical and Electronic Information, Huazhong University of Science and Technology, Wuhan, China

A skyrmionium is composed of two skyrmions with opposite skyrmion numbers and different sizes in the same track. In recent years, the motion of a skyrmionium driven by spin-polarized current has been investigated. However, the motion of a skyrmionium driven by a spin wave has not been reported. In this paper, we report our work concerning the numerical analysis of spin wave-driven motion of a skyrmionium in a nanotrack. The results show that the motion of a skyrmionium was significantly influenced by varying the frequency and amplitude of the AC magnetic field for exciting a spin wave, the distance between the spin wave source and the skyrmionium, and the damping coefficient of the ferromagnetic track. We found skyrmionium deformation during its initial motion process, but its shape could be recovered as it moved farther away from the spin wave source. Additionally, a series of velocity peaks were observed in the frequency range between 25 GHz and 175 GHz. When compared to a skyrmion, the skyrmionium could be driven by a spin wave to move in a wider frequency range at a higher velocity, which offers the skyrmionium potential application in wide-frequency spintronic devices.

Magnonics studies the utilization of spin waves in magnetic materials for applications like wave based information processing and logic. Spin waves and their quanta, the magnons, are a type of quasi particles which belongs to the family of bosons, and can be considered as the low energy excitations of the spin ensemble of a magnetically ordered system. Magnons carry a quantized amount of energy and momentum, and due to their bosonic nature, they can occupy a single energy state at the same time, e.g. form a Bose-Einstein Condensate (BEC) [1] at room temperature. Since the first observation of this macroscopic quantum state in 2006, numerous studies have been performed to explore the rich physics of the magnon BEC and the novel dynamics that can emerge in a BEC, like supercurrents [2] or condensation in ultra-hot gases [3]. However, these experimental studies have been restricted to BEC formation in bulk samples and the theoretical description has been performed using effective theories and not by the full solution of the Landau-Lifshitz-Gilbert equation. Here, we present a micromagnetic study of the possibility of the formation of a magnon BEC in magnetic microstructures. We use the finite difference code Mumax 3.0 [4] to solve the full LLG including Gilbert damping in micron sized rectangular waveguides made of Permalloy (Py) and Yttrium Iron Garnet (YIG). By specifically designing the band structure and the excitation source, we show that the magnons occupy the lowest energy level in the systems which can be explained in favor of a BEC formation in the case of YIG and by asymmetric parallel pumping in case of Py. Fig. 1a shows the frequency spectrum close to the band bottom of a 500 nm wide Py waveguide magnetized along its long axis and driven by a localized, high power microwave source at f_p = 16.5 GHz which is used to parametrically inject magnons [5]. The dispersion relation of the first waveguide mode calculated based on [6] is displayed in Fig. 1b. The injected magnons directly occupy the mode at f_{BEC} = 7.75 GHz and a secondary mode f_{sec} =8.95 GHz, without populating the mode at $f_p/2$. It can be seen that f_{BEC} corresponds to the BEC point which is the band bottom of the first waveguide width mode. This asymmetric parallel pumping, which populates directly the BEC point, is possible due to the localized pumping source and it is favored due to the vanishing radiation losses at this spectral point (vanishing group velocity). In contrast to the Py case, the observation of the formation of a magnon BEC by nonlinear magnon scattering is possible in YIG. Fig. 2 shows the band structure of a 500 nm wide YIG waveguide also magnetized along its long axis and driven by a localized excitation source at f_p = 10 GHz. Due to multi-magnon scattering processes which occur in the system when the excitation power is high enough, magnons condense at the global minimum and form a BEC. We found that after switching off the excitation, the magnon population at the BEC point further increases whereas the directly injected magnons decay. This confirms that the redistribution of magnon energy via scattering processes, which is facilitated by the long life time of the magnons in YIG, is the underlying mechanism of the BEC formation in this case.

FV-08. Phase locking, intermittency and chaos, of an array of magnonic crystal cavities driven by spin torque nano oscillators.

N. Kumar[1] and A. Prabhakar[1]
1. Electrical Engineering, IIT Madras, Chennai, India

Magnonic crystals created by an array of periodically arranged holes on a thin ferromagnetic film show frequency bandgaps in their spin wave spectrum. By removing a few holes, or anti-dots, from the array, we are able to create magnonic crystal cavities (MCCs) where spin waves of a particular wavelength are resonant. By adding a nano-contact and driving spin polarized current, or a spin torque nano-contact oscillator (STNO) to each cavity, we are able to simulate a gain element within that cavity. The combination of gain and a resonant cavity, lead to the creation of a SWASER, whose optical analogue is the commonly used LASER. We have previously reported how a MCC can be designed to generate a narrow linewidth spin wave excitation [1]. The aim of the present work is to demonstrate how arrays of these cavities can be arranged to transfer power, in phase, to an adjacent magnonic crystal waveguide (MCW). The radius of the anti-dot and the lattice constant of the magnonic crystal are 40 nm and 150 nm, respectively. The full geometry consists of 49 x 49 unit cells, and the MCW was created by removing one row of anti-dots. The MCCs were placed on either side of the MCW, again separated by one row of anti-dots. Each MCC was created by removing 3 anti-dots, and a STNO placed at the center of the MCC. We work with the magnetic properties of permalloy, assume a damping constant of 0.01, and apply a static external field along the direction of the MCW. The simulation data was probed in a region of the MCW and saved every 10 ps, with sufficient resolution to observed spin wave oscillations up to 50 GHz. Other aspects of the simulation methodology have been previously reported [1]. The locations of the MCCs, relative to each other and the adjacent waveguide, are restricted by the very nature of the peridocity of the underlyig lattice. We use the GPU accelerated parallel micromagnetic solver, MuMax [2], to study the performance of different numbers of MCCs, and observe that the coupling between cavities can cause a loss of resonant spin wave precession. However, this can be mitigated by changing the spin polarized current that drives the spin torque within each cavity. We find that it is possible to lock adjacent cavities using 20% lower spin polarized currents, as compared to a single cavity. The same (lower) spin polarized current when applied to a single cavity requires a much longer time to drive the spin waves into resonance, as shown in Figure 1. Our studies thus establish one means to scale the spin wave power that can be generated using spin polarized current pumping into nano-contacts. This has immense practical significance, as it has been thus far difficult to use arrays of nano-contacts to generate sufficent spin wave amplitudes that can be used in RF devices. Changing the spin polarized current in the STNO allows us to tune the wavelength of the SWs in the cavity, and find the correct phase locking between cavities. However, we must be cautious to report that in the process of scaling to arrays of SWASERs, we have observed the onset of intermittency and chaos in the SW oscillations that are reminiscent of similar phenomena in LASERs [3]. These nonlinear phenomena have been traditionally observed in SW propagation in magnetic films [4]. However, we believe that these are the first observations, albeit through simulations, of the possible onset of these nonlinearities in coupled SWASER cavities.

Excitation of spin waves (SW) and their detection in magnetic materials can be accomplished all-optically by the femtosecond laser pulses using the pump-probe technique [1, 2]. However, usually broad spectrum of optically excited magnons hides the microscopic spin dynamics and results in fast decay of the magnetization precession. In this work we identify a novel feature of the periodic optical excitation of SWs. In particular, we excited magnetization of the sample with a sequence of circularly polarized pulses (Fig 1) at high repetition rate so that interval between pulses was shorter than the decay time of the oscillations, which provides a collective phenomenon. SWs of the frequencies multiple to the laser pulse repetition rate are mostly supported while SWs of the frequencies that are semi-integer multiples to the laser pulse repetition rate become suppressed. As a result, SWs are generated in a specific narrow range of wavenumbers. Furthermore, modifying laser pulse repetition rate or value of the external magnetic field provides significant level of SW wavelength tunability. In our particular case, we have chosen a magnetic film with such magnetic parameters and thickness that allow to change SW wavelength by about 20 times from 15 μm to 290 μm with just tiny modification of the external magnetic field by a few percent. This work was financially supported by Russian Science Foundation (Project No. 17-72-20260).

Although a phenomenological description, the inverse Faraday effect (IFE) is generally adopted for all optical magnetic switching (AOS) study, and has been successfully incorporated into the dynamics of AOS. The origin of IFE has been investigated theoretically by Pitaevskii[1], and predictions made by the study have been proved by experiments in 1966[2]. However, the effective field of IFE is deduced within the nanosecond time scale, which means the approximations valid in nanosecond scale are not quite suitable for femtosecond scenario. Further, the ~10-times mismatch between the duration of IFE in magnetic materials and the width of the incident laser pulse remains an open question for magnetic materials which exhibit AOS[3]. We investigate the process of AOS with quantum mechanical descriptions. The interactions between the incident femtosecond laser and magnetic materials are attributed to Rashba effect and stimulated Raman scattering (SRC): the incident femtosecond laser breaks the space inversion symmetry and splits the energy band of the electrons of magnetic material into two due to Rashba effect, which in turn maintains a quasi-stationary state for SRC (The three level system is depicted in Fig.1). The fine energy structure is spin dependent, so each sub-band is exclusive for spin up or spin down. The adiabatic transition of the states of electrons among the fine energy bands and the excited state gives rise of the spin direction switching, which switches the orientation of the magnetization of the material. The process discussed above can be described by Rabi model[4]. Simulation carried on this model shows that by tuning the center frequency of the incident femtosecond laser regarding the energy gap of the ground state and the excited state, the spin flip could be realized, results are shown in Figure 2. The further investigation will be focused on the details of decay rate for the two sub-bands.

All-optical magnetic switching (AOS) observed on some materials provides a potential recording option due to its ultra-short recording-time [1]. In most studies, it is attributed to inverse Faraday effect (IFE) that circularly polarized laser will induce an opto-magnetic field [2, 3] or magnetic circular dichroism (MCD) that one magnetization orientation will absorb more energy than another [4, 5]. L10-FePt is a promising candidate for high density magnetic recording due to its high perpendicular anisotropy [6] whose magnetization is fixed out of plane either up or down. However, the mechanism about AOS on FePt is still under debate. In our research, we show that it benefits from both IFE and MCD. Taking both the thermal effect and the induced opto-magnetic field into account, we calculate the switching probability of L10-FePt nanoparticles for a single laser pulse with different opto-magnetic fields by atomistic level simulation [7], as shown in Fig. 1(a-d). We consider the effect of multi-shot pulses by an accumulative model, assuming that the switching probability after each shot is identical. Fig. 1(f) shows the normalized net magnetisation variation with different MCD ratios when the opto-magnetic field induced by left circularly laser pulse (σ-) is -0.1 Tesla. Obviously, when the MCD ratio is 2%, the final magnetisation is in agreement with the experiment result of Lambert et al. that the magnetization induced by circularly polarized laser is ~10 to 20% of saturation magnetization [8]. This MCD ratio is reasonable for FePt [5, 9]. Fig. 2(a-c) show the final magnetisation over multiple linearly (L), left (σ-) and right (σ+) circularly laser pulses respectively with different initial magnetization states, which verify that AOS is helicity-dependent but independent of the initial state. Fig. 2(d) shows the magnetisation variation over laser fluence with different opto-magnetic fields. Applying an external magnetic field 0.03 Tesla when the opto-magnetic field is -0.1 Tesla, the corresponding effective magnetic field is -0.07 Tesla. In this case, the net magnetisation roughly equals to 0 at a wide laser fluence range, which is qualitatively consistent with the results of Lambert et al. that a 700 Oe field could eliminate the all-optical switching. In addition, when the opto-magnetic fields are ±0.4 Tesla, there will be a deterministic switching that the final magnetization is greater 90% of the saturation magnetization. Taking the opto-magnetic field -0.4T as example, the net magnetisation after multiple laser pulses is shown in Fig. 2(e), and the fastest deterministic switching occurs at 34 mJ/cm2 after 34 left circularly laser pulses. Although our simulation is simplified, these results demonstrate the possibility of reaching deterministic all-optical magnetic recording by optimizing the parameters presented above.

Since the magnetization was demonstrated to be reversed by a femtosecond laser pulse without any external magnetic field, this all-optical switching (AOS) has been extensively studied in recent years. All-optical manipulation of magnetism becomes attractive due to its potential technological applications. AOS in the ferrimagnetic GdFeCo alloy, the initially investigated material for AOS, is demonstrated to be a pure laser-induced thermal effect via a transient ferromagnetic-like state. Very recently, ultrafast electronic heat currents have been shown experimentally to be sufficient to switch the magnetization in GdFeCo, which further verifies the thermal origin of AOS in GdFeCo. Consequently, AOS in GdFeCo is independent to the circular helicity of laser pulses, which is named as helicity-independent AOS (HI-AOS). To explore the roles of the thermal effect and laser helicity in HD-AOS and the time scales in this process, we used the ultrafast laser pump-probe technique, also known as time-resolved magneto-Kerr effect measurement, to measure the transient magnetization change after single laser pulse irradiation in TbFeCo. The transient reflectivity change is also monitored in the same time. TbFeCo is a very similar ferrimagnet compared to GdFeCo in so much as the Tb sublattice is antiferromagnetically coupled with the FeCo sublattice. However, because of the large difference between the spin-orbit coupling of Tb and Gd, Gd- and Tb-based alloys show different ultrafast spin dynamics as well as a distinct switching mechanisms. Also, with a large coercive field, TbFeCo is suitable for magnetic recording applications. Using time-resolved magneto-optical Kerr effect (TR-MOKE) method, helicity-dependent all-optical magnetization switching (HD-AOS) is observed in ferrimagnetic TbFeCo films. The thermal effect and opto-magneto effects are separately justified after single circularly polarized laser pulse. The integral evolution of this ultrafast switching is characterized on different time scales and the defined magnetization reversal time of 460 fs is the fastest ever observed. Combining the heat effect and inverse Faraday effect (IFE), micromagnetic simulations based on a single macro-spin model are performed that reproduce HD-AOS following a linear reversal mechanism. In summary, the HD-AOS is unambiguously demonstrated in TbFeCo film by one single circularly polarized laser pulse. The thermal and opto-magnetic effects are seen to have different time scales, respectively. High pump fluences are required for the effect of the laser helicity, which is consistent with other reported works. Besides, the reflectivity change relaxation time is quite small in our measurements so the effect of accumulative heat should not play a role. The interplay between laser heating and helicity is stimulated by a single laser pulse. The integral evolution using the TR-MOKE method including the time points when it comes peak electron temperature, fully demagnetized state, magnetization switching triggered and a new magnetization direction is defined. Furthermore, from the sub-picosecond time domain evolution of HD-AOS, the observed magnetic switching time in 460 fs is the fastest among the reported times. On the other hand, this sub-picosecond switching is reproduced using a single macro-spin model based on the stochastic Landau-Lifschitz-Bloch equation, confirming the linear reversal mechanism without spin precession in the all-optically induced magnetization switching. Also, the simulation suggests that heating the electrons system to a critical temperature may play an important role in this kind of magnetization reversal. Above all, the finding of the ultrafast helicity-dependent all-optical magnetization switching in a high anisotropy system triggered by single laser pulse brings all-optical magnetic recording a major step close to the high data rate and high data density applications.

TbCo alloy films possess ferrimagnetic structure and high perpendicular anisotropy and have been proven to rapidly reverse their magnetic moments irradiated with an ultra-short pulse laser, which have the potential to use as all optical switching media [1-2]. In this paper, we have adopted a two-temperature model [3] and a general theoretical framework [4] to calculate the temperatures of the electron gas (T_e) and the phonon (T_p) and the magnetization dynamics of $Tb_{26}Co_{74}$ films, respectively, and found that electron-phonon coupling factor (G) plays a significant influence on the T_e and magnetization reversal dynamics of TbCo films. In our simulation, the laser wavelength and pulse width, laser fluence are 560 nm, 100 fs and 15 J/m^2, respectively. The G values vary from 1 to 10×10^{17} W/m^3. K. Fig 1 shows the time evolution of T_e and T_p. T_e rapidly increases to the peak temperature within about 0.3ps and then decreases with different rates until reaching the same value as T_p. TbCo films with a smaller G have a higher peak temperature of T_e and exhibit a slower cooling rate, and thus experience a longer heat exchange time between the electron gas and phonon. Fig 2 presents the computed time-resolved magnetization dynamics of Co- and Tb- sublattices. When G is just 1×10^{17} W/m^3. K, only the rapid demagnetization process occurs in Co- and Tb- sublattices and no magnetization reversal is observed due to the higher T_e and slower cooling rate. As G continues to increase, the demagnetization time of Co- sublattice rises slowly, but the initial reversal time of Co- sublattice drops gradually from 1.27ps to 0.66ps, which is attributed to the decreasing T_e and the increasing cooling rate of electron gas. Moreover, Tb- sublattice delays to reverse its magnetic moment with the increase of G perhaps owing to the lower T_e and the slower demagnetization of Tb- sublattice. Furthermore, although Co- and Tb- sublattices both generate magnetization reversal, the total magnetization reversal of $Tb_{26}Co_{74}$ films does not occur within the timescale of 5ps and will happen after a relatively longer recovery of magnetic moments of Tb- sublattice. Magnetic skyrmions are chiral quasiparticles that show promise for future spintronic applications such as skyrmion racetrack memories and logic devices because of their topological stability, small size (typically ~ 3 - 500 nm), and ultralow threshold force to drive their motion. On the other hand, the ability of light to carry and deliver orbital angular momentum (OAM) in the form of optical vortices has attracted a lot of interest. In this work, we predict a photonic OAM transfer effect, by studying the dynamics of magnetic skyrmions subject to Laguerre-Gaussian optical vortices, which manifests a rotational motion of the skyrmionic quasiparticle around the beam axis. The topological charge of the optical vortex determines both the magnitude and the handedness of the rotation velocity of skyrmions. In our proposal, the twisted light beam acts as an optical tweezer to enable us displacing skyrmions over large-scale defects in magnetic films to avoid being captured.

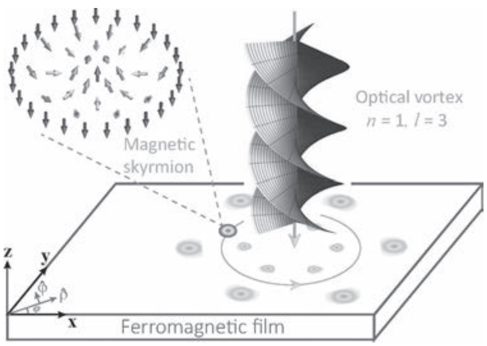

Fig. 1. Schematic of the rotational motion of a Néel skyrmion in a thin ferromagnetic film driven by an optical vortex with radial index n = 1 and OAM l = 3. The solid circle with a red core represents the skyrmion. The flower-like pattern (pink and blue spots) sketches the induced magnetization profile by the optical vortex field shinning on the magnetic film. In the main text, the origin of Cartesian coordinates coincides with the beam center, while it does not in the figure for clarity.

FV-15. Dependency of Spin Pumping on Seed and Capping Layers in Co Ultrathin Films.

Generation of pure spin current and its effect on the switching of the magnetization by spin transfer torque via spin orbital torque has been subject of major research in last one decade. Switching of magnetization by current at lower current density is required for fast processing and low power consumption devices. The potential applications of pure spin current are in spintronics/spin-orbitronics [1-4], spin torque- oscillator [5], magnetic random memory devices [6], magnonics [6] etc. Pure spin current is produced by asymmetric scattering of the two electrons with opposite spin angular momentum in the presence of spin orbit coupling at the interface which is known as spin Hall effect [1-3]. Ferromagnetic resonance (FMR) is widely used technique to excite the spins by microwave frequency. The excitations of spin in ferromagnetic (FM) layer and their dissipation into a paramagnetic heavy metal (NM) are called "spin pumping" [7]. The understanding of magnetic dynamics dissipation in the material is very important to get sustainable spin current. The interfaces are very important for creating pure spin current and its dissipation. In order to understand the effect of seed and capping layers on spin pumping dynamics we fabricated the multilayer structure *Seed layer/Co/Capping layer.* The seed layer and capping layers are the combination of heavy metals like Ta, Pt, and Au. The samples are deposited at room temperature in a high vacuum system (Mantis Deposition Ltd., UK) having base pressure better than 5.0×10^{-7} mbar. The Ta, Cu, and Co layers are deposited by dc sputtering. While Pt and Au thin films are prepared by rf sputtering and electron beam evaporation, respectively. We deposited the multilayers Ta(3)/HM^T/Co(3)/HM^B/Ta(3) (nm) on Si(100) substrate in which HM^T and HM^B stands for heavy metal for top and bottom layers, respectively as shown in Figure 1. We measured the samples using ferromagnetic resonance spectroscopy (FMR) [8]. The FMR data were fitted with Kittel's equation to extract the values of damping constant and g-factor. A strong dependence of seed and capping layers on spin pumping has been observed. The value of damping constant (α) is found to be relatively large i.e. 0.0326±0.0008 for the Ta(3)/Pt(3)/Co(3) /Pt(3)/Ta(3) (nm) multilayer structure, while it is 0.0104±0.0003 for Ta(3)/Co(3)/Ta(3) (nm). Increase in α is observed due to Pt layer that works as a good sink for spins due to high spin orbit coupling. In addition, we evaluated the effective spin conductance $= 5.82 \pm 0.08 \times 10^{18}$ m^{-2} for the structure Ta(3)/Pt(3)/Co(3)/Pt(3)/Ta(3) (nm) as a result of the enhancement in α relative to its bulk value (Table I).

Abstract: Hybrid distribution transformer (HDT) is significant for the intelligence of the power network due to its powerful controllability. In this paper, a three-phase circuit scheme of HDT is presented. To reduce the number of discrete magnetics and make high efficient use of the magnetic material, a magnetic integration structure of HDT (MIHDT) is proposed, which is realized by creating the adjustable magnetic circuit, setting up the common magnetic circuit and shifting windings' phase. In this way, the large numbers of discrete magnetics in HDT are integrated together. Furthermore, the magnetic density of MIHDT is analyzed and the inductance matrix is calculated by 3-D Finite Element Method, and then the model of MIHDT based on the inductance matrix is established. Finally, the correctness of IMHDT is verified. 1 Introduction HDT is a novel transformer that combines the conventional distribution transformer with the PWM convertors, which is quite useful for the construction of the future intelligent distribution power network. [1-3] presents several topologies of HDT based on the DC-AC convertors, and discuss various issues on HDT, such as the reactive power compensation, high efficient design, and capacity calculation. Compared with the conventional distribution transformer, HDT is much more controllable, but which contains large numbers of discrete magnetics, such as the main transformer, isolation transformer and the output inductances of convertors. Obviously, a system constructed with discrete magnetics will be complex and the total volume and electromagnetic capacity of HDT will be quite large, which can't make the most of the magnetic material, therefore, it is significant to design the integrated structure for HDT. The magnetic-integration techniques has been widely used in the optimization design of the convertors used in the low and medium power application [4,5], but which has not been used in the design of the magnetic integration HDT (MIHDT). The design principle of MIHDT is integrating the discrete magnetics together under the precondition of inheriting the original functions of HDT. In this paper, a MIHDT based on the above design principle is presented, and the magnetic field is analyzed by 3-D Finite Element Method, then the mathematical model based on the inductance matrix of MIHDT is established, and the simulation results verifies the correctness of MIHDT finally. 2 Basic working principle of HDT Fig.1 (a) shows the three-phase circuit scheme of HDT proposed in this paper, T_1 and T_2 are the main and isolation transformer respectively. CV_t and CV_p are two convertors shared a common DC-bus. T_1 contains W_1(W_{1a}, W_{1b}, W_{1c}. same as the other windings), W_2, W_3 in each phase, Where, W_3 is the auxiliary winding. T_2 consists of W_4 and W_5 in each phase. CV_p and CV_t are connected to W_3 and W_4 through the output inductance L_p and L_t respectively. The basic working principle of HDT is that: CV_p and CV_t can be controlled as controllable current and voltage source, thus the grid current i_s and load voltage u_2 can be compensated to be sinusoidal, symmetrical and steady in real time. 3 Magnetic integration structure of HDT HDT shown as Fig.1(a) usually contains the following discrete magnetics: T_1, T_2, L_p and L_t. Where, T_1 is usually a three-limb concentric-type transformer, and T_2 can be a three-phase four-frame shell-type transformer, L_p and L_t should be 6 separated inductances. The MIHDT presented in this paper is shown as Fig.1(b), which is a shown as 3-D Finite Element model. Where, W_1, W_2 and W_3 are concentric windings wrapped around the core limb of T_1 in each phase, the arranging sequence of which is W_2, W_1, and W_3 from the inside of the core limb to the outside. W_4 and W_5 are pancake windings folding around the core frame of T_2 in each phase. T_1 and T_2 are integrated together by sharing the common iron yoke. The adjustable iron cores for leakage flux of T_1 are set between W_1 and W_3, while the which of T_2 are set between W_4 and W_5. Furthermore, the windings of T_2 are arranged by phase shifting, which can avoid the superposition of the flux amplitudes of T_1 and T_2 in same phase, thus, the cross-sectional area of common iron yoke can be reduced prominently. 4 Simulation and analysis The flux density of iron core is shown in Fig.2(a), which indicates that iron core of MIHDT is not saturated, and the flux density in the common iron yoke is less than the superposition of the flux density of each limb due to phase shifting. Fig.2(b) compares the flux density between W_1 and W_3 of phase A when the iron core for leakage flux exists or not, which indicates that the iron core for leakage flux will increase the leakage flux greatly, and then will increase the leakage inductance of W_1 and W_3 (shown as l_{k13} in Fig.2(b)). In this way, L_p can be replaced by the leakage inductance and be integrated into the transformer equivalently. Based on the model shown in Fig.1(b), the inductance matrix of MIHDT can be calculated, regarding the matrix as the equivalent circuit of MIHDT and according to the control strategy of PWM convertor, the control system of MIHDT can be established in MATLAB. Fig.2(c) shows the compensating effect of i_s and u_2, which indicates that MIHDT can also compensate the i_s and u_2 to be sinusoidal, symmetric, stable, and unity power factor as HDT.

FW-02. Analytical and FEM Calculation of Electrical Parameters of Carbon Steel Pipelines for DEH systems.

A. Chen[1], A. Nysveen[1], M. Høyer-Hansen[2] and J. Lervik[2]
1. Electrical power engineering, Norwegian University of Science and Technology, Trondheim, Norway; 2. SINTEF Energy Research, Trondheim, Norway

Introduction Direct Electrical Heating (DEH) is a flow assurance technology developed for subsea process to safeguard well stream through production pipelines to topside process platform or shore, where the magnetic production pipelines directly conduct one-phase AC current to generate heat to prevent the oil from formatting hydrates or wax. The heating source is the conductive power and hysteresis power losses in the pipelines. The required power is supplied from topside via a power cable. Comparing to conventional chemistry treatment, this method is more cost-efficient and environmentally friendly. All currently implemented DEHs operates at 50/60Hz. To further improve the effectiveness of a DEH-system, consequently reducing the cable size and the corresponding installation cost, higher operation frequency and high magnetic permeability material such as carbon steel for the pipeline is preferable. Operating at higher frequencies, the hysteresis power in carbon steel pipeline becomes considerable and have to be taken into account for evaluating the electrical parameters of the pipeline, which is essential for dimensioning power system in a DEH design. These parameters are not available from pipe manufactures, since the pipes are not originally designed for this purpose. This paper presents how to analytically evaluate the electrical parameters of the pipeline based on experimentally measured properties of the material sample. The hysteresis power loss has been considered as the power from an equivalent resistance. The analytical results are verified by FEM simulations. *Electrical parameters of the pipeline* The production pipeline in a DEH system is an active conductor in the electric circuit, and both conductive power and hysteresis power losses in the pipeline contribute to the heating. For a DEH system design, the total power can be considered as the active power from the pipeline resistance. Therefore, the calculated pipeline resistance R_p includes the pipeline conductive resistance R_c and an equivalent resistance R_h representing the hysteresis power loss. The inductance of the pipeline L_p consists of the pipeline internal inductance L_{in} and the external inductance L_{ex} introduced by the field from the power cable. *Current distribution due to skin effect* The current distribution in the production pipeline due to skin effect is governed by Maxwell equations. In the discussed case of conducting a large current of 1500A, the displacement current in the pipeline is negligible, therefore the current density is determined by (1) $\nabla^2 J = j\omega\mu\sigma J$ (1) In carbon steel material, the magnetic permeability μ is a non-linear function of magnetic field. Including such a function, equation (1) becomes too complicated to be analytically solved. Moreover, both μ and conductivity σ vary with temperature. To simplify the problem for the analytical study, following assumptions have been made: ■ Constant room temperature ■ Neglect proximity effect from the cable ■ Homogeneity of σ over the pipe. ■ Constant effective permeability:the effective permeability is obtained by curve fit tool in MATLAB based on the measured BH curve. In the investigated frequency range of 50-200Hz, the penetration depths into the pipeline are less than 1.7 mm,much less than the wall thickness of 18.3mm. It is therefore applicable to consider the current distribution in the pipeline similar to a plane analysis. The internal resistance and inductance are respectively evaluated by (2) and (3). $R_c=\sqrt{(\mu\omega/2\sigma)}/(2\pi r_o)$ (2) $L_{in}=\sqrt{(\mu\omega/2\sigma)}/(2\omega\pi r_o)$ (3) The external inductance between the cable and pipe is determined by (4) $L_{ex}=(\mu_0/2\pi)\ ln(D/r_o)$ (4) where r_o is the outer diameter of the pipe, and D is the distance between the cable and pipe. *Hysteresis power loss and equivalent resistance* The hysteresis power loss P_{hys} is evaluated by integrating the hysteresis energy over the pipeline volume and multiplying frequency f and mass density ρ as: $P_{hys}=2\pi\rho f \int r E_{hys} dr$ (5) The hysteresis energy E_{hys} is the area enclosed by hysteresis loop of B-H curve at DC condition, and it is material dependent and determined by the maximum flux density B_{max}, but independent of frequency. The relation between E_{hys} and B_{max} is experimentally obtained by measuring a rod made of the pipe, and it can be expressed by (6) $E_{hys}=0.285B_{max}^{1.55}$ (6) The B_{max} distribution in the pipeline can be derived based on (1) with peak input current, and Fig. (1) shows the analytical calculated B_{max} distribution in the pipeline with constant current 1500A at 50, 100, 150 and 200 Hz, respectively. Then the equivalent resistance for the hysteresis power is $R_h= P_{hys}/I_{in}^2$. To verify the analytical results, FEM simulation is performed, and Fig.2 shows the comparison of the analytical calculated R_p, L_p, R_c and R_h to those from the FEM simulation. *Conclusion* The paper has presented an analytical modeling for evaluating electrical parameters of the pipeline in DEH system, and the calculated resistance includes an equivalent resistance representing the hysteresis power loss, which is derived based on experimentally measured hysteresis loop energy at DC condition. It shows that the hysteresis power loss in carbon steel pipeline contributes around one third of the total power loss. FEM simulation are carried out to verify the analytical results. The results match each other satisfactorily. More detailed information will be given in the final paper.

Universal motors are now widely applied to household appliances and tools because of their advantages of high starting torque and high speed operation without additional power conversion device in a commercial power supply. However, there is a serious drawback that arc discharge and electromagnetic interference problems may occur due to the mechanical commutation method. In motor design, it is better to avoid such problem, but it is difficult to accurately predict the mechanical commutation characteristics through conventional FEM analysis. Currently, when designing a universal motor, the design is being carried out through existing design experience and trial and error. If a reliable mathematical commutation model is developed, the brush commutation characteristics can be predicted and reflected in the motor design process. To create a commutation model of a universal motor, the inductance of the armature coil must be mathematically expressed in order to establish the voltage equation in the commutation coil. In particular, the commutation coil can be viewed as a short-circuited coil through the brush. Finding the commutation coil current can be seen as a process of finding the equilibrium solution of the first-order differential equation in the RL circuit without input power when ignoring the EMF voltage. Therefore, it is necessary to accurately predict the inductance of an armature single coil to make a reliable commutation model. To understand the commutation phenomenon occurring in the commutating coil, information on the inductance term associated with the armature single coil is needed. These include self-inductance, leakage inductance, and mutual inductance with field coil of the armature single coil as shown in figure 1 (a). Assuming that the center of the field core of the universal motor is the d axis, and the axis separated 90 degrees from the d axis is the q axis, The calculation result of the magnetic flux, permeance, and inductance components obtained from the d and q axis magnetomotive force components can be obtained from the simplified design parameter of the universal motor as shown in figure 1 (b). The magnetomotive force is calculated from the magnitude of the armature input current and the number of coil turns, and the total flux magnitude can be calculated. In the process of calculating the total flux linkage when the magnetic flux component links the coil, the permeance and the inductance value can be separately calculated. In this process, the position of the brush and the width of the stator core are the most important design parameters. To calculate inductance of an armature single coil accurately, the coil pitch angle should be considered. Through this, the leakage magnetic flux component of the commutating coil can be accurately considered. In this study, it was confirmed that magnetic flux leakage through the stator core exists when considering the coil pitch angles of the armature single coil, and reflected in the inductance calculation process. In this process, mathematically calculation result of the armature coil inductance using the design parameter of the example universal motor model is compared with the inductance calculated from the magnetic flux distribution obtained by the FEM analysis. And it was confirmed that the proposed inductance calculation method in this study is reasonable. Finally, the inductance calculated through above method was used to decide the coil current in the commutation period by solving the voltage equation, and compared with the test results as shown in figure 2.

1.Introduction With the development of renewable energy, grid-connected inverter technology has become an important research area [1-3]. Compared with the traditional L or LC filter, LCL filter is widely used in the grid-connected inverter due to its harmonic attenuation performance and system stability. According to the IEEE 519-STD as shown in [4] that the grid current harmonic order higher than 35 times must be less than 0.3% and the total harmonic distortion (THD) should be lower than 5%. LCL filter is a third-order circuit which is selected based on the grid current quality requirements. However, according to the electromagnetic analysis, the filtering inductor value will not be constant but display a nonlinear relationship between magnetic field and magnetization [5-7]. The inductor nonlinear behavior is usually ignored in the LCL filter design, but the magnetic characteristics of the inductance would obviously affect the resonant frequency of LCL filter and underestimate the parameters of filter design [8]. 2.LCL filter design and inductor nonlinearity modeling Fig. 1 shows the LCL type grid connected inverter system with the controller and inductor nonlinearity. The output LCL filter is a necessary part for the harmonic limit requirement in the grid connected system [9-11]. L_i is the inverter side inductor, C_f is the filtering capacitor, L_g is the grid side inductor, V_i is the inverter side voltage and V_g is the grid side voltage. Design filtering inductors having inductance L, which carries maximum current I_{max} without saturating. The copper and core loss must be dissipated through the surface of magnetic core. From the theory of electromagnetism [12], the inductance of a coil is defined as the relationship between magnetic strength and flux density. The inductor model can be built with a controlled current source, an integrator for the flux, a divide unit and a look-up table which stores the B-H mapping of Fe-Si-Al. Inductor nonlinearity consideration would improve the accuracy and efficiency of filter parameters design. 3.Controller design and analysis According to previous analysis, it is necessary to adopt an active damping method to suppress the resonance peak [13]. If adding a damping resistor in filtering capacitor branch, the proportional gain must be chosen to a small value. When the proportional gain is increased, the partial poles would be distributed in the right half of the S-plane, resulting in poor system stability. The inverer side current i_i is used as the inner loop that wouldn't improve the system stability significantly. Hence, the capacitor current i_c is used as the inner loop control loop to further improve the control performance of the system. The closed-loop transfer function of the double-loop controller is a typical fourth-order system, it is difficult to obtain accurate parameters, so the pole assignment method is used to calculate the parameters. Using the output current i_g as the outer control loop and the capacitor current i_c as the inner control loop. The double closed-loop active damping method makes the system more stable compare with other control methods [14]. Simulation and experiment results The simulation of LCL three - phase grid - connected inverter is carried out based on Matlab/Simulink with the consideration of inductor nonlinearity. The grid phase voltage V_g is 220 V/50 Hz, the DC-link voltage V_{dc} is 750 V, the switching frequency f_s is 15 kHz and the rated power P is 5 kW. In order to analyze the effect of taking the nonlinear feature of inductor, the grid current harmonic distortion analysis is analyzed to evaluate the LCL filter design. The grid-connected inverter system with the inductor nonlinearity consideration is simulated, it can be found that the THD is acceptable but grid current harmonic distortion over 35 order is larger than 0.3%. Thus it is essential to take nonlinearity of inductor into consideration in order to improve the accuracy of LCL filter design. In term of the above analysis and the magnetic nonlinearity of inductor, two larger inductors 4 mH and 2 mH are selected to replace the original 3 mH and 1.5 mH inductors in the experiment. The experiment set-up and its results considering the nonlinearity of inductor is shown in Fig.2. It can be seen that the total harmonic distortion of the grid side current is reduced to 2.49% and the harmonic distortion at switching frequency is below 0.3%. Compared with the system model without taking the nonlinearity of the inductor, the design accuracy and efficiency has been improved obviously. 5.Conclusion In this paper, LCL there-phase grid-connected inverter with double close loop control is analyzed in detail. Also the nonlinear characteristics of filtering inductors is analyzed and modelled based on the B-H curve of Fe-Si-Al. The parameters of LCL filter without inductor nonlinearity consideration is underestimated and harmonic distortion is not compatible with the standard. Considering the nonlinearity of the inductor could improve the accuracy of the LCL filter design that have been verified in the simulation and experiment results.

1. Introduction Recently, energy problems such as depletion of resources have been emerging and electric power demand has been increasing. As a result, discussions on ways to improve the efficiency of the existing power system have been continuously posed. The problem of improving the efficiency of the power system is much more economical to improve the existing system efficiency than to replace the existing built and installed power equipment in a completely new form. Therefore, accurate loss analysis is needed to improve the efficiency. Transformer losses are largely divided into load loss and no-load loss. Load loss is the sum of eddy current loss and stray loss. The no-load loss is the sum of the hysteresis loss and the eddy current loss. The total loss of the transformer accounts for about 10% to 15% of no-load loss and about 85% to 90% of load loss, and the stray loss generated in the transformer structure part accounts for about 10 to 40% of the total load loss. In order to improve the transformer efficiency, many researches have been conducted to reduce the stray loss generated in the structure[1]. A common method is to using a magnetic wall shunt for the transformer tank. Most of them researches, however, rely on analysis using commercial tools[2]. The results from these methods are not accurate. In addition, it is very difficult to measure the stray load generated in the transformer structure through testing. Therefore, accurate loss calculation must precede loss reduction. In this paper, the stray loss predicate in the wall shunt of the transformer due to the leakage flux. To verify the validity of the analysis, proto-types were manufactured and tested. The manufactured proto-type consists of two exciting coils and a laminated magnetic steel plate. The magnetic flux density of the magnetic steel plate was measured using a search coil. The validity of the analysis was verified by comparing the measured magnetic flux density value with the analyzed value. The stray loss was then predicted using the comparative flux density. 2. Stray Loss Analysis 2.1 Skin Effect The skin effect is the effect that the high frequency current flows on the conductor surface and attenuates toward the center. This skin effect should be considered in order to accurately calculate the eddy currents generated in the transformer structure. The eddy current density and skin depth considering the skin effect can be expressed as the following equation[3]. $J_e=J_o \times e$^$(d/\delta\}$, $\delta=1/\sqrt{\pi f\mu\sigma}$ Where δ is skin depth [m] and f is frequency [Hz]. 2.2 Stray Loss The power loss in the wall shunt of the transformer is caused by the leakage flux. This power loss is called stray loss. The leakage flux, frequency, conductivity and permeability determine the stray loss. The stray loss considering the skin depth can be expressed[3]. $P = \iint_s \sqrt{(\omega\mu/2\sigma)}(H_0^2/\ 2)ds$ Where ω is angular frequency [rad / s] and s is area [m^2]. 3. Result and Discussion In this paper, we predicted stray loss in transformer wall shunt due to leakage flux. The magnetic flux density of the manufactured proto-type was measured using a search coil. The proto-type is shown in Fig 1. In order to analyze the effect of leakage flux on the wall shunt, the measurement was made according to the change of the current direction in the excitation coil. Also, the validity of the analysis was verified by comparing the measured value with the analyzed value. The stray loss was predicted using the verified magnetic flux density. The 3-D magnetic flux density distribution and 2-D magnetic field distribution is shown in Fig 2. The magnetic flux density was measured by changing the number of laminations of magnetic steel plate. These results confirm the validity of the analysis and are expected to be applicable to future stray loss prediction of power transformers. The results of analyzing the measured magnetic flux density values by changing the number of laminations of magnetic steel plate are expected to be economically advantageous because it is possible to optimize the technology for the loss reduction in the transformer tank.

FW-06. A Novel Multi-unit Out-rotor Homopolar Inductor Machine for Flywheel Energy Storage System.

J. Yang[1], C. Ye[1], X. Liang[1], F. Xiong[1] and W. Xu[1]
1. State Key Laboratory of Advanced Electromagnetic Engineering and Technology (AEET), School of Electrical and Electronic Engineering (SEEE), Huazhong University of Science and Technology, Wuhan, China

Abstract— Homopolar inductor machine (HIM) has been widely applied in the field of flywheel energy storage system (FESS). However, conventional HIM suffers from the low power and torque density due to its unipolar air-gap flux density. To solve this problem, a novel multi-unit out-rotor HIM (MOHIM) with bipolar air-gap flux density is proposed. First, the structure and operation principle of MOHIM are illustrated. To simplify analysis, MOHIM is divided into unit machines (UMs) based on the equivalent magnetic circuit. The back-EMF, flux density and output torque of MOHIM and UM are respectively compared, which proves the effectiveness of UM. Finally, the performance of MOHIM is investigated by three-dimension finite element analysis (3-D FEA), which indicates that this machine is a good candidate for the application of FESS. Keywords-Homopolar inductor machine (HIM); multi-unit out-rotor HIM (MOHIM); bipolar air-gap flux density; unit machine (UM). I.Introduction Homopolar inductor machine (HIM) has good applications in the field of flywheel energy storage due to its merits of robust rotor structure, brushless exciting, high-speed operation, and so on. Continuous free-wheeling losses of HIM caused by magnetizing flux could be significantly reduced by cutting off the field current, especially in a long-term standby state [1]. While HIM would suffer from the low power and torque density due to its unipolar air-gap flux density [2]. To solve this problem, a novel multi-unit out-rotor HIM (MOHIM) with bipolar air-gap flux density is proposed in this work. II.Structure and Operation Principle Structure of the proposed MOHIM is shown in Fig. 1(a) and (b). As drawing here, the rotor of MOHIM consists of two parts: a non-magnetic conductive rotor sleeve and (m+1) segments rotor cores. The salient iron poles of adjacent segments rotor cores are differed π electrical degree from each other. m segments laminated stator cores are set on a back-iron and evenly placed in the axial direction. (m+1) field coils encircle the back-iron and are sandwiched by the stator cores. The dc current directions of all field windings are the same. The magnetizing flux paths of MOHIM are shown in Fig.1(b). In this paper, m is equal to 3. III. Performance of MOHIM A.Equivalent magnetic circuit of MOHIM Fig.2(a) shows the equivalent magnetic circuit (EMC) of MOHIM, where Rsn and Rrn are the reluctances of stator and rotor, respectively; Rσn is the reluctance of air-gap; Rln is the leakage reluctance between two salient iron poles; Nf is the number of field winding and If is the excitation current. It can be obtained that the MOHIM can be divided into three unit machines(UMs)through the analysis of EMC, as shown in Fig. 2(b). The performance of MOHIM could be predicted by analyzing UM. B.Performance of MOHIM Fig.2 (c) shows the flux density distribution of UM and that of air-gaps I,II and III of MOHIM in Fig.1(b). It can be found that the air-gap flux density distributions of MOHIM are bipolar and are the same. Besides, the air-gap flux density waveforms obtained by UM and MOHIM are good agreement. Fig. 2(d) shows the back-EMF of MOHIM and UM when the rotation speed is 10,000r/min. It can be found the back-EMF of MOHIM can be well predicted by UM. Comparing the output torque waveforms presented in Fig. 2(e), it indicates that the results obtained by UM agree well with that of MOHIM. IV. Conclusion A MOHIM with bipolar air-gap flux density is proposed in this paper. The analysis process of MOHIM divided into UMs is investigated based on the EMC. The performance of MOHIM can be well predicted by UM. More detailed analysis and results will be given in the following full paper.

 I. Abstract Advances in power conversion technologies have highlighted the need for development of new class of magnetic components (inductors, transformers etc) with lower footprint and higher efficiency. Presently, the sizes of these magnetic components have been limited due to the use of low flux density ferrite as a core material. In this paper, the assembly and working of an amorphous ribbon transformer with low loss performance as a replacement for ferrite based ones were studied. The minimum amount of power loss of the material was measured as <750 kW/m^3 at 100 kHz. The paper also shows the significant reduction in the footprint of the fabricated inductor. II. Introduction A key metric for an inductor and transformer is their magnetic material power loss performance. Presently, ferrites, iron powder and tape wound cores are primarily used for power applications. However, the low flux density of ferrites (0.3-0.4 T) requires considerable cross-sectional area in many deployments [1]. As the major size, weight, and cost drivers of electrical components are converters, using alternative materials with higher flux density can result in smaller, lighter and cheaper electrical components. In this study, the assembly and characterization of a magnetic transformer, using ultra-low loss soft magnetic ribbon core were presented. III. Low loss Magnetic Material The master Co-based, soft magnetic alloy was prepared by arc-melting of pure elements Co, Fe, B and Si in a highly pure argon atmosphere. The ingots were re-melted in quartz tubes by induction heating. Structure analysis of the samples was carried out by X-ray diffraction (XRD) method using Cu-Kα radiation (λ=1.54 Å). The absence of crystalline peaks confirms the amorphous structure of the in-situ ribbons. Therefore, a novel 8-12 μm thick Co-based amorphous ribbon was developed. This thickness is much lower than the thickness of Vitrovac, Vitroperm from Vacuumschmelze, Toshiba MT series etc causing reduction in the eddy current losses at high frequencies. A detailed review of high flux density ribbon materials was presented in previous works from the authors [2, 3]. Based on B-H loop tracer and in-plane magnetic hysteresis loops measurements, the coercivity of the ribbon was measured to be about 0.1 A/m which implies the ultra-soft magnetic properties of the ribbons as a result of near-zero magnetostriction of Co-based amorphous alloy. Additionally, the saturation flux density of the ribbons was more than 1 T which can be considered as an acceptable amount for high frequency applications. Amorphous structure of ribbons results in 150 mΩ as their resistivity. The AC loss measurement was performed over a number of frequencies, 100 kHz to 500 kHz, and various signal amplitudes. The ribbons were wound on the 150 μm sticky tapes to make 30 windings in total around a straw and two arrays of copper wire used to make two 25 turns which one of them considered as primary and the other one as secondary coil. The detail of the instrument and equivalent circuit for loss measurement is published in our previous studies [4, 1, 5]. Power loss density in the material which was extracted from the respective hysteresis loops and plotted logarithmically (Fig. 1), increases with applied AC flux density, B_{AC}, and frequency values which was expected due to rise in eddy current and hysteresis loss. It is well understood that as the operating frequency (f) increases, the eddy-current loss (P_{LE} α f^2) increases more sharply than the hysteresis loss (P_{LH} α f) and the total core energy loss becomes dominant at f > 100 kHz [4]. IV. Conclusion This paper describes development of low loss magnetic transformers for high efficiency dc-dc converter. The transformer uses laminated amorphous magnetic ribbons as core materials. The footprint of the fabricated transformer was more than 68% smaller than the commercial equivalent which can be considered as the lighter and smaller transformer compared to the Ferrite ones.

FW-08. Prediction of Heating Power in Magnetic Pipe Conducting Large AC Current with High Frequencies Up to 200Hz.

A. Chen[1], A. Nysveen[1], J. Lervik[2] and M. Høyer-Hansen[2]
1. Electrical power engineering, Norwegian University of Science and Technology, Trondheim, Norway; 2. SINTEF energy, Trondheim, Norway

In direct electrical heating system (DEHs), which is developed for subsea process to safeguard well stream through pipelines to topside process platform or shore, the production pipeline is also acts as an active conductor conducting large AC current to generate heat. The heating source is conductive and hysteresis power losses in the pipe. Currently, the all implemented DEHs operate at 50Hz. There is a potential to further improve the heating capacity of the DEHs by operating the system at higher frequency so that the same power can be achieved at lower current. Consequently, the cross-session of the power cable can be reduced. Furthermore, operation in higher frequency directly results in better system utilization and less AC corrosion of the pipeline. This will further reduce the installation and operational cost and increase the system lifetime. For DEHs design it is critical to predict the heating power as function of input current and frequency so that proper frequency and current can be selected correspondingly. This paper analytically evaluate the heating power as functions of current and frequency based on experimentally measured material properties such as mass density, conductivity, B-H curve and hysteresis B-H loop energy. To verify the analytical results, both FEM simulation and prototype test are performed. *Current distribution* Comparing to the conducting current in the carbon steel pipe, generally in several hundred amperes, the displacement current is the pipe is negligible. The current distribution in the pipe is therefore determined by $\nabla^2 J=j\omega\mu\sigma J$ (1) The permeability of carbon steel is a nonlinear function of magnetic fields. To solve the problem analytically, it is common to assume an effective constant permeability uniformly over the pipe and this will be discussed later in detail. The solution of (1) for an isolated thick tubular conductor can be derived as $P_R=k_R I_{rms}^2\sqrt{(\mu f)}$ *(2) where* $k_R=1/(2r_o\sqrt{(\pi\sigma)})$ *(3) Hysteresis power loss* Due to the varied electric field produced by the AC current in the pipe, magnetic field in the pipe also varies, which causes hysteresis loss that is part of the heating power. The dissipated hysteresis energy per unit volume (or weight) in one cycle is the area enclosed by the hysteresis loop of B-H curve. The area and shape of the B-H loop is dependent on maximum magnetic field. This hysteresis B-H loop of the pipe is measured at laboratory in DC condition (< 0.003Hz) to eliminate the influence from eddy current loss. So the hysteresis energy is independent of frequency. Hysteresis energy in a magnetic material is usually expressed as a function of the maximum flux density B_{max} $E_{hys}=k_h B_{max}^{k_p}$ (4) where k_h and k_p are material dependent constants, and k_p as "Steinmetz coefficient" is generally near to 1.6. The hysteresis power in unit length can be evaluated by integrating the hysteresis energy over the pipe volume and multiplying frequency f and mass density ρ as $P_{hys}=2\pi\rho f\int rE_{hys}dr$ (5) Based (1) and (5), the hysteresis power in the pipe can be derived and finally expressed as $P_{hys}=k_c I_{rms} k_p \mu^{(k_p-0.5)}\sqrt{f}$ *(6) where* $k_c=2r_o k_h\rho\sqrt{(\pi/\sigma)}/(k_p(\sqrt{2}\pi r_o)^{k_p})$ *(7) Effective permeability* As given in (2) and (6), both the conductive and hysteresis powers are a function of effective permeabililty in addition to frequency and input current, so the effective permeability should satisfy following two conditions: 1) The effective permeability should be acceptable for both conductive and hysteresis power loss calculations. 2) The effective permeability should be obtainable based on the measured permeability and the input current of the pipe. An effective permeability as function of input current has been derived here and the result is shown in Fig.(1), where the effective constant relative permeability used for the analytical calculation is plotted as function of the maximum magnetic flied that is determined by the input peak current. *Result verification* To verify the result, both FEM simulation and prototype test are carried out for a specific case, a 12" carbon steel pipe having tube thickness of 17.1mm where the current varies between 300 and 1000 A, and the frequency between 50 to 200Hz. A rod example is made of the pipe for measuring the properties. The results are expressed as resistance per km ($R=P/I_{rms}^2$) and presented in Fig.(2) *Conclusion* An analytical method to predict the heating power in magnetic pipe is derived, in which the heating power is expressed in terms of operating frequency and input current. Effective permeability for the analytical calculation is also derived based on measured B-H curve of the magnetic material and its value is determined by the peak input current. The analytical results are compared with FEM simulation and prototype test, and they match each other satisfactorily. More detail will be presented in final paper, including proximity effect.

I. Introduction In order to protect high voltage direct current(HVDC) system from destructive damage caused by large DC fault current, a HVDC system saturable core type fault current limiter(DCSFCL) is proposed previously. However, through principle investigation and simulation analysis of DCSFCL, coil inductance of DCSFCL do not have a large changing rate (CR) when a fault occurs, so clipping performance of it will not be quite satisfying. In order to increase CR and improve clipping performance of original DCSFCL, further improvements need to be carried out. In this digest, a modified three limb structure of DCSFCL(TSFCL) is proposed and equivalent magnetic and electric circuit are analyzed. Simulations carried out on ANSYS shows that clipping performance is improved by a large scale. II. Basic Principle Analysis Previous deduction and design shows that a fixed inductance value is required in normal state so that proposed DCSFCL can replace normal smoothing reactor. Besides, inductance value of DCSFCL depends on total magnetic resistance of the flux path and among those different parts that form the core, PM account for the major proportion. However, when normal inductance value is designed to be constant, those changing parts of the core that desaturate from saturation state define the CR of DC coil's inductance value when a fault occurs. In that case, once CR rises, DC coil's inductance value will rise simultaneously and therefore, fault current will be restricted more efficiently. Thus, if somehow the magnetic resistance of changing parts increase and even account for the main part in total magnetic resistance, CR will increase and the clipping performance will be enhanced. Based on deductions mentioned above, a novel TSFCL is proposed and Fig.1 illustrates original topology of DCSFCL, TSFCL and its equivalent electric and magnetic circuits, respectively. Based on previous works[1,2], another PM limb is added into the original topology to "force" the flux flows through center limb. After analyzing those two circuits and applying Faraday's law of electromagnetic induction and the constitutive relationship between voltage and inductance, inductance value of TSFCL can be derived: $L_{fcl}=(N_{dc}^2)/[R_e+2R_{u1}+(2R_c+R_a)(2R_m+2R_{u2}+2R_{u3}+R_y)/(2R_c+R_a+2R_m+2R_{u2}+2R_{u3}+R_y)]$, where N_{dc} is number of DC coil. R_e, R_c, R_y, R_u, R_a, R_m are the magnetic resistance of left limb, center limb, right limb, left yoke, center PM and upper yoke PM, respectively. By inserting this center limb, flux generated by DC coil is inclined to flow through this center limb instead of original PM path due to obvious difference in magnetic resistance between these two paths. Hence, proposed new topology makes the CR increases in the premise of normal inductance value. Besides, the cross-sectional area of the center limb can be designed to be larger than yoke, thus further increase the proportion of saturated parts and render the CR of inductance value rise more when fault occurs. In that case, fault current can be restricted more efficiently. III. Simulation Study To verify our deductions, simulation using ANSYS is performed and comparison studies are carried out. Fig.2(a), (b) and (c) show flux density distribution of TSFCL and its inductance value variation. It is obvious that normally, left limb, upper and downer yoke stays in critical saturation state and the presented inductance of DC coil is exactly 300mH owing to the structure design. When a fault occurs(t=0.02s), limb and yoke of proposed TSFCL desaturate very fast and make inductance value of DC coil rises immediately. From Fig.2(c) and (d), it is obvious that compared with former proposed DCSFCL, the new three limb structure has 19.5% rise in fault state inductance value, i.e., from 0.82H to 0.98H. As for the fault current limiting performance compared with fixed 300mH smoothing reactor, traditional DCSFCL makes fault current drop for 28% in less than 5ms. This number, on the contrary, goes straight up to 41.2% for the proposed new TSFCL. Therefore, proposed new structure is more efficient. IV. Conclusion In this digest, a novel three limb structure saturable core fault current limiter for HVDC system is proposed. Working principle is analyzed and simulations are carried out. Comparative study shows that proposed TSFCL has about 20% increase in clipping performance than traditional DCSFCL and over 40% increase than normal smoothing reactor. Considering that length of center PM is quite important to CR and final clipping performance of TSFCL, different PM length and related optimization study will be carried out soon. Detailed information and investigation will be shown in the full paper.

1 INTRODUCTION Power transformers especially UHVDC converter transformers, need not only to bear the working voltage, but also to have the ability to withstand a certain degree of overvoltage, such as lightning, operation overvoltage, and very fast transient overvoltage (VFTO) which is characterized by a fast rise time of several nanoseconds and an oscillating waveform caused by switch operation in Gas-insulated substation. In order to study the propagation of the transient overvoltage on the transformer windings, a model is needed which is able to simulate the transient potential distribution along the transformer winding. Obviously, an accurate computational model of transformer winding for potential distribution analysis under impulse voltage is very important for the design of transformer interturn insulation especially for large capacity transformers such as UHVDC converter transformers. Quite a lot of research have been done to seek an appropriate transient computational model for transformer windings. Two basic physical methods have been obtained. They are multiconductor transmission line models and equivalent circuit models. For the multiconductor transmission line model, the transformer winding is represented by distributed parameters, but the losses caused by hysteresis, eddy current and proximity effect cannot be modeled. On the contrary, the equivalent circuit model can take saturation and losses caused by the core into account, but always assumming that the influence of magnetic core is negligible at frequencies higher than 10kHz,which is not always valid in practice. Lightning impulse or VFTO waveforms usually contain abundant frequency components higher than 10kHz. To obtain a more accurate model and also to provide a wide-band frequency response, in this paper, a new equivalent circuit representation of UHVDC converter transformer winding is given taking into consideration of comprehensive frequency characteristic of core lamination stack. 2. Equivalent Circuit Model and Calculation of its Parameters A. Effective Permeability of Core Lamination Stack Considering the skin effect and saturation effect of the core lamination stack, the effective permeability of the core is obtained through the finite element method. The loss of the core is performed as a reduced permeability, then the law of permeability varies with frequency is acquired. B. Parameters Calculation The equivalent capacitance and the interturn capacitance between the continuous winding pancakes are calculated by the plate capacitor formula. The frequency dependent parameters such as the self-inductance and mutual inductance of the winding are calculated using the equivalent permeability of the core lamination stack, and the conductor resistance is calculated considering the skin effect. C. Establishment of the Equivalent Circuit Model According to the structure parameters of the UHVDC converter transformer, and taking two pancakes as one unit, the equivalent circuit of the winding is established by using the calculated resistance, inductance and capacitance parameters. The equivalent circuit of two units is shown in fig.1. Each unit consists of a capacitance branch between the core (grounded) and winding, a inductance and a resistance series branch, N-1 interturn capacitances, N-1 capacitances between pancakes (where N is the number of turns of one pancake). For UHVDC converter transformers there are usually more than one windings as the fig.1 shows, and there are coupling inductances and capacitance between the conductors of the two windings. Note that the resistance and inductance parameters mentioned above are functions of frequency. So the problem is difficult to solve with ATP or PSPICE. It is efficient to use MATLAB's powerful matrix calculation capability to solve the problem, and the potential distribution of the windings under transient overvoltage is obtained. 3. Results and discussion The equivalent circuit model is realized in MATLAB, taking lightning overvoltage for an example, and the propagation of voltage and the transient potential distribution in the winding are studied carefully. The potential distribution of the winding is presented in fig.2. The detailed results will be shown in full text. 4. Conclusion This paper has proposed an equivalent circuit for modelling the UHCDC transformer winding (especially inserted capacitance continuous winding) to study the potential distribution property. Considering the eddy current and skin effect which are variable with frequency, the inductance and resistance parameters of the model vary with the frequency, respectively. Using MATLAB programming to solve the voltage equation of the equivalent circuit to obtain the potential distribution properties of the windings, the new proposed model may provide more accurate winding potential distribution prediction for transformer interturn insulation design.

FW-11. Dynamic Transformer Core Model Based on the Inverse Three-component Preisach Model.

W. Sima[1], *D. Peng*[1], M. Yang[1], M. Zou[1] and Y. Liu[1]
1. Chongqing University, Chongqing, China

Transformer is one of the crucial equipment in power systems. A precise transformer model is very essential for most of the electromagnetic transient studies. Iron core, the most complicated part of a transformer, may have different hysteresis trajectories, and be saturated when suffering variety of excitations. For transformer modeling, the hysteresis of the iron core is one of the most complicated phenomena to be accurately modeled because it is a nonlinear, history- and frequency-dependent phenomenon. The classical Preisach model is one of the most practical methods to model the hysteresis of ferromagnetic materials due to its good history-dependent wiping-out and congruency properties. The most important point of the Preisach theory is that the magnetic field in the ferromagnetic material can be considered as a set of elementary hysteresis loops, which have only two states, $+B_S$ and $-B_S$. Despite the physical meaning of Preisach theory is not clear, the classical Preisach model (CPM) is widely used for modeling hysteresis phenomenon. In the application of power system transients, the voltage U and the current I are the most common variables that can be accurately measured in the filed. The flux Φ is obtained by the integration of U. In most of the EMTP platforms, the Φ-I curve is the priority to model the iron core hysteresis. Therefore, this paper presents the hysteresis characteristic of a transformer core by Φ and I. Compared with the current, the voltage is much easier to be measured and more accurate in power systems. Therefore, the flux linkage is more suitable to be the input variable of a model than the current. Moreover, the integration of U can avoid the oscillation of calculation. So it is necessary to build the inverse Preisach model denoted by I-Φ expression. The I-Φ Preisach plane is shown in Fig.1. It also reveals the variation trend of plane under the different direction of flux linkage. Considering the conveniences of the applications, the distribution function of I-Φ Preisach model is determined by quasi-static sinusoidal loops, which is easy to be generated. The center cycle method is utilized here to identify the Preisach distribution function (PDF). The Preisach plane is discretized to uniform cells by the method. According to the principle of the method, the distribution function of the cell is determined by the difference of the flux linkages of two adjacent curves in the same current. Therefore, although the data is easy to acquire, the accuracy requirement of the measured data is high. By assuming the symmetry of the PDF, the computation is reduced to half. The determination result can calculate the current from the flux linkage accurately. The static Preisach model can predict the major hysteresis loop as well as any symmetrical or asymmetrical minor loops at zero frequency. However, in power systems, flux linkage in a transient is a complex waveform containing various frequency components. Therefore, the exciting current I depends not only on the magnitude of the flux linkage, but also on the magnetization frequency and hence on the voltage which represents the differential of the flux linkage. In this situation, a simple three-component dynamic hysteresis model can be used to represent the transformer core. In the composite model, the total current is decomposed into the hysteresis component I_h(t), classical eddy-current component I_{ec}(t), and excess component I_{exc}(t). The inverse Preisach model is applied here to depict the static hysteresis current I_h(t). $I_{ec}(t)$ can be given by the well-known formula $I_{ec}(t)=v(t)lk_{ec}/(N^2S)$. l and S is the equivalent length and the cross section of the magnetic circuit, respectively, and can be calculated from IEC 60205:2016. The constant $k_{ec}=d^2/(12\rho)$ is determined by the lamination thickness and resistivity of the core material. The excess component $Iexc(t)$ can be acquired by $Iexc(t)=\delta|v(t)|^{\alpha}lkec/(N^{\alpha+1}S^{\alpha})$. δ is the direction coefficient of v(t). G(Φ) and α are usually obtained from fitting the measured dynamic loops. When the dynamic loops are obtained, the measured Φ is used to calculate I_h, and the measured V is used to calculate I_{ec}. The last component Iexc was acquired by the function G(Φ) and α. They are obtained by minimizing the deviation of the calculated dynamic loop from the experimental loop using the nonlinear optimization algorithm. The dynamic inverse Preisach model was tested on a two-winding transformer. The calculated dynamic hysteresis loops are compared with the measured loops. In order to demonstrate the frequency dependence of the model, different frequencies are chosen, they are 25Hz, 50Hz, 60Hz, 100Hz, respectively. The primary current and the secondary voltage waveforms are obtained from the transformer simulation studies and also the laboratory test results corresponding to the no-load steady state. The results demonstrate that the proposed model coincides with the measurements in the acceptable engineering accuracy. It shows that the dynamic hysteresis model can accurately simulate the dynamic magnetization of the transformer core in a certain frequency range.

FW-12. An Analytical and Numerical Hybrid Model for Static Characteristics of a Interior Permanent Magnet Machine.

P. Jin[1], Y. Guo[1] and Y. Zhu[1]

1. School of Energy and Electrical Engineering, Hohai University, Nanjing, China

I.Introduction Recently, permanent magnet (PM) machine having high dynamic performance, good power/mass ratio, and simple structure has been proposed [1]. A number of numerical techniques are used to analyze its performance while some pure analytical modeling with magnetic scalar potential are also employed [2-4]. However, on one side numerical techniques such as the Finite Element (FE) Method are time-consuming and less insightful when looking into the influence of design parameters upon the machine's behavior. On the other entire analytical methods just can be used in limited topologies, such as surface PM machine, but ineffectively for general topologies like interior PM machine,. This paper presents an analytical and numerical hybrid model for static characteristics of an interior PM machine. II.Analytical and Numerical Hybird Model II-A.Interior PM Machine As shown in Fig. 1, the interior PM machine prototype has a tubular rotor, in which there are alternately polarized iron poles along the *q*-direction, and a stator with distributed windings. Region I ($R_m \le r \le R_s$) is air region and region II ($R_r \le r \le R_m$) is rotor region with the PMs and iron poles. In the 2D model, the end effects are not taken into account; the PMs have a linear demagnetization characteristic, and are fully magnetized in the direction of magnetization. II-B.Field Distribution on the surface of the rotor A knowledge of the magnetic field distribution on the air region produced by the rotor is fundamental to establishing an accurate model of the PM machine for design optimization and dynamic modeling. In region I, the static magnetic field is governed by the Laplace equation only and the boundary on the stator's inner surface where $r=R_s$ is of the Dirichlet boundary condition. In order to obtain the magnetic field distributions in the other boundary where $r=R_m$, a simplified partial 2D FE model contained rotor and stator without coils will be established. The nonlinear magnetic field of the machine which can be treated as static field and analyzed by ignoring the eddy current, satisfies the governing equation (1) (equations and functions are all given in Fig. 2) and boundary conditions functions (2), where S_Ω is the outer boundary of the solution domain. A is the magnetic vector potential. H_c is the residual flux intensity of PM. By using the FE method, flux density $B_S(\theta, r)$ in the different points of the rotor's surface where $r=R_m$ can be calculated by equation (3) where B_{rS} and $B_{\theta S}$ are *r*- and θ-direction flux density components respectively. By using the discrete Fourier transform, B_{rS} and $B_{\theta S}$ which are calculated by the FE model, are decomposed into the equation (4) where ν=np; C_{rkn} and $C_{\theta kn}$, are the *n*th harmonic coefficients of the Fourier Transform. II-C.Field Distribution in the air region In the polar coordinate system, based on the magnetic scalar potential (MSP) ϕ, the magnetic field intensity components can be expressed by equations (5) where ϕ is governed by the Laplace equation in the air region as equation (6) whose general solution is equation (7) and boundary conditions can be expressed by equation (8). By solving the Laplace equation in region I subject to former boundary conditions, the Fourier expansions of the flux density components in the *r*- and θ-direction in region I in the polar coordinate system can be given. The electromagnetic torque of the machine can be subsequently predicted by the hybrid method. III.Verification by Integrated FE model To verify the correctness of the analytical solutions, we calculated magnetic field of the interior PM machine using an integrated FE model. The meshed elements are triangular-shaped and the free mesh algorithm is imposed. The predicted flux densities along the r-direction in an electrical period of the tubular rotor and along the q-direction with different methods are compared. Some excellent agreements verify the validity of the hybrid model. The electromagnetic torque and the flux linkage of the stator winding are subsequently derived and validated by the integrated FE model in the full paper. IV.Acknowledgment This work was jointly supported by the NSFC (51407061) and the NSF of Jiangsu Province (BK20140854).

FW-13. AC Loss Analysis of a Flux-coupling type Superconducting Fault Current Limiter.

S. Yan[1], Y. Tang[1], L. Ren[1] and Z. Wang[1]
1. Hua Zhong University of Science and Technology, Wuhan, China

I. Introduction Large short-current level has a severe impact on the transient stability, operational life of electrical equipment and leads to other unforeseen troubles in the power systems[1]. A flux-coupling type SFCL (FC-SFCL), which has the advantages of low steady-state impedance, easily adjustable current-limiting impedance ratio, and helping with system reclosing, is developed. An improved AC loss calculation model for the SFCL is studied and a scheme to reduce the AC loss is proposed. II. Principle and structure The FC-SFCL [2],[3]with a pair of HTS parallel windings is developed here. The limiter is based on disconnecting coupling windings for current-limiting, which has a low steady impedance at normal state and higher limiting one after fault. Fig. 1(a) shows the basic structure of the FC-SFCL, the current-limiting unit is made of two HTS windings W_1 and W_2 carrying current in opposite directions. It is installed in series with the power system, which can be divided into three operating conditions: normal condition (the system operates normally with S_1 closed), fault condition (fault happens before opening S_1), and limiting condition (after opening S_1, the limiter acts). The layer winding with a 2G Super Power SCS 4050 4-mm wide YBCO tape is used for the two windings. To reduce the total length of the tape and increase inductance of the single winding, an iron core made by silicon steel sheet, 30Q120, is chosen to manufacture the magnet shown in Fig.1 (b). Due to air gaps in the core column and yokes, the inductance value is stable and large iron core volume can be avoided. III. An AC loss calculation model Due to the larger leakage flux and greater fault current impulsion on the online HTS winding after disconnecting, AC losses will increase rapidly and lead to the reduction of thermal stability. An improved AC loss calculation model is used to analysis the influences of different winding structures on losses and current distribution. A 10 kV / 500 A FC-SFCL single prototype with windings wound on the iron-core with air gap is regarded as a calculation sample. The method of modeling local tapes in detail is used to improve the speed of calculation. However, the non-linearity of the iron core permeability leads to poor convergence and large time consumption. This problem can be solved rapidly by a formula using the pre-defined Magnetic Field (mf) module in Comsol Multiphysics. The permeability of the core region in the PDE module is transmitted from the mf module. Integral constraints are used to impose an explicit transport current in each superconducting conductor. The two modules, PDE and mf, are fully coupled and simultaneously solved [4],[5]. IV. Improved method and result The superconducting winding of the SFCL is made of two cross-connection sub-modules in series, which adopt the layer-wound structure, as shown in Fig. 2 (a)(b). Each HTS winding is made of 3×n tapes in parallel, with 3 tapes arrayed in the z direction and n tapes arranged along the r direction. Model I is with 3×6 tapes in parallel for each winding, and Model II is with 3×7 tapes in parallel for winding 2 and 3×5 tapes for winding 1. They have the same total parallel numbers. Fig. 2(c) shows the currents and AC loss in two windings in the two Models. There is no quench on the windings. The changes of current and magnetic field lead to large AC loss and uneven magnetic distribution on the two windings. In Model I, the AC loss of winding 2 is large after decoupled for the low I_c margin. In addition, inductive AC loss on winding 1 is also great. In Model II, the total AC loss obtains remarkable improvements and magnetic field distribution becomes more uniform. While the current in each tape of winding 1 is higher than that of winding 2, AC loss of winding 1 is also larger than that of winding 2 in fault condition. After decoupling, AC loss of winding 2 is still larger than that of winding 1, but compared with Model I, AC loss in winding 1 is minished due to the reduction of the number of parallel tapes, and AC loss in winding 2 has also reduced because of the increasing critical current margin with adding the parallel tapes. The scheme of adding the parallel number of winding 2 and reducing that of winding 1 is reasonable for improving the SFCL performance. V. Conclusion This work studies an AC loss calculation method for a Flux-coupling SFCL with an iron core. The non-linearity of the iron core permeability leads to poor convergence and large time consumption. An improved AC loss calculation model is used to analysis the influences of different winding structures on losses and current distribution. Then a scheme to reduce losses is proposed. Through adjusting the parallel numbers of the two windings, the losses characteristic has significant improvements, with losses on each winding balancing, total losses declining, and magnetic field distribution uniform. GA-01. Highly Manufacturable Embedded STT-MRAM Technology.

K. Nam[1]
1. Samsung Electronics, Hawsung-City, The Republic of Korea

STT-MRAM (spin transfer torque-Magnetic random access memory) has a wide range of potential for its various applications as a versatile device and deserves attention on the perspective of manufacturing embedded device with non-volatility, high speed and excellent reliability. Furthermore, embedded STT-MRAM has an excellent extendibility that can easily plug into various CMOS platform from 28 LPP to extending 28/22 FD-SOI and beyond. Recently, as a tipping point of MRAM product, several companies have commenced with eMRAM development from several years ago and some of companies are embarking on eMRAM business to make it. In the meanwhile, we demonstrated eMRAM using perpendicular STT-MRAM with 28nm logic process and successfully fabricated as mass production level [1]. However, for mass production of eMRAM, there are still lots of issues to overcome such as optimal MTJ stack with a wide read/write operation margin, integration-induced damage, robust MTJ stack with standing 400C BEOL process. In this presentation, we will show the recent progress in the commercialization of embedded MRAM and discuss the key factors influencing the mass product that should be stably handled. STT-MRAM integration is quite difficult to control due to inherently structural vulnerability such as very thin MgO barrier, laminated magnetic/non-magnetic multi-layer and sensitive heat properties, etc, which can cause an unwanted short failure, electrical and magnetic distribution and properties degradation. Perpendicular MTJ stack consisting of CoFeB/MgO has been developed to achieve higher TMR, low switching current and strong retention. Each feature strongly interdigitate with each of parameters, for example, large thermal stability is prerequisite to long retention time, but there is a trade-off between retention and switching current. Therefore large switching current can help it gain a higher retention, but it is inevitable to impinge the write fail. Those kinds of relationships can be alleviated by optimizing MTJ stack and process integration. Fig.1 shows the retention time vs switching current in terms of the improved MTJ stack and process. Retention time is approximately 5 times higher than that of before at similar switching current range by optimizing process, which means that efficiency (Δ/I_{sw} : Δ thermal stability, Isw switching current) factor corresponding to the feature of MTJ stack is significantly improved with other properties intact. Here, efficiency can be defined as a relationship with retention and switching current of MTJ cell, which is considerably hard to break between both since they have physically strong dependency. Thus, it is more important to find the optimum sweet spot of retention and switching current of MTJ cell in the light of the improving thermal stability while maintaining switching current and it can be found not merely by optimizing MTJ stack but also by specializing integration scheme without any compromising structural integrity. Fig.2 indicates the dependence of MTJ degradation on various patterning process. MTJ degradation and MTJ short fail during the process involving MTJ patterning has been unavoidably accompanied so far, due to thin MgO barrier and multiple metallic layers as mentioned above. By adopting IBE (ion beam etching) process for MTJ patterning, we were able to reach MTJ short fail below 1ppm level and simultaneously to lower the propensity of MTJ degradation. For minimizing the integration-induced damage, we additionally tweaked IBE parameters such as power, angle, etching sequences and consequently could obtain the significant improvement of MTJ degradation as shown in Fig. 2. With process optimization, we were able to achieve the scalability technology for MTJ cell shrink and it has become possible to improve manufacturing technology and close to mass production. In the presentation, Key technologies and feasibility for highly manufacturable eMRAM would be discussed more detail.

Embedded Flash (eFlash) technology has been the dominant embedded non-volatile memory (eNVM) solution for microcontroller (MCU) products, primarily used for data and code storage. The latest eFlash technology has reached 28 nm for product level and is a few generations behind the most advanced logic technology. Scaling down eFlash below 28 nm has been demonstrated [1], however it is becoming increasingly difficult to integrate conventional floating-gate-based eFlash technology with advanced CMOS logic process features (e.g. HKMG, FinFET). This scalability challenge has driven industry to actively explore emerging eNVM technologies. Embedded MRAM (eMRAM) has been considered one of the most promising emerging eNVM technologies due to fast write speed and high endurance. This unique feature makes eMRAM capable of replacing eFlash, SRAM and other miscellaneous memory blocks in MCU, which may eventually improve overall cost, power and performance at the system level beyond brute-force device scaling [2]. In addition, increasing demands for low-power MCU, particularly in the automotive sector and emerging MCU markets, make eMRAM more attractive than power-hungry eFlash. Since the first chip-level demonstration of spin-transfer-torque MRAM in 2005 [3], we have observed tremendous progress in eMRAM technology, fueled by continuous improvements in magnetic tunnel junction (MTJ) processes. However, there are still remaining challenges to establish eMRAM as an eNVM platform for a variety of memory blocks in MCU products. Multiple flavors of eMRAM bitcells and magnetic tunnel junction (MTJ) film stacks need to be developed and validated to cover a range of system specifications in the consumer, industrial and automotive sectors. In this work, we present eMRAM technology fully integrated into 2x-nm CMOS logic platforms and show the status of eMRAM technology as a next-generation MCU platform. Key challenges for enabling MRAM-based MCU products are also discussed in terms of reliability and scalability.

Perpendicular Spin-Transfer-Torque Magnetic Random Access Memories (pSTT-MRAMs) combine fast read/write, low voltage operation, low power consumption, non-volatility and quasi-infinite endurance. Moreover, owing to STT physics used for writing bits, Magnetic Tunnel Junction (MTJ) devices at the heart of the technology can be tailored to emphasize low current/high speed, data retention and/or high operation temperature, depending on the specific application. This versatility makes pSTT-MRAM an ideal candidate for next generation "universal" embedded memory, potentially capable of replacing technologies spanning from embedded Non Volatile Memory (eNVM) to working memory and Last Level Cache (LLC). However, for pSTT-MRAM to fulfill its promises and emerge as a mainstream embedded memory, the technology must both satisfy stringent technical requirements and demonstrate its competitiveness compared to established alternatives. In this presentation, we will discuss recent advances that have overcome major technical hurdles and demonstrated the viability of pSTT-MRAM technology for mass production. Compatibility to CMOS processes is a prerequisite for most embedded applications. Standard back-end-of-line (BEOL) CMOS processes such as low-k dielectric deposition or forming gas annealing are performed at 400°C. Thus, the MTJ stack must withstand this temperature for an extended period of time. Exactly how long depends on the number of metal layers following the fabrication of pSTT-MRAM. For high-density applications, for which the memory is embedded just above the logic level, where lithographic features are the smallest, the total time at 400°C may exceed 3 hours. Submitting a multilayered MTJ stack comprising many atomically thin layers to such a thermal treatment leads to detrimental effects such as recrystallization and grain growth, which can impact the roughness and microstructure of the stack, as well as elemental diffusion within each layer and between layers. Moreover, BEOL 400°C processes must take place after patterning the MTJ stack. Thus, sidewall damage, etch residues and encapsulation materials also play a major role, the more so at advanced lithography nodes, for which devices smaller than 30nm will likely be needed. Solving these problems requires thorough engineering of not only the MTJ stack constituting layers, but also of the top and bottom electrodes and encapsulation materials, as well as process conditions. Since we first reported 400°C compatibility in 2013 [1,2], significant progress has been made, as shown by our recent demonstration of perpendicular magnetic anisotropy (PMA) exceeding 10 kOe for sub-30nm devices submitted to 2.5 hours annealing after patterning [3]. Adoption of pSTT-MRAM as an alternative to eflash for eNVM applications poses specific challenges. For example, for practical as well as cost considerations, the memory must be programmed before the chips are packaged and soldered to a printed circuit board. The soldering process uses reflow soldering for a total of 90 seconds at 260°C. Thus, pSTT-MRAM must retain data during solder reflow with a low error rate [4]. This is particularly challenging because the thermal stability factor Δ, which determines data retention, decreases rapidly with increasing temperature. Indeed, since $\Delta = E_B/k_BT$ (where k_B is the Boltzmann constant, T the absolute temperature and E_B the energy barrier separating parallel and antiparallel states), increasing temperature from 25°C to 260°C has a twofold effect. First, the denominator increases, reducing Δ by almost half. Second, E_B is a function of the PMA of the free layer of the MTJ, which is also strongly temperature dependent. We have shown that this combined effect leads to an almost linear decrease of Δ over a wide range of temperatures, with a variation coefficient as high as 0.45 per degree for standard MTJ stacks [5, 6]. To account for such a rapid decrease, extremely high values of Δ would be needed at room temperature. However, since STT write current is also proportional to Δ, such devices would be extremely hard to write. To solve this challenge and qualify pSTT-MRAM for reflow soldering, we have designed a MTJ stack with high PMA and low Δ temperature coefficient. As shown in Fig. 1, all 30 chip tested pass reflow qualification without compromising write performance [4, 7]. pSTT-MRAM technology is also an attractive alternative to SRAM at advanced nodes for LLC applications. Indeed, the 1Transistor-1MTJ STT-MRAM cell is much more compact than the standard 6 transistors SRAM cell. Even though L1 and L2 cache memories operate at rates beyond today's pSTT-MRAM capabilities, LLC cache is within reach if write speeds below 10 ns can be achieved. As shown in Fig. 2, full array switching is achieved on a 10 Mb test chip without ECC for write pulses as short as 3 ns [8]. It should be emphasized that pSTT-MRAM is the only emerging non-volatile memory capable of such nanosecond write speed. Moreover, we have reported recently sub-30nm devices with PMA fields exceeding 10 kOe [3], promising excellent data retention beyond 1X lithography nodes.

GA-04. High Performance pMTJ with Ir as RKKY and PMA enhancing Layer.

Y. Huai[1]
1. Avalanche Technology, Fremont, CA, United States

I. INTRODUCTION After decades of research and development, the long sought-after STT-MRAM technology is now entering the mass production phase.[1] High performance perpendicular magnetic tunnel junction (pMTJ) with large TMR and thin total stack thickness is critical for high yield STT-MRAM production. A TMR ratio of over 200% after the high temperature BEOL processing of 400 °C and a total stack thickness of less than 10 nm are required.[2] The former is critical for large sensing margin and the latter is important for etching and integration yield. Thin reference layer with low magnetic moment and strong perpendicular magnetic anisotropy (PMA) is key to improved TMR and reduced total thickness of the full pMTJ stack. II. pMTJ WITH Co/Ir INTERFACIAL ANISOTROPY For the conventional pMTJ design, Ru has been considered as the best RKKY material. However, interface engineering is difficult for Ru at high annealing temperature, partly due to the complete solubility of Ru in Co up to 420 °C. In addition, owing to the lack of perpendicular anisotropy at Co/Ru interface, thin reference layer MTJ design using Ru as RKKY layer is often plagued by the weak anisotropy of the reference layer. In this talk, we will present results that demonstrate both strong interfacial PMA and perpendicular Ruderman-Kittel-Kasuya-Yosida (RKKY) exchange interaction in the Co/Ir system. Figure 1(a) shows the structure of pMTJ that incorporates Ir as the RKKY layer. The total MTJ film stack is only 8.6 nm thick. Figure 1(b) shows the VSM loop after 30 min and 150 min annealing at 400 °C, respectively. The magnetic performance is stable with high RKKY field after extended hours of annealing, which may be partly attributed to the low solubility of Ir in Co up to 1000 °C.[3] Figure 1(c) shows the CIPT measurement after annealing at 400 °C for 30 min and 150 min, respectively. The TMR results are shown in Figures 1(d) and 1(e). The combination of the additional high PMA at the Ir/Co interface and the conventional CoFeB/MgO interface in the Ir/Co/Mo/CoFeB/MgO reference layer results in the full film pMTJ attaining a TMR ratio of over 210%. In addition, there is almost no degradation of TMR after long hours annealing. III. DEVICE PERFORMANCE To further evaluate Ir based pMTJ device performance, test chips incorporating the advanced pMTJ design were fabricated from wafers processed through BEOL at temperatures of up to 400 °C. The MTJ devices have a diameter of 55 nm and a pitch of 130 nm, which allows the STT-MRAM to have a capacity beyond 1 Gb. The pMTJ has a RA value of 10 $\Omega\mu m^2$. The final device TMR ratio is over 210%, which is comparable to the full film level CIPT measurement, suggesting little, if any, degradation owing to the BEOL process. We also obtained an Hc larger than 2k Oe, a Vc around 550 mV with a conventional tri-layer free layer structure shown in Figure 1(a). In addition, we performed 400 °C annealing for 150 min at device level. Almost no degradation of MTJ performance is observed. These results demonstrate Ir/Co system can have large TMR, high spin transfer efficiency, and superior thermal stability, which are suitable for high density and high performance STT-MRAM application.

GA-05. Advances in three-terminal spin-orbit torque MRAM devices.

R. Buhrman[1]
1. Cornell University, Ithaca, NY, United States

With the successful development of STT-MRAM and its progression into commercial products, the question arises as to whether the strong spin-orbit torques (SOT) resulting from the spin Hall effect (SHE) [1,2] can provide utility by improving some of the performance parameters of magnetic memory devices, hence broadening the scope of spin-torque applications. In a SOT device the transverse spin current generated in a heavy metal layer results in damping-like and field-like torques being exerted on an adjacent ferromagnetic (FM) free layer of a nanoscale magnetic tunnel junction (MTJ) in a three-terminal configuration (3T-MTJ) [3]. While SOT devices certainly have a larger footprint than two-terminal STT-MRAM, they could be capable of a much shorter write time, and due to the separate read and write channels may offer additional advantages with respect to faster read-out without read disturbance, and lower write energy. Currently there are two distinct implementations of SOT devices, the first where the MTJ electrodes are perpendicularly magnetized (PM), and the second where the electrodes are in-plane magnetized (IPM). In the former case the magnetic reversal is driven by the effective field(s) of the SOT, which at least in principle could result in very high-speed performance. In the ideal situation, the free layer behaves as a single domain and the reversal is quasi-ballistic, but unless the MTJ is very small it is more likely to be the case that the reversal proceeds by the nucleation of a sub-volume domain, with that domain then being expanded by the effective field of the anti-damping torque acting on the domain walls against the pinning field [4]. In either situation a small in-plane bias field, or its functional equivalent, is required; in the first instance to break the symmetry, or in the second instance to overcome the DMI imposed chirality on the domain wall. A number of approaches have been identified to deal with this bias field requirement, but that is not the main concern with PM SOT devices. Instead the issue is the very high current (density) levels required to drive the effective-field reversal of a nanoscale, thermally stable free layer due to the limited efficiency by which even the best SHE materials to date can generate an interfacial effective field. At present the required current densities in the SH channel of PM devices are $\geq 1.4 \times 10^8$ A/cm^2 [5], which is equivalent to current levels >> than can be readily supplied by a scaled CMOS transistor. Even at those current density levels low write error rate switching with ns scale pulses has yet to be demonstrated, due in part at least to heating and thermal fluctuation effects [4,6]. For IPM SOT devices the reversal is driven by antidamping excitation and the expectation has been that fast, 1 ns, highly reliable anti-damping switching would not be achievable, based largely on previous experience with IPM STT-MRAM devices and on macrospin calculations. Recently we have shown that 3T-MTJs devices can exhibit characteristic pulse switching times of ≤ 0.5 ns, considerably faster than expected from rigid domain modeling, with no indication of an "incubation delay," and with a critical current density of $\approx 5 \times 10^6$ A/cm^2. This approach is also capable of yielding reliable switching in the short pulse regime with the best results to date being write error rates (WER) $\approx 10^{-6}$ with 2ns pulses as shown in Fig.1b [7]. There are a number of factors that combine to yield these results. First with respect to switching speed, as indicated by micromagnetic modeling the spin-torque driven reversal does not appear to proceed uniformly but non-uniformly with reversal beginning at one end of the FL structure and then sweeping across the ellipse. Second, the in-plane (effective) magnetic field generated by the Oersted effect and/or by the field-like torque effect will, if the sign is correct, act to help suppress the formation of localized magnetic inhomogeneities during the reversal process, speeding the reversal and apparently reducing reversal errors [8]. The low switching currents are the result of the development of SHE materials with high (> 20%) damping-like spin torque efficiency, beta-W and several different Pt alloys, in combination with the use of atomic and sub-atomic Hf layers to (a) passivate the HM/FM interface, reducing the effective damping, and (b) to controllably enhance the interfacial magnetic anisotropy energy density of the FM/MgO interface thereby lowering the effective demagnetization field of the FL to 2 kOe or less for FL thicknesses of ≈ 2 nm; both of which directly reduce the required pulse switching current [7]. In this presentation I will discuss the factors involved in obtaining this level of performance from IPM SOT devices, summarize our latest results with respect to switching current, speed and WER, and discuss pathways that might lead to further enhancements in SOT device performance.

I. INTRODUCTION MRAM has been developed since 1980s until now with several ups and downs. The ultimate purpose is to realize non-volatile working memories to save energy consumption of conventional volatile working memories such as SRAM and DRAM. However all of non-volatile memories including MRAM have been facing a dilemma of non-volatility and high energy consumption in their active mode because non-volatility has led to large writing-energy consumption, E_w. As a result, they have been used as data storages and none of them overcame the historical dilemma for busy applications. This is the one of the reasons why MRAM has not had big markets so far. Recently, the possibilities of overcoming the dilemma were demonstrated by both STT-MRAM and VoCSM [1], [2]. STT has better maturity but less room for further improvement. On the other hands, VoCSM has poor maturity but better potentials in terms of higher writing efficiency and better endurance [3]. In this talk, STT technologies and VoCSM technologies is reviewed with respect to saving energy consumption and remaining issues for VoCSM will be discussed at the conference. II. POSSIBILITY OF SMALL CRITICAL SWITCHING ENERGY PER BIT, e_{csw}, OF VoCSM Critical switching current for VoCSM with voltage, V, applied is given by the equation (1) [3]. $I_{csw}(VoCSM) = 8\pi e\alpha^*_{eff}/h\theta_{SH}\times\Delta E_{sw}(V)\times t_{SH}/w_f$ (1) Here, α^*_{eff}, e, h, θ_{SH}, ΔE_{sw}, t_{SH}, w_f are the effective damping constant, charge of an electron, Plank's constant, the spin-Hall angle(spin polarization), the switching energy-barrier, the thickness of a storage-layer, and the width of the storage-layer, respectively. In this case, the width of spin-Hall electrode is assumed to be the same as w_f, i.e. MTJs are self-aligned with the electrode. An example of voltage dependence of critical switching current density is shown in Fig.1. If negative voltage is applied, I_{csw} is reduced to less than half of spin-Hall switching current, I_{csw} with no voltage applied. The VoCSM-writing can be addressed as voltage-assisted spin-Hall writing. Small I_{csw} of 37μA at write pulse-width of 20nsec. was successfully demonstrated due to high efficiency of spin-Hall writing and combined voltage-assist [4]. The value of the I_{csw} is almost the same as that for STT-writing, even though the size of MTJ for VoCSM-writing (~50nm×150nm) is much larger than that of STT-writing(30nmø). Critical switching energy per bit for VoCSM-writing, $e_{csw}(VoCSM)$, is the product of I_{csw}, write pulse-width (t_p), and voltage across the spin-Hall electrode. It is roughly given by the equations (2), assuming the spin-Hall electrode has square in-plane shape. $e_{csw}(VoCSM) = \{8\pi e\alpha^*_{eff}/h\theta_{SH}\times\Delta E_{sw}(V)\times t_{SH}/w_f\}^2\times t_p\times R_{sh}$ (2) Here, R_{sh} is the sheet resistance of spin-Hall electrode with the typical value of 200-400Ω. Similarly, critical switching current for STT-MRAM is given by the equation (3) [3]. $I_{csw}(STT) = 8\pi e\alpha_{eff}/h\, g(\theta)\times\Delta E_{sw}$ (3) Here, α_{eff} and $g(\theta)$ are the effective damping constant and the spin polarization. And critical switching energy per bit for STT-writing, $e_{csw}(STT)$, is given by the equation(4). $e_{csw}(STT) = \{8\pi e\alpha_{eff}/h\, g(\theta)\times\Delta E_{sw}\}^2\times t_p\times R_{MTJ}$ (4) Here, R_{MTJ} is the resistance of MTJ with a typical value of 10kΩ. Fig.2 shows reduction trend of the e_{csw}s for STT-writing and VoCSM-writing. Even though the maturity of VoCSM is poor, the smallest e_{csw}s of about 100fJ/bit have been demonstrated by VoCSM. III. PRACTICALLY UNLIMITED ENDURANCE of VoCSM In VoCSM, write-current flows in the spin-Hall electrode made of heavy metal such as Ta having high melting temperature. Due to this, unlimited endurance of 1E+13 was demonstrated even at write pulse-width of 5nsec. [3]. V. CONCLUSION Both non-volatility and low energy consumption have been proved to coexist in VoCSM. Further, VoCSM cell has practical unlimited endurance of 1E+13. VoCSM also has a future reduction potential of I_{csw} by the factor of t_{SH}/w_f. Therefore, it is concluded that VoCSM has a potential to solve the historical dilemma of non-volatility and high energy consumption even for busy applications. ACKNOWLEDGMENT This work was partly supported by the ImPACT Program of the Council for Science, Technology and Innovation (Cabinet Office, Government of Japan).

Rapidly solidified nanostructured Nd-Fe-B melt spun ribbons have unique magnetic properties not obtainable with the conventional powder metallurgy. Due to the grain size that is of the order of the single-domain size, the room temperature coercivity is much higher than the values of sintered magnets with similar composition, where the grains are a couple of orders of magnitude larger. This works even in the case without the addition of the critical heavy rare earth (HRE = Dy or Tb) elements. The temperature coefficient of coercivity is smaller, which effectively increases the performance of the magnet at high temperature. Some applications like traction motors for electric vehicles and electric power steering motors require magnets with high coercive force, since the operating temperatures are high and magnets are exposed to large demagnetizing fields. The standard approach is to use magnets with homogeneously distributed Dy or Tb in order to prevent the overall reversal of magnetization. HREs increase the magnetocrystalline anisotropy of the hard magnetic $Nd_2Fe_{14}B$ phase. Since the magnetic moments of the HRE atoms couple antiparallel to the moments of Fe atoms, the remanent magnetization is reduced consequently. We present a new strategy to achieve the resource efficiency and to minimize the loss of the magnetic flux density without degrading the performance of the magnet [1]. A magnet with locally different magnetic properties (multicomponent magnet) can be used in applications where only certain parts of the specimen experience strong demagnetizing fields and significant increase in temperature. We employed "Spark Plasma Sintering" (SPS) approach to prepare a dense nanostructured multicomponent magnet containing a high-coercivity region. For this purpose, a HRE-free nanostructured powder was used in combination with a Dy-containing powder. We showed that this type of magnets can be manufactured in a single step by stacking both powders in the desired manner while avoiding mixing. Alternatively, individual single component magnets with different magnetic properties are prepared in the first SPS step. Afterwards, the respective parts are placed together and condensed into a single magnet body in a second SPS step. The grain growth during the SPS consolidation was supressed and the magnetic properties of the respective Nd-Fe-B powders were preserved in the multicomponent magnet. Information on the specimen's local magnetic properties was obtained by cutting the two-part magnet in half and measuring the individual parts separately with a closed-loop permeameter (Figure 1). Short manufacture time and low consolidation temperature of the SPS process inhibit the diffusion of Dy into the Dy-free region of the magnet. SEM and EDX analysis of the interface between both parts of the multicomponent specimen revealed that the microstructural characteristics and chemical compositions of the respective parts were comparable to the single component magnets prepared from the individual powders, which corresponded with the results of the magnetic characterization. In summary, magnets with locally different magnetic properties were prepared from the nanostructured melt-spun ribbons with the SPS approach. Alternatively, the SPS technique can be used to consolidate other types of Nd-Fe-B powders into dense magnets, including highly anisotropic jet-milled powders, at significantly lower temperatures than conventional sintering.

GB-02. Ultra thin films of $L1_0$-MnAl on GaAs (001): tuning the properties of the Mn-Ga-As-Al interphase.

C. Navío[1], M. Villanueva[1], E. Céspedes[1], F. Mompean[2], M. García-Hernández[2], J. Camarero[3,1] and A. Bollero[1]
1. Division of Permanent Magnets and Applications, IMDEA Nanoscience, Madrid, Spain; 2. Instituto de Ciencia de Materiales de Madrid, ICMM-CSIC, Madrid, Spain; 3. Condensed Matter Physics, Universidad Autónoma de Madrid, Madrid, Spain

In the last years, the scientific community is making a great effort on developing new combinations of materials to overcome the problem on the scarcity of certain elements. For this purpose, the use of the ferromagnetic Manganese-based alloys has been proposed for certain applications as rare earth free permanent magnets, due to their well-known high magnetic anisotropy constants [1, 2, 3]. In particular, the $L1_0$-MnAl (or τ-MnAl) is the only ferromagnetic phase of the Mn-Al phase diagram. This phase has been widely studied showing that the growth of this material on different semiconductors enhances the potential applications on the fields of spintronics, ultra high-density recording media and non-volatile magnetoresistive random access memory [2, 4, 5]. In this study, ultra thin films of MnAl have been grown on GaAs (001) by MBE (Molecular Beam Epitaxy) with thickness varying from 1 to 5 nm and without any buffer layer. XPS (X ray Photoelectron Spectroscopy) and LEED (Low Energy Electron Diffraction) were performed *in situ* in order to characterize the chemical states and the arrangement of the surface atoms. In order to prevent from ambient oxidation, a protective capping layer of Ta was deposited before the sample was withdrawn from ultra high vacuum and magnetic and structural characterization was done *ex situ* by SQUID magnetometry and XRD, respectively. In this work, well-oriented ultra thin films of $L1_0$-MnAl with coercivities over 8 kOe have been obtained. The X Ray Diffraction measurements show the main reflections of the $L1_0$-MnAl phase in register with the substrate orientation, as it was expected for the epitaxial growth. This result is correlated with the magnetic properties, where it is found that there is a strong magnetic anisotropy with all the magnetization pointing out of the film surface. The use of a GaAs (001) substrate has allowed the simultaneous formation of a ferromagnetic interphase of Mn-Ga-As-Al which contribution competes with the MnAl one and can be tuned by the experimental growth conditions. Thanks to the surface analysis techniques available *in situ* in the MBE chamber, it was possible to discriminate the signal coming from the interphase compound (Figure 1-a) [6]. Further experiments of growth of only Al or only Mn on the GaAs (001) at the same experimental conditions of the previous $L1_0$-MnAl films, played the role of simulated interphase compounds and contributed to the understanding of the magnetic contribution of the interphase to the magnetic properties (Figure 1-b) of this multicomponent system. GB-03. Mechanochemical synthesis of Dy substituted $Nd_2(Fe,Co)_{14}B$ magnetic nanoparticles.

Y. Zhong[1], V. Chaudhary[2], H. Parmar[2], X. Tan[1] and R.V. Ramanujan[1]
1. School of Materials Science and Engineering, Nanyang Technological University, Singapore, Singapore; 2. Rolls-Royce@NTU Corporate Lab, Nanyang Technological University, Singapore, Singapore

Abstract We report the synthesis of the Dy substituted $(Nd_{0.9}Dy_{0.1})_2(Fe,Co)_{14}B$ nanoparticles with a coercivity value of 10.4 kOe, by a "green" and low cost mechanochemical technique. The properties of these $(Nd_{0.9}Dy_{0.1})_2(Fe,Co)_{14}B$ nanoparticles can be improved by magnetic alignment. The remanence (M_r) tripled after alignment, with an average misalignment angle of 34.2°. The thermal coefficient of remanence (α) is -0.12%, comparable to the room temperature value of commercial Nd-Fe-B magnets. Introduction High performance permanent magnets are extensively used in many applications, e.g., energy generation and conversion systems [1, 2]. Recently, the quest to develop novel processing routes to produce improved magnets has become urgent [2]. Nd-Fe-B based permanent magnets have attracted enormous attention due to their superior magnetic properties. However, applications of Nd-Fe-B magnets at elevated temperatures is limited by their Curie temperature and strong temperature dependence of magnetocrystalline anisotropy [3]. Co substitution for Fe can increase the Curie temperature [4-6], while Dy substitution of Nd can extend the operating temperature range [7]. Conventional physical synthesis of Nd-Fe-B magnets are associated with high cost and limited control, while most chemical synthesising methods have limited magnetic properties and poor scalability [8, 9]. In previous work, we successfully produced $Nd_2(Fe,Co)_{14}B$ nanoparticles with relatively good magnetic properties through a "green", low cost mechanochemical technique [10]. To further improve magnetic properties, Dy-substituted $(Nd_{0.9}Dy_{0.1})_2(Fe,Co)_{14}B$ nanoparticles by the mechanochemical method was prepared. Experimental Details $(Nd_{0.9}Dy_{0.1})_2(Fe,Co)_{14}B$ nanoparticles were prepared through processing a mixture of commercially available Nd_2O_3, Dy_2O_3, Fe_2O_3, CoO, B_2O_3, CaO (99.9% Sigma Aldrich) powders and Ca granules (99.9%, ~ 6 mesh, Sigma Aldrich) via the mechanochemical ball milling process. Excess 50wt% of Nd_2O_3 and 100wt% of Ca granules were added to ensure full reaction. All precursors were milled with a Fritch Pulverisette-7 planetary ball mill under Ar atmosphere, at 500 rpm for 6 h, with a ball to powder ratio of 14:1. The milled powder samples were collected in Ar atmosphere and pressed into a pellet. The pellet was then heat treated in a vacuum furnace (~10^{-5} torr) at 850°C for 90 min, followed by washing in NH_4Cl/methanol solution to remove the by-product. The structure and phase were determined by X-ray diffraction (XRD) using a Bruker D8 X-ray diffractometer (CuKα radiation). The magnetic properties measurements were performed by using the PPMS (EverCool-II, Quantum Design). For alignment, a small amount of sample was sonicated within an adhesive and then dried and aligned on a glass slide under 1.8 T uniform magnetic field. Results and discussions Figure 1 shows the room temperature hysteresis loop for the aligned $(Nd_{0.9}Dy_{0.1})_2(Fe,Co)_{14}B$ nanoparticles measured // and $\perp$to the c-axis, respectively. A high coercivity of 10.4 kOe is observed $\perp$to the c-axis. The M-H loops // and$\perp$to the c-axis are substantially different. The magnetic nanoparticles can be crystallographically aligned and their properties are highly sensitive to magnetic alignment. After alignment, the M_r value increases drastically from 1.1 memu for the $\perp$ samples to 3.9 memu for the // samples. The average misalignment angle ϕ (ϕ=arctan((2$M_r^{\perp}$)/($M_r^{//}$))) is calculated to be 34.2°, comparable to the angle range (20° – 47°) of aligned $SmCo_5$ nanoparticles prepared by surfactant assisted ball milling [11]. Figure 2 shows the temperature dependent magnetic hysteresis loop for the aligned $(Nd_{0.9}Dy_{0.1})_2(Fe,Co)_{14}B$ nanoparticles measured // to c-axis. The thermal stability was studied. The thermal coefficient of remanence (α) and thermal coefficient of coercivity (β) in the temperature range of 100 to 400 K was found to be -0.12% and -0.31%, respectively. The thermal coefficient of remanence improved considerably after alignment. Typically, Nd-Fe-B magnets have a thermal coefficient of remanence of -0.12% [7]. Our aligned particles shows comparable thermal stability as commercial Nd-Fe-B magnets. Conclusions Dy substituted $(Nd_{0.9}Dy_{0.1})_2(Fe,Co)_{14}B$ nanoparticles with a coercivity of 10.4 kOe was successfully synthesized by a "green" and low cost mechanochemical process. The properties of these nanoparticles were highly sensitive to magnetic alignment, with an average misalignment angle of 34.2°. The thermal stability of these nanoparticles was comparable to those of commercial Nd-Fe-B magnets.

GB-04. Large improvement in magnetic properties of hot deformed HREE-free Nd-Fe-B magnets using the rapid heating technique of the powder.

Y. Nakazawa[1], R. Kato[1], Y. Shintani[1] and H. Shimizu[1]
1. Honda R&D Co., Ltd. Automobile R&D Center, Haga-machi, Haga-gun, Japan

1. BACKGROUND AND GOAL The traction motors of electric vehicles generally use neodymium sintered magnets, with heavy rare-earth elements, which are added to increase heat resistance. Honda and Daido Steel have succeeded in making the traction motor without heavy rare-earth elements by using hot-deformed neodymium magnets that have high heat-resistance potential, and by modifying the motor design [1]. Meanwhile, higher traction-motor performance is increasingly demanded, which calls for further enhancing of the magnetic properties employed in traction motors while still keeping them heavy rare-earth element-free. The goal of this study was to enhance the properties of hot-deformed magnets, hence the authors focused on the coarse grain presence within the microstructure of these magnets, investigated the coarsening mechanism, and verified a method to suppress coarsening by rapid heat treatment of the raw powder. 2. EXPERIMENTAL METHOD $Nd_{10.5}Pr_{3.5}Fe_{77.1}Co_{2.5}B_{5.7}Ga_{0.7}$ (at%) composition alloy ribbons were obtained by using single roller melt spinning. Then the ribbons were crushed into powder. Hot-deformed magnets were made by hot-pressing the raw material powder at 650°C to mold it into a solid that was then compression formed at 700°C to 750°C. Transmission electron microscopy (TEM) and scanning electron microscopy (SEM) were used to observe the structure, and a superconducting type of vibrating-sample magnetometer (VSM) was used to measure the magnetic properties. The free-fall type heat-treatment furnace was used to rapidly heat treat the raw material powder at 700°C in an argon atmosphere in order to suppress crystal grain coarsening. 3. RESULTS AND DISCUSSION A. Coarsening Mechanism The crystal grain coarsening of hot-deformed magnets occurs at the powder interface. The reason of this coarsening is considered to be related to the powder. Therefore, we studied behavior of crystal grain growth in the powder heated at 600°C and 700°C in an argon atmosphere and investigated where crystal grain coarsening occurred in the powder. Fig. 1 shows the microstructure of the raw-powder before and after heat treatment. The raw-powder structure before the heat treatment is in an amorphous state. In contrast, the raw-powder structure after heat treatment at 600°C has $Nd_2Fe_{14}B$ crystalized in the center area. However the roller contact surface side crystalizes into Nd_2O_3 and α-Fe, and the amorphous phase also remains between the surface and the interior, resulting in a heterogeneous microstructure. In addition, the raw-powder structure after heat treatment at 700°C exhibited crystal grain coarsening on the single roller contact surface side, indicating that the coarsening occurred in the same manner as that after hot-deformation. Therefore, crystal grain coarsening of hot-deformed magnet is assumed to occur on the roller contact surface side of the powder due to heterogeneity of the crystallization and growth processes of the structures within the raw powder. B. Method to Suppress Coarsening Based on the coarsening mechanism described above, $Nd_2Fe_{14}B$ crystal grain coarsening is considered to originate in the primary crystals NdOx and α-Fe and the amorphous phase. Therefore, a method of controlling the crystallization process of the raw-powder structure was investigated. It is reported that in Nd-Fe-B type amorphous alloys with a low Nd content, α-Fe crystallizes even at temperatures of 500°C or less, but $Nd_2Fe_{14}B$ crystallization starts at around 600°C. Therefore, to suppress α-Fe crystallization and increase the $Nd_2Fe_{14}B$ crystallization, this study focused on the heating rate of annealing in order to reach to the $Nd_2Fe_{14}B$ crystallization temperature in a short time. The induction heating and lamp heating are generally used as annealing methods with rapid heating rate. However, both of these methods have poor temperature uniformity and have difficulty in scale-up, hence they are not suitable for heat treatment of powder. Therefore, we selected the free-fall type heat treatment method. In this method, the raw powder falls freely from the top of a stainless steel pipe with a heated length of approximately 6 m. As a result of using this method, the powder was heated instantly during the few seconds of free fall and a heating rate of 10^3 to 10^4°C/min was realized. The free-fall type annealing heat treatment method continuously heats small quantities of powder, thus heating can be performed rapidly while providing thermal uniformity and continuous treatment can also be performed to enable mass treatment. Fig. 2 shows SEM images comparing the structures of a hot-deformed magnet using conventional powder and a hot-deformed magnet made using powder with the rapid heat treatment method. The addition of rapid heat treatment to the raw material powder suppresses crystal grain coarsening at the powder interface and realizes a homogeneous and refined structure. The magnetic properties of the conventional magnet were M_r = 1.33 T, H_{cj} = 1584 kA/m, and H_k = 1470 kA/m. In contrast, the addition of rapid heat treatment suppressed the coarsening and enhanced the respective magnetic properties to M_r = 1.40 T, H_{cj} = 1614 kA/m, and H_k =1536 kA/m. The paper and scheduled presentation will provide a detailed report of the coarsening mechanism and the method used to suppress coarsening.

GB-05. Sustainability In The Production Of Sr-ferrite Magnets: Understanding Microstructure-Magnetic Correlation Translates To A Successful Recycling Case In Industry.

A. Bollero[1], J. Rial[1], M. Villanueva[1], A. Seoane[2], J. Almunia[2] and R. Altimira[2]
1. Permanent Magnets and Applications, IMDEA Nanoscience, Madrid, Spain; 2. Ingeniería Magnética Aplicada, IMA S.L., Barcelona, Spain

Ferrites are the most widely used permanent magnets throughout the world [1,2]. They are used in low field and low power applications, high-frequency systems, biotechnology... Based on the high demand of these magnets, recycling of the residues generated in the manufacturing process is beneficial from an environmental point of view but also economically to reduce costs at the magnet company while additionally guarantying sustainability by closing the loop in production line. Despite the large amount of ferrites waste generated during manufacturing, there is a lack of studies dealing with the possibility of recycling Sr-ferrite (SF) waste. There are only studies dealing with the possibility of recycling the elemental constituents from different sources, but not the SF material after completion of magnets manufacturing. A successful recycling procedure for the SF residues produced in the manufacturing process of ferrite magnets will be explained in detail. The aim of this study is to establish a proper correlation between morphological, microstructural and magnetic properties in SF and make use of this understanding to develop a method that can be easily and cost-efficiently implemented in a permanent magnets manufacturing plant. Highlights from this study are: (i) The recycling process makes use of the facilities already existing in the company. (ii) The parameters comprising the recycling process are comparable to those used in the processing of the SF commercial powder. (iii) The magnetic quality of the recycled material is by far superior to that of the starting brand new material, resulting in a more competitive product. The prices of both the constituent elements and the processing route are very low for ferrites by comparison with those of rare earth-based magnets. Based on this, recovery and recycling of the residues generated during the manufacturing process might be interesting only from an environmental point of view but prohibitive in terms of implementation costs for a company. However, a recovery and recycling process fulfilling the attained requirements listed as highlights of this study has guaranteed straightforward implementation in production with no economical looses but gain. Residues used in this study were collected in the permanent magnet factory from a line of cutting machines used to shape ferrite magnets. The residue consisted of moisture comprising Sr-ferrite ($SrFe_{12}O_{19}$) powder, water and coolant fluid. In this study the residues were dried in air at 250°C for 1 h for removal of organic components (see Fig. 1(a)). Calcination in air at 1000°C was carried out straightforward on the wet residues in an industrial muffle to modify their properties. SEM images shown in Fig. 1 prove the particle size refinement and homogenization induced by the cutting process, when comparing the dried SF residue (Figs. 1(b)) and the starting commercial powder (Fig. 1(c)). Application of the calcination process to the commercial SF powder results in an increased coercivity of 1.8 kOe (Fig. 2(a)), proving the possibility of quality enhancement already in the case of the starting material. More striking is the effect of calcination on the residues, which results in a recycled SF powder with a large coercivity of 3.3 kOe, i.e. well beyond the increased value (1.5 kOe) achieved through exclusively drying of the residue and more than 3.5 times larger than that of the brand new commercial SF powder acquired by the company (Fig. 2(b)). It will be shown that the improvement in magnetic properties is the result of an efficient nanostructuration and homogenization of the powder through processing and subsequent heat treatment [3]. Moreover, and for the aim of properties comparison, brand new SF powders, identical to those used to fabricate the magnets, were milled by application of a self-developed surfactant-assisted rapid-milling method [3-5]. This comparison proves the fundamental importance of microstructure refinement on the enhancement of permanent magnet properties in SF. Consequently, a recycling procedure for the Sr-ferrite residues produced in the manufacturing process of ferrite magnets has been developed, resulting in a ferrite powder with coercivity and remanence values superior to those of the starting commercial material. The developed process guarantees sustainability by demonstrating a recycling method that can be cost-efficiently implemented in a permanent magnet manufacturing plant. *Acknowledgements* This research has been supported by EU-FP7 NANOPYME Project (No. 310516), MINECO through ENMA (MAT2014-56955-R), EUIN2017-88502 and from the Regional Government of Madrid through NANOFRONTMAG project (Ref. GB-06. Effects of Hot Pressing Temperature on Magnetic Properties of Hot Pressed Nanocrystalline Nd-Fe-B Magnets.

Z. Jing[1], *Z. Guo*[1], M. Li[1], M. Zhu[1] and W. Li[1]
1. Central Iron & Steel Research Institute, Division of Functional Materials, Beijing, China

Introduction The hot deformation technique is an important method for fabricating nanocrystalline anisotropic Nd-Fe-B bulk magnets [1]. This technique consists of two steps, namely hot pressing and hot deformation. The magnetic properties of hot deformed magnets are determined not only by the process route of hot deformation but also by the status of hot pressed magnets [2-4]. As the precursor of hot deformation, the hot pressed magnet plays a very important role in determining the magnetic properties of the final hot deformed magnets. Therefore, it is necessary to explore the factors impacting the hot pressed magnets, which will contribute to preparing high performance hot deformed magnets. In this paper, the effects of hot pressing temperature on magnetic properties of hot pressed nanocrystalline magnets have been discussed by analyzing the magnetic properties, phase composition, and microstructure. Experimental Procedure The starting melt-spun powders with a nominal composition of $(Nd,Pr)_{29}Fe_{bal}Co_4Ga_{0.42}B_{0.92}$(wt.%) were hot pressed in vacuum at different temperature (450 °C, 500 °C, 550 °C, 600 °C and 650 °C) under 500 MPa for 70s to obtain nanocrystalline isotropic bulk magnets. The hot pressed magnets prepared at 450 °C, 500 °C, 550 °C, 600 °C and 650 °C were denoted as HP450, HP500, HP550, HP600 and HP650, respectively. Magnetic properties of the magnets were measured on a physical property measurement system (PPMS) without demagnetization correction. Phase composition and microstructure were identified by X-ray diffraction (XRD), simultaneous thermal analyzer (STA) and transmission electron microscope (TEM). Results and discussion The densities of the magnets increase from 7.04g/cm^3 to 7.60 g/cm^3 with the hot pressing temperature increasing from 450 °C to 650 °C. The results of magnetic measurement show that the coercivity increases from 15.15 kOe to 20.42 kOe with the temperature increasing from 450 °C to 650 °C, while the remanence increases when the temperature is lower than 600 °C, then decreases with the temperature further increasing to 650 °C. The best magnetic properties with coercivity of 17.29 kOe, remanence of 8.25 kGs and energy product of 17.69 MGOe are obtained at 600 °C. Figure 1 shows the initial magnetization curves and hysteresis loops of hot pressed magnets prepared at different temperature. For the magnets prepared below 600 °C, from the initial magnetization curves it can be seen when the field is low, the magetization increases slowly, and then increases sharply after the applied field exceeding a critical field(H_p), which can be interpreted by the pinning of the domain walls. The values of H_p increases with the temperature increasing from 450 °C to 600 °C. Two steps occur on the initial magnetization curve of the HP650 magnet, the magnetization increases fast when the field is lower than 7000 Oe, which are different from that of the magnets prepared below 600 °C. The critical field (H_p) of HP650 magnet increases further compared with that of HP600 magnet. The demagnetization curve of the HP650 sample contains a shoulder localized in the second quadrant, which results from the decoupling between the soft phase and the hard phase. Figure 2 shows the δM curves of hot pressed magnets prepared at different temperature. δM curves indicate when the applied field is low, the exchange-coupling interaction of neighboring grains is dominant, and the magnetostatic interaction increases with the field increasing and only one positive peak can be observed on the δM curve for the magnets prepared at the temperature not higher than 600 °C. Two positive peaks can be seen on the δM curve for the HP650 magnet. The first peak near 7000 Oe is corresponding to the first step on the initial magnetization curve of HP650 magnet, resulting from the exchange-coupling interaction of the soft and hard phase, and the second peak near the coercivity of HP650 magnet is attributed to the exchange-coupling of neighboring $Nd_2Fe_{14}B$ grains. XRD results show when the temperature is less 600 °C, the magnets are composed of single $Nd_2Fe_{14}B$ phase, while in the HP650 magnet the soft magnetic phase formed is $NdFe_2$. The peak occurred on the TG curve at 778 °C is due to the Curie transition of $NdFe_2$. TEM reveals that the grains in all the hot pressed magnets are equiaxed and the grain size is less than 150 nm. Conclusion In summary, the effects of hot pressing temperature on magnetic properties of hot pressed nanocrystalline Nd-Fe-B magnets have been investigated. The coercivity of the magnets increases with the temperature increasing, while the remanence increases when the temperature is lower than 600 °C, then decreases with the temperature further increasing to 650 °C. There are two steps on the initial magnetization curve as well as two positive peaks on the δM curve for the HP650 magnet, which are different from that of the magnets prepared at the temperature not higher than 600 °C The first step and peak occurred near 7000 Oe due to the exchange-coupling interaction of soft and hard phase. XRD results indicate in the HP650 magnet the soft phase formed is $NdFe_2$, resulting in the change in magnetization behavior of the HP650 magnet. TEM reveals that the grains in all the hot pressed magnets are equiaxed and the grain size is less than 150 nm. The grain size increases with the temperature increasing.

GB-08. Structural Evolution and Magnetic Properties of Bulk MnAl-C Prepared by High Pressure Compaction of Gas-atomized Powders.

P. Si[1,2], H. Qian[1], J. Park[1], C. Choi[1], S. Han[1] and H. Ge[2]
1. Korea Institute of Materials Science, Changwon, The Republic of Korea; 2. China Jiliang University, Hangzhou, China

The ferromagnetic Mn-Al system has been studied for more than one century since 1908 [1]. The report on the metastable tetragonal ferromagnetic Mn-Al with about 54 at.% manganese in 1958 had attracted intensive research work to optimize the materials and to understand the phase transformation mechanisms in Mn-Al [2-5]. However, the research on MnAl was soon interrupted by the discovery of Nd-Fe-B. Recently the ferromagnetic τ-phase MnAl is attracting increasing research interests for its potential in plugging the gap between Nd-Fe-B and ferrites [6-8]. Various techniques such as hot extrusion, backpressure equal channel angular extrusion, hot deformation, hot compaction, spark plasma sintering, and microwave sintering have been employed to make bulk MnAl magnets in the previous work [9,10]. The precursors for hot extrusion and deformation are usually bulk materials while the precursors for the other methods are milled powders, which usually shows a higher coercivity and lower magnetization than that of the bulk. When the powders were consolidated in bulk magnets, both magnetization and coercivity would be decreased. The previous methods to make bulk samples usually involve high temperature processes that may result in a partial decomposition of the τ-phase, and thus a reduced magnetization. In this work, nanocrystalline MnAl-C bulk magnets were prepared by pressing the τ-phase gas-atomized micro-powders under high pressures and at low temperatures. The as prepared gas-atomized powders were mainly composed of ε-phase and a small fraction of γ_2-phase. The phase transformation temperature of the ε-MnAl-C to τ-phase were determined by using magnetization measurements. The triggering temperature for massive phase transformation of the ε-MnAl-C gas atomized powders is around 720 K. The phase transformation accomplished at temperatures above 806 K. The gas-atomized powers are spherical in shape with size ranges from several to 10 micrometers, as shown in Fig.1. Bulk nanocrystalline MnAl-C magnets were prepared from the gas atomized powders by using high pressure compaction, which results in a severe deformation of the spherical micro-powders and thus the grain size of the τ-phase was refined in the bulk materials, as shown in Fig.2. The compacted bulk materials show an enhanced coercivity and a higher magnetic performance to that of the powders. The structure, phase transformation, and magnetic properties of the powders and bulk samples were studied systematically.

GB-09. Additive Manufactured Magnetic Structures with Locally Varying Magnetization Direction in 3D.

C. Huber[1,2], F. Bruckner[1,2], C. Abert[1,2], M. Groenefeld[3] and D. Suess[1,2]
1. Physics of Functional Materials, University of Vienna, Vienna, Austria; 2. Christian Doppler Laboratory for Advanced Magnetic Sensing and Materials, Vienna, Austria; 3. Magnetfabrik Bonn GmbH, Bonn, Germany

Polymer bonded magnets enable the manufacturing of complex shapes and features by design flexibility regarding shape and magnetizing structure. Recently it was shown that an end-user 3D printer can be used to print polymer bonded NdFeB magnets with a specific complex shape [1]. An advantage of isotropic polymer-bonded magnetic materials is the possibility to magnetize various regions of a magnetic structure into different directions, even if the magnet is already solid. This characteristic of the bonded magnetic materials can be used to upgrade the 3D printer to a magnetic pixel ("maxel") printer. This work describes the possibility and a procedure to print "maxels" not merely on the surface of a magnet, but rather on each layer of the 3D printed magnetic structure. For the magnetization process, pulse coils would have the most advantages regarding flexibility. Due to the relative low saturation magnetization of bonded magnets, and the fact that a "maxel" printer with a pulse field coil would lead to a relative complex electronic setup, another technique should be discussed. The "maxel" printer is realized with cylindrical NdFeB permanent magnets (Grade N35, B_r=1.21 T) and ARMCO Pure Iron frustums to concentrate the magnetic flux of the NdFeB permanent magnets. Two of such contrary magnetized structures are fixed in a 3D printed jig (Fig. 1(a)). Fig. 1(b) shows a magnetic field scan (1.5 mm above surface) of the z-component of the magnetic flux above a 3D printed flat structure with different orientated "maxels" on the surface. The "maxel" pattern shows the letters "TU". To test the effectivness of our system, two cuboid of size 10x5x3 mm^3 (LxWxH) are printed with the polymer-bonded NdFeB material Neofer25/60p from Magnetfabrik Bonn GmbH. Different structures such as a stripes pattern and a chessboard pattern are realized. Both patterns are produced with the minimum resolution of 0.5 mm. After each 3D printed layer, the "maxel" printer magnetize the surface of the cuboid with the characteristic pattern. The result of printed stripes structure is pictured in Fig. 2(a) and for the chessboard pattern in Fig. 2(b). Furthermore, we developed an inverse stray field method based on finite elements that allows us to deduce the magnetization of the magnet from stray field measurements. This method can be used to deduce the quality of the printed magnets. Moreover the inverse method allows us to find an optimal magnetization density for a given target field distribution [2].

GB-10. Magnetic Force Equations based on Computer Simulation and the Effect of Load Line.

C. Chen[1,3], H. Meng[2] and M. Fan[1]
1. Quadrant at San Jose, San Jose, CA, United States; 2. Quadrant at Hangzhou, Hangzhou, China; 3. Magnet Energy LLC, San Jose, CA, United States

The Maxwell magnetic force equation $F = B^2A/(2\mu_0)$ [1-6] can be used for determining the magnetic force of magnetic components, where F is the force in newton (N), B is the flux density in tesla (T), A is the area of cross-section in square meter (m^2), and μ_0 is the permeability of the vacuum ($4\pi\times10^{-7}$ H/m). The formula can be converted to an easy to remember expression of $F = 40B^2A$, in which the unit of A is cm^2. This equation says that if the field is 1T, and the area is $1cm^2$, then the magnetic force is 40N or 4kgf. However, it is somehow difficult to determine the B value in many practical cases, and the accuracy is usually not satisfactory. Computer simulation using finite element method can determine the magnetic forces with various boundary conditions, but usually it is not convenient for industrial users. In this paper, we report several simple equations, which are established based on the large database generated by using 3D computer simulation. The users can use the equations to obtain the force by simply inputting the magnet's B_r, area and thickness. The effect of load line is also analyzed in this paper. Infolytica's MagNet software was chosen for the simulation. Parameterization function with newton tolerance 0.1% was used to systematically solve the problems for NdFeB cylinders, rings, and rectangular blocks interacting with CR1010 steel. The steel plates are both thicker and larger than the magnets. The maximum sizes for the magnets are shown in Table 1. The result database for each gap in a single boundary condition includes 62500 data points for rectangular blocks, 30625 data points for rings, and 1250 data points for cylinders. The gaps between the magnets and steel plates are in the range of 0.01 – 15mm with 23 unequal intervals. The itemized data were then plotted and analyzed to establish the force equations for the magnets with relative high load lines. Figure 1 shows the magnetic force vs the area of N52 magnet rings with gap = 0.01mm to steel plates. Fig. 1a and 1b have different boundary conditions: 1a has CR1010 steel on both ends of the magnets, and 1b has the steel only on one end. The load line of a standalone magnet can be estimated by using the equations described in Parker's book [7], but the magnets in this project have much higher load lines compared to the standalone magnets since steel plates are associated with these magnets. Boundary condition 1a obviously gives much higher load line compared to boundary condition 1b. For these ring magnets with higher load line in condition 1a, the force value vs area for each thickness can generate 2nd degree polynomial formulas, which has R-squared R2 >0.9997 as shown in Figure 1. (R^2 of 1.0000 was obtained for all the thicknesses of rectangular blocks). These formulas were then analyzed to establish a general equation $F = B_r^2(aA^2+bA)$. Using the equation, the magnetic force for any B_r value can be determined by inputting magnet's B_r, area, and thickness. As shown in Table 1, the factor *a* is a function of thickness in 2nd degree polynomial, and the factor *b* is also a function of thickness but in power form. The effect of boundary condition is tremendous. Condition1b has much lower load line compared to condition 1a, hence the magnetic force values vs the area cannot generate satisfactory equations. As shown in the Fig. 1b, for the same magnet area, the magnetic force values are in a range with various values due to different load lines. For example, the ring magnets with exact the same thickness 0.1cm and area $2.8cm^2$, the force values range from 18.4N to 74N for ID/OD values from 0.1/1.9cm to 4.3/4.7cm. Details for all the magnet shapes with two boundary conditions will be reported in this paper, and the effect of load line will be analyzed.

GB-11. High $(BH)_{max}$ (Nd,Dy)-(Fe,Co)-B Hard Magnetic Powders Synthesized by Microwave Processing.

X. Tan[1], H. Parmar[1,2], V. Chaudhary[1,2], Y. Zhong[1] and R.V. Ramanujan[1]
1. Materials Science and Engineering, Nanyang Technological University, Singapore, Singapore; 2. Rolls-Royce@NTU Corporate Lab, Nanyang Technological University, Singapore, Singapore

Abstract $Nd_{14}Dy_1Fe_{67}Co_{10}B_8$ magnetic nanoparticles were synthesized by microwave combustion followed by reduction diffusion (RD). Our nanoparticles exhibit coercivity of 9.2 kOe with good maximum energy product ($(BH)_{max}$) of up to 13 MGOe at room temperature. The temperature coefficients of remanence(α) and coercivity(β) of the particles were found to be -0.82% and -0.21% in the temperature range of 300 K to 400 K. Dy was found to be uniformly distributed in the nanoparticles. Introduction Recently, there is increasing demand for high performance permanent magnets for cutting edge technologies, such as hybrid and electric vehicles, wind turbines, motors, etc. Hence, there is considerable interest in the development of nanostructured Nd-Fe-B based magnetic materials, since such magnets exhibit the highest $(BH)_{max}$ among all permanent magnets. However, limitations for this family of permanent magnets are its low Curie temperature (~585K) and relatively low coercivity. One solution is to substitute Nd by heavy rare earth elements such as Dy[1]. Dy-substituted Nd-Fe-B magnets have a higher coercivity; $Dy_2Fe_{14}B$ has a higher magnetocrystalline anisotropy than $Nd_2Fe_{14}B$[2]. The high cost of heavy rare earths and reduction of remanence due to antiferromagnetic coupling of Dy and Fe limit the Dy content [3]. Co alloying can be used to increase the Curie temperature[4-6]. Hence, we employed a microwave based chemical method to synthesize Dy,Co substituted $Nd_2Fe_{14}B$ powders. Since the starting materials in this method are metal salts rather than elemental metals, the material cost is much lower[7]. For example, the price of Dy metal(99.9%, Sigma Aldrich) is 13.2 SGD/gram while that for Dysprosium nitrate hydrate(99.9%, Aldrich) is only 2.8 SGD/gram. In addition, since it is a bottom-up approach, Dy can be easily alloyed by incorporating Dy salts in the precursor solution, further decreasing the processing cost. The targeted composition was $Nd_{14}Dy_1Fe_{67}Co_{10}B_8$, which was selected to increase the coercivity while keeping remanence almost constant[1, 4]. The crystal structure and magnetic properties between 300 K and 400 K were investigated. We observed that nanoparticle coercivity of up to 9.2kOe and $(BH)_{max}$ as high as 13 MGOe. Experimental Details The starting materials were neodymium nitrate hexahydrate (Alfa Aesar, purity 99.9%), Dysprosium nitrate hydrate (Sigma Aldrich, purity 99.9%), iron nitrate nonahydrate (Sigma Aldrich, purity 98+%), cobalt nitrate hexahydrate (Alfa Aesar, purity 98%), boric acid(Alfa Aesar, purity 99.8%), glycine (Sigma Aldrich, purity 99%) and calcium hydride(Alfa Aesar, purity 92%). Calculated amount of metal salts and glycine were dissolved in deionized water (total metal slats: glycine = 1:1). The solution was irradiated by the microwave system (HTVF-3, Dawnyx Technologies Pte Ltd) at a microwave powder of 2.8kW. The solution was converted into fine Nd-Dy-Fe-Co-B mixed oxide powders after combustion. $(Nd,Dy)_2(Fe,Co)_{14}B$ alloy was obtained by RD using CaH_2 as reducing agent *via* a vacuum furnace heat treatment at 800^{o}C for 2 hours. Results and Discussions Room temperature M-H curves measured for randomly oriented powders is shown in figure 1(black line). The Hc, Mr and Ms were 9.2 kOe, 55 emu/g and 103 emu/g, respectively. The powder sample was then aligned under a 2 T external magnetic field. Room temperature magnetic measurements were carried out in the direction perpendicular (figure 1, blue line) and parallel (figure 2, red line) to the alignment. It was found that the Mr and squareness are highly sensitive to this alignment process. The Mr almost doubled from 55 emu/g to 100 emu/g. Mr/Ms increased from 0.53 to 0.86.The (BH)max of the random powder and samples after alignment were calculated. We assumed a theoretical density of Nd-Fe-B (7.5 g/cm^3). Figure 2 shows the demagnetization B-H curves at room temperature. It is interesting to note that the $(BH)_{max}$ increased from 5.11 MGOe (for the random powder) to 13.04 MGOe (parallel to the aligned direction). The good (BH)max is attributed to the high Mr and high squareness resulting from the alignment of the nanoparticles along the easy axis. M-H hysteresis loops were also measured, at temperatures ranging from room temperature to 400 K, for the synthesized $Nd_{14}Dy_1Fe_{67}Co_{10}B_8$ powder. The thermal coefficient of remanence (α) and thermal coefficient ofs coercivity (β) were found to be -0.82 % and -0.21 %, respectively. Scanning Transmission electron microscopy (STEM) (JOEL, 2100F) of the $Nd_{14}Dy_1Fe_{67}Co_{10}B_8$ particles revealed an uniform distribution of Dy in the nano particles.

Nd-Fe-B magnets are widely used in electrical machines such as motors and generators because of their high remanence and energy product. High operating temperatures as well as large stray fields in extreme situations present harsh demagnetization conditions. Therefore, Dy-rich Nd-Fe-B magnets have to be used in such machines which offer the large coercivities necessary to reliably avoid demagnetization in operation. However, the high Dy content makes such magnets very expensive and also lowers their remanence and energy product. In the light of the very volatile market for rare earth metals, reducing the Dy content of high-performance magnets is one of the main goals of current permanent magnet research. Dy-containing Nd-Fe-B magnets that are in commercial use today are typically very homogenous in composition and magnetic properties. However, the required coercivity of magnets operating in electrical machines may differ spatially. Thus, expensive Dy-rich, high coercivity magnet compositions may not be required throughout the full magnets within electrical machines, presenting an opportunity to decrease the total Dy content and material cost of the magnets. [1] In order to test this hypothesis, the areas of demagnetization in different peak overload and short circuit scenarios were simulated for different types of electrical machines with an adapted version of the finite element electrical machine simulation tool FCSmek. In surface mounted permanent magnet geometries, demagnetization seems to occur randomly in different parts of the magnets. For embedded permanent magnet geometries, however, demagnetization occurs mainly on the magnet edges (Figure 1). Therefore, in machines with such geometries, high coercivity regions are only required at the edges, whereas the magnet cores may have a Dy-poorer composition giving lower coercivity. Next, the feasibility of producing such magnets with different coercivity regions, termed multicomponent magnets, was investigated. Dy-free and Dy-rich jet-milled Nd-Fe-B powders were carefully placed next to each other into one mold, magnetically aligned in a magnetic field, and pressed to a green body. The green body was then sintered at a temperature suitable for both magnet powders, yielding one mechanically coherent multicomponent magnet (Figure 2). The interfaces between Dy-rich and Dy-free components were investigated using scanning electron microscopy (SEM), energy-dispersive X-ray spectroscopy (EDX) as well as mechanical property measurements. Conventional magnetic property measurements of the multicomponent magnets only show the integrated magnetization of the whole magnet. A first glance at the spatial distribution of coercivity and remanence was therefore obtained using small cutouts from different magnet regions. Additionally, measurements with a 3D magnetic field mapping device using 3-axis Hall probes allow non-destructive analysis and visualization of the desired multicomponent magnets with different coercivity regions. In conclusion, we show that multicomponent magnets containing regions of different coercivity can significantly improve the cost-effectiveness and performance of some electrical machines, especially with embedded permanent magnet geometry. According to our simulations, less Dy is required for multicomponent magnets withstanding the same operating conditions as regular Dy-rich magnets, which significantly lowers the magnet material cost. In addition, the higher remanence of the multicomponent magnets increases the magnetic loading of electrical machines, so that for a given electrical loading, the machine stack length can be reduced. First multicomponent magnets have been produced by the traditional sintering method. Careful analysis of the interface microstructure and strength proves that the multicomponent magnet approach is feasible for commercial application.

Magnetic nanostructures with perpendicular magnetic anisotropy (PMA) [1] materials are attracting a large amount of attention for their potential applications such as high density magnetic random access memory (MRAM) [2], bit patterned media [3], or magnetic logic [4]. The scalability of these applications toward ultimate technology nodes is in general limited by the structural variability of the nanostructures. This leads to a dispersion of the magnetic properties, which strongly affects the switching mechanism when the dimension of the nanostructures becomes smaller. In this work, we have studied the magnetization reversal of CoFeB/MgO-based nanodots with sizes ranging from 400 nm to 1 μm. Contrary to previous results [5,6], we observe that the switching field distribution (SFD) is shifted towards lower magnetic fields when the size is reduced. Using the framework of the elastic interface (e.g. soap bubbles), we show that the Laplace pressure applied on a domain wall (DW) nucleated and pinned at the edges of the nanodots is responsible for such mechanism. In our study, the magnetic multilayers were fabricated into nanodots array by electron beam lithography and ion milling process. The switching process of the nanodots was investigated using magneto-optic Kerr imaging microscopy at room temperature. The film was first saturated with a large positive magnetic field along the perpendicular direction (easy axis) and then successive negative magnetic field pulses were applied with the same width but different magnitude. The switching probability of the array was obtained by calculating the ratio of the reversed nanodots to the overall number of the nanodots. Fig. 1(a) and 1(b) show the typical magnetic switching process of the nanodots arrays for a size of 1 μm and 600 nm respectively. Surprinsingly, a lower magnetic field is needed for the array of 600 nm to reverse the same number of nandots. The average switching probabilities as a function of magnetic field for different dot sizes are shown in Fig. 2(a). We observe a clear shift of the SFD toward lower fields when the size is reduced without noticeable change for the width of the distribution. This results can be explained by the pinning of the DW at the edges of the nanodots together with the action of a Laplace pressure. When an external field is applied, the DW nucleation first occurs at the edges where the anisotropy is significantly reduced due to the patterning process. However, the DW cannot further propagate towards the inner part of nanodots because a strong DW pinning is induced by a gradient of anisotropy [7]. As a result, in addition to the driving magnetic field, a Laplace pressure is applied on the DW for the domain wall depinning process, as shown in Fig. 2(b). This Laplace pressure results from the DW energy that favors the collapse of magnetic bubbles and the strength of this pressure increases when the radius R of the bubble is reduced. The Laplace pressure just acts as a simple effective field proportional to inverse of the dot size, which only shifts the distribution without modifying its width. Therefore, we observed the decrease of the reversal fields as the dot size reduces. A DW energy density of 6.8 mJ/m^2 is calculated from the experimental data, which is in very good agreement with the previous study [8]. Our results suggest a path toward scalable devices based on controlling the nucleation and pinning potential of DWs at the edges of the nano-elements. In this case, benefiting from the Laplace pressure and keeping the same thermal stability given by the gradient of anisotropy, a lower switching current can be expected when reducing the size of the devices.

The spin-orbit torque (SOT), which is an electric current induced phenomenon that utilizes spin currents generated by spin orbit interactions, enables the ultrafast deterministic switching in magnetic thin films with perpendicular magnetic anisotropy (PMA). However, the oscillatory switching behavior with respect to the applied current duration has not yet been reported in the SOT switching with PMA systems, while it was demonstrated in the conventional spin-transfer torque (STT) switching [1]. This is attributed to the different switching mechanisms in the STT and SOT schemes. Whereas the STT switching is governed by the coherent rotation of magnetization, the SOT switching in PMA systems is reported to be an incoherent process where the switching occurs through expansion of magnetic domain [2]. In this work, we report for the first time the oscillatory SOT switching behavior in a PMA system [3] as shown in Figure 1. The studied structure is Ta (6 nm)/$Co_{40}Fe_{40}B_{20}$ (0.9 nm)/MgO (2 nm)/SiO_2 (3 nm) whose field-like torque (FLT) component of SOTs is large and is of opposite sign to that of damping-like torque (DLT) component (FLT/DLT = –3.2). Careful measurements of the SOT switching behavior under tilted in-plane assist-fields revealed that the large FLT, where its role was usually neglected in the deterministic SOT switching process, plays a dominant role in breaking the determinism in SOT switching dynamics. The oscillatory switching behavior is not observed in the Pt layer based device which exhibits a small FLT/DLT ratio of –0.5. Estimated domain wall velocities during the forward and backward switching processes, supported by the micromagnetics simulations, suggests that a large FLT can dynamically influence the domain wall chirality which determines the direction of SOT switching. By utilizing the oscillatory switching behavior, we also demonstrate the unipolar deterministic SOT switching scheme as shown in Figure 2, which operates by controlling the duration of the current pulses, while keeping the magnitudes and polarities of the current and the assist-field constant. The PMA circular dot patterned on top of the Ta channel switches alternatively between the two stable states under nanosecond current pulses. Our study provides the underlying physics behind the FLT induced oscillatory behavior of the SOT switching and a potential to significantly increase the scalability of SOT devices by replacing transistors with diodes.

GC-03. Magnetization damping in spin-orbit coupled magnetic textures.

C.A. Akosa[1], Z. Yuan[3], A. Takeuchi[2] and G. Tatara[1]
1. RIKEN Center for Emergent Matter Science (CEMS), Wako, Japan; 2. Department of Physics and Mathematics, Aoyama Gakuin University, Sagamihara, Japan; 3. The Center for Advanced Quantum Studies and Department of Physics, Beijing Normal University, Beijing, China

The recent years has witnessed a surge in research efforts geared towards utilizing the spin degree of freedom of electrons in combination with its charge, to create new functionalities and devices. The performances of these devices such as magnetic random access memories, hard drives and sensors, strongly depends on the magnetization damping - as it detects the energy required, the speed and efficiency at which these devices operate. Over the past years, several microscopic theory of magnetization damping have been proposed in which, spin-orbit coupling is the mediating interaction by which energy is transferred from the magnetization to the spin of itinerant electrons[1,2,3]. It was recently pointed out that magnetization damping being a material parameter should in principle reflect the symmetries inherent in the system by virtue of Neumann's principle, and therefore should include a *chiral* contribution in non-homogeneous magnets with broken inversion symmetry[4,5]. This prediction is appealing for realizing of ultra-low damping, however, little information is known about the relative strength and the symmetry of the damping in spin-orbit coupled magnets. In this study, we propose a scheme based on the scattering theory[6,7] to qualitatively estimate the chiral contribution of damping in spin-orbit coupled non-homogeneous magnets characterized by broken inversion symmetry. We elucidate the different contributions and the angular dependence of chiral damping in the presence of the Rashba and Dresselhaus spin-orbit coupling. We show that in the absence of relaxation, the damping torque takes the same form as the adiabatic spin transfer torque proportional to the divergent of the electric field expressed in terms of the electromagnetic vector potential. Furthermore, our result indicates that the effective gauge fields of *any* origin contributes to the torque in exactly the same way as the electromagnetic gauge field.

GC-04. Structural and magnetic study by nonmagnetic (Ti^{4+} and Ga^{3+}) doping at Ru site in $SrRuO_3$.

R. Gupta[1] and A. Pramanik[1]
1. School of Physical Science, Jawaharlal Nehru University, New Delhi, India

Abstract: In this, we report the study of structural and magnetic behavior in Ru-based doped perovskite structure of $SrRuO_3$ and $SrRu_{0.9}M_{0.1}O_3$ (M = Ti and Ga). $SrRuO_3$ has an orthorhombic structure which has not change by Ga as well as Ti doping and also shows decreasing lattice parameters. The $SrRuO_3$ known to as an itinerant ferromagnet (FM) with Tc ~ 160 K and having bifurcation between Zero-field-cooled (ZFC) and field-cooled (FC) magnetization below T_c which decrease by nonmagnetic (Ti and Ga) doping. Further analysis of dc magnetization shows that the inverse susceptibility (χ^{-1}) in paramagnetic (PM) and high-temperature region fitted by modified Curie-Weiss law (CWL) in the form of $\chi(T) = \chi_0 + [C/T-\theta_p]$, where θ_p is the Curie temperature. The effective PM moment ($\mu_{eff} = [3k_BC/N]^{1/2}$) and θ_p decreases by nonmagnetic (Ti and Ga) doping. The χ^{-1} (T) revealed some upward deviation by nonmagnetic (Ti and Ga) doping from perfect CWL behavior above T_c because of the formation of FM clusters in the PM background which has characterized as Griffiths phase (GP). The critical exponent (β) fitting of FC magnetization of $SrRuO_3$ near T_c shows as mean-field type behavior and fitted in the form of $M(T) = M_0(T_c\text{-}T)^\beta$. By nonmagnetic (Ti and Ga) doping, the value of β has increased. The isothermal magnetization at 5 K of $SrRuO_3$ is showing hysteresis which is not changed by nonmagnetic (Ga and Ti) doping and also saturation moment (μ_H) has decreased. The Arrott's plots are confirming FM nature with the value of spontaneous magnetization (M_S) which decreases by nonmagnetic (Ti and Ga) doping. The observation of Rhodes-Wohlfarth ratio shows, the value of q_c/q_s increased by nonmagnetic (Ti and Ga) doping, showing the itinerant nature of $SrRu_{0.9}M_{0.1}O_3$ (M = Ti and Ga) compounds increase, where $S=q_c/2$ in $\mu_{eff} = g[S(S+1)]^{1/2}$and $q_s = \mu_H$. INTRODUCTION In the strongly correlated oxides, there have been large interrelation effects between charge, spin, lattice and orbital ordering which gives various types of phenomena such as metal-insulator transition, superconductivity (SC), colossal magnetoresistance and multiferroics. Among them, the Ru-based 4d transition metal oxides are of current interest because a variety of physics are coming out due to the combined effect of electron correlation (*U*) as well as spin-orbit coupling (SOC). After the discovery of SC in Sr_2RuO_4, the $SrRuO_3$ has quite an interest. $SrRuO_3$ is the rare example of 4d based itinerant FM with T_c ~ 160 K [1], and due to crystal field splitting, $SrRuO_3$ adopts low spin state by 4 electrons of Ru^{4+}($4d^4$, 0.62 Å) orbitals occupy in t_{2g} state and leave the higher e_g state empty under octahedral crystal formation. The theoretically calculated saturation moment of $SrRuO_3$ is 2 μ_B/f.u ($\mu_H = gS\mu_B$, S = 1) but the experimentally observed saturation moment is ~ 1.4 μ_B/f.u even 30 T of high field believed due to itinerant nature of magnetism [4]. The itinerant FM follows the stoner criteria of magnetism i.e. $UN(\varepsilon_F) \geq 1$, where $N(\varepsilon_F)$ is the density of state (DOS) at Fermi level [5]. So by change in U or $N(\varepsilon_F)$, the stoner criteria will be modified, as our previous study [2]. With this motivation, we compare the nonmagnetic doping in $SrRu_{0.9}M_{0.1}O_3$ (M = Ti and Ga) in which U is same, but $N(\varepsilon_F)$ are different. Further, the similarities between Ti and Ga is that both are non-magnetic and the ionic radii match (Ga^{3+} = 0.62 Å and Ti^{4+} = 0.605 Å). The main difference between Ga and Ti is DOS which increases in Ga doping and decreases by Ti doping, and in Ga doping one another change is the charge state disorder. So by considering these similarities and dissimilarities, we study the structural and magnetic properties. Results and Discussion The X-ray diffraction (XRD) patterns of $SrRu_{0.9}M_{0.1}O_3$ (M = Ti and Ga) compounds crystallize in a single phase without any new peak. The Rietveld refinement of XRD data of $SrRuO_3$ forms an orthorhombic-Pbnm structure which also sustained by Ti as well as Ga doping at Ru^{4+} (0.62 Å) site. The lattice parameters decrease by nonmagnetic (Ti and Ga) doping at Ru site [3]. Our observation of decreasing lattice parameters is the formation of Ru^{5+}(0.565 Å) due to Ga^{3+} (0.62 Å) similar charge amount by Ga doping and due to less ionic radii of Ti^{4+}(0.605 Å) by Ti doping. $SrRuO_3$ has shown the PM-FM phase transition at ~ 160 K and follow the Curie-Weiss law (CWL) in the paramagnetic state and high-temperature region. By Ti and Ga doping, the value of Curie temperature (θ_p) and μ_{eff} decreases. There is some upward deviation from perfect CWL due to ferromagnetic cluster formation in the PM background reveal as Griffiths phase (GP) just above T_c. In the ferromagnetic phase, there is more bifurcation between ZFC and FC magnetization which is decreases by nonmagnetic (Ti and Ga) doping. Below T_c, the critical exponent fitting of $SrRuO_3$ gives β ~ 0.5 is showing mean field type behavior. The value of β increases by nonmagnetic (Ti and Ga) doping at Ru site. The isothermal magnetization of $SrRuO_3$ shows hysteresis which also sustained by nonmagnetic (Ti and Ga) doping at Ru site with decreasing saturation moment (μ_H). The Arrott's plot confirms the FM state with the value of M_s and by nonmagnetic (Ti and Ga) doping, the value M_s decreases. CONCLUSIONS The polycrystalline samples of $SrRuO_3$ and $SrRu_{0.9}M_{0.1}O_3$ (M = Ga and Ti) compounds have been prepared by solid state reaction method.

Plasmonic nanostructures enable strong local enhancements of the optical field in areas that are substantially smaller than the wavelength of incident light. This remarkable capability, which underpins the rapid expansion of research into nanophotonics, also offers prospects for magnetic switching. In heat-assisted magnetic recording (HAMR), plasmonic near-field transducers reduce the switching field of high-anisotropy materials via local heating [1,2]. Besides, plasmonic nanoantennas can confine ultrafast all-optical switching effects to areas that are much smaller than the laser spot [3]. In both examples, noble-metal plasmonic elements are integrated with the magnetic medium that needs to be switched. Despite stronger ohmic damping, magnetic metals also support the excitation of surface plasmon resonances [4,5]. Here, we explore the possibility of using the magnetic material itself as a plasmonic nanoantenna and demonstrate that the excitation of surface plasmons enhance the optical switching efficiency. We focus on an array of circular Ni nanoparticles exhibiting strong magneto-optical activity and magnetic circular dichroism [6,7]. The particle diameter and height are 100 nm and 110 nm, respectively, and the periodicity of the square lattice is set to 420 nm. The optical transmission spectrum of the array has an asymmetrical Fano-type line shape, which originates from hybridization between broad localized surface plasmon resonances in the Ni nanoparticles and sharp diffracted orders of the lattice. Thus, the optical field within the Ni nanoparticles vary strongly with the wavelength of incident light. We perform two types of experiments using a variable-wavelength femtosecond laser. After saturating the nanoparticles in a perpendicular magnetic field, we use femtosecond laser pulses to (1) demagnetize the nanoparticles in zero magnetic field or (2) switch the magnetization in a magnetic field, more than one order of magnitude smaller than the coercive field. In both cases, we find that the threshold laser fluence for demagnetization or magnetic switching varies with the wavelength of incident light in a similar fashion as 1/E (Fig. 1(a)), where E is the optical extinction of the array. The lowest threshold fluence thus coincides with maximum optical absorption at a wavelength of 660 nm. From this correlation, we conclude that plasmon-induced heating of the Ni nanoparticles to their Curie temperature of 600 K causes demagnetization and field-assisted magnetic switching. Model calculations of the threshold fluence based on plasmon-induced heating of the Ni nanoparticle array confirm the experimental results (Fig. 1(b)).

Switching the magnetization of nanoscale magnetic dots is one of the most crucial processes for use in electronics applications such as MRAM [1,2] and logic [3,4]. The unique ability to switch magnetization entirely optically has been shown possible in a limited selection of materials often using either circularly polarized or linearly polarized light [5,6]. The material GdFeCo, however, is rare in that it can be switched all-optically without the need for a particular polarization of light, and for which the switching occurs on ultrafast, picosecond timescales [7,8]. This work explores the potential for use of GdFeCo in nanoscale ultrafast magnetic devices. To do so, we first fabricate nanoscale dots of the magnetic material, and then we experimentally determine its all-optical switching (AOS) properties down to nanometer dot dimensions. Previous works have mostly focused on micrometer scale dots of GdFeCo [8-11], with some work down to 400 nm squares [12], but with vortex-like in-plane magnetization states. Here, we first demonstrate helicity-independent all-optical switching in GdCo, a material chosen for stronger perpendicular magnetic anisotropy (PMA) than GdFeCo but with similar ferrimagnetic properties; furthermore, we achieve reliable AOS down to 200 nm diameters. The greater challenge to scaling was maintaining the perpendicular magnetic anisotropy for smaller dot dimensions, as was found to be a challenge in [12]. While ion milling is a common method for patterning MTJ pillars for MRAM, it was found to destroy the integrity of the PMA. Instead, a lift-off process with electron-beam lithography was used to pattern the nanodots, ranging in size from 15 μm down to 50 nm, into arrays. Each dot size of diameter d was arrayed with a pitch of 3d in a 25 μm x 25 μm square region, as shown in Fig. 1. The pitch was chosen to be large enough to prevent magnetistatic coupling between the dots, while simultaneously allowing a high areal density of the dots for maximum magnetic signal during subsequent optical measurements. Although up until now, AOS experiments focused on GdFeCo films, such films did not sustain their PMA below approximately 900 nm diameters. Rather than GdFeCo, this work utilizes GdCo, with high cobalt concentrations to contribute stronger PMA [13]. The nanoscale dots were fabricated from a material stack of Ta (3)/Pt (3)/$Gd_{30}Co_{70}$ (10)/Pt (5), where layer thicknesses in nanometers are indicated in parentheses. Despite the exclusion of iron, these material films still exhibit AOS, as shown in Fig. 2, therefore expanding the library of materials with the capability of ultrafast helicity-independent all-optical switching. Single shots of a Ti-Sapphire laser with pulse width of approximately 70 fs were shot at an array region with uniform sizes of nanoscale dots. Afterwards, a train of laser pulses with much lower power, having a repetition rate of 252 MHz modulated by a photoelastic modulator at 50.028 kHz, was used to detect the magnetization state by Magneto-Optical Kerr Effect (MOKE). For each dot size, a hysteresis loop was first measured and used to identify the signal levels corresponding to the two magnetization states, as detected by laser MOKE. Then, illustrated in Fig. 2, AOS tests were executed with single shots of the laser, followed by MOKE detection of the magnetization state. The conventional toggle switching associated with GdFeCo films was successfully observed in these GdCo dots for each of the nanodot sizes, down to the smallest detectible diameter of 200 nm. Such results are demonstrated in Fig. 2 for the 200 nm dots, where Fig. 2b and 2c present the laser MOKE hysteresis loop and the single-shot toggle switching results, respectively. Slight variation in the MOKE intensity levels was seen for each of the two magnetization states, however a clear gap between the two states is consistently seen; variation is assumed to be due to drift of the laser power and shift in its overlay position in the nanodot array, leading to a change in the number of nanodots being detected. Using laser MOKE as the detection technique, AOS was confirmed down to 200 nm dot diameters, representing the smallest patterns optically switched to date. There is a high probability that smaller dots are also switched all-optically, however, detection of the magnetization state was not possible due to the laser diffraction limit and decrease in the detected signal level. Nevertheless, by demonstrating the possibility of scaling the AOS effect in GdCo nanoscale dots, we bring these materials one step closer to realistic applications. Acknowledgement Funding and support for this work was provided by the Center for Energy Efficient Electronics Science. Part of this work was performed at the Marvell Nanofabrication Laboratory at the University of California Berkeley, and the Stanford Nanofabrication Facility and Stanford Nano Shared Facilities at Stanford University.

The interaction between magnon and photons in cavities has attracted much attention in the past few years. The material of choice is the electrically insulating ferrimagnetic insulator yttrium iron garnet with exceptional high magnetic quality. The interest has, on one hand, been focused on (infrared) light scattering in monolithic YIG spheres that act as spherical optical resonators. On the other hand, both YIG spheres and films have been loaded into microwave cavities, from which the magnetization dynamics could be read-out by microwave transmission/reflection spectra or, electrically, with heavy metal contacts. In this talk I will report our theoretical efforts to understand experimental results and predict new effects in both research areas, both published [1-4] and unpublished.

GC-08. Cavity Spintronics.

C. Hu[1]
1. Department of Physics and Astronomy, University of Manitoba, Winnipeg, MB, Canada

Cavity Spintronics [1] (also known as Spin Cavitronics) is a newly developing interdisciplinary field that brings together microwave cavity community with researchers from spintronics. This field started around 2014 when it was found that ferromagnets in cavities hybridize with both microwaves and light via light-matter interaction [2-5]. Since then, the emergence of this field has attracted broad interests. At the center stage of the topic is the physics of a quasi-particle called cavity magnon polariton (CMP) [5,6]. Via the quantum physics of spin-photon entanglement on the one hand, and via classical electrodynamic coupling on the other, CMP connects some of the most exciting modern physics, such as quantum information and quantum optics, with one of the oldest science on the earth, the magnetism. In this new community, the focus so far is on the development of cavity-mediated coupling and transducing techniques for both spintronic and quantum applications. This stream of research, including our recent demonstration of cavity- mediated distant control of spin current [7], roots on the single-particle hybrid nature of CMP. In this talk, we will present a new feedback-coupled cavity-spintronic technique, which we develop to study the cooperative dynamics of trillions of CMP. Utilizing the coherent dynamics of CMP ensembles, we demonstrate the control of magnon-photon Rabi frequency by changing the photon Fock state occupation, and we discover the evolution of CMP to cavity magnon triplet and cavity magnon quintuplet [8]. Our results may open up new avenues for exploiting the light-matter interactions using cavity spintronic approach.

GC-09. Tunable magnon photon coupling using a BLIG ($(LuBi)_3Fe_5O_{12}$) film and a split ring resonator.

M. M[1], S. S[2], G. Venkat[1], K. Arunachalam[2] and A. Prabhakar[1]
1. Electrical Engineering, Indian Institute of Technology Madras, Chennai, India; 2. Engineering Design, Indian Institute of Technology Madras, Chennai, India

Split ring resonators (SRR) are a common metamaterial with good microwave absorption, ease of fabrication, low weight and they can be hybridized with complementary metal-oxide-semiconductor (CMOS) platforms. The planar SRR structure also allows coupling of microwave photons and magnons. The photon-magnon coupling strength needs to be greater than the mean energy loss in each subsystem, and occurs when both sub-systems are close to resonance. In a ferromagnetic system, the magnon bands can be controlled by an externally applied magnetic field or electric current. 3D structures of YIG (Yttrium iron garnet) films were first used to study magnon polariton coupling [1], [2]. Recently, the coupling of SRR and FMR (ferro magnetic resonance) modes have been observed in a planar YIG film placed inside an SRR cavity [3] and an enhanced coupling is experimentally demonstrated in planar YIG kept in an inverted SRR [4]. The photon-magnon coupling strength of a planar YIG film was improved by using with a notch filter on a stub line [5]. Microwave photons also allow for excitation of the higher order spin-wave (SW) modes, which contribute to stronger photon-magnon coupling. Spin waves can be excited in in-plane configurations namely backward volume spin waves and the magnetostatic surface SW. These ferrites find tremendous applications in transport of spin waves, realization of SW based logic and microwave devices etc, [6]. Unlike a 25 μm YIG used in [3], we use a bismuth lutetium iron garnet (BLIG) epitaxial film of thickness 7.9 μm, grown over gadolinium gallium garnet substrate. BLIG films are known to have better Faraday coefficients, than YIG, which could influence the photon-magnon coupling. A SRR of dimensions as shown in Fig. 1 was simulated in HFSS and resonant frequencies of 2.5 GHz, 4.9 GHz and 7.5 GHz were obtained. We fabricated the SRR on a Roger substrate (ε ~ 3.66), with copper lines of thickness 35 μm, ensuring a 50 Ω termination. The characterization setup consists of a 20 GHz RF signal generator (Hittite), an RF circulator and a spectrum analyzer (Rhode & Schwarz). An electromagnet and a Gauss meter are used to apply the static in-plane magnetic field, in a direction perpendicular to the microstrip line. We used the flip chip method for placing the BLIG film in the cavity on top of a microstrip line, and excited spin waves at ferromagnetic resonance [3]. The RF current flowing through the microstrip line also excites microwave photons in the SRR. A static applied magnetic field, greater than 200 Oe, saturates the BLIG film while the resonant fields of the SRR cause the magnetization to precess and excite SWs. We place the BLIG film to cover the SRR and a part of the microstrip line, and vary the excitation frequency from 2 to 5 GHz and the applied field from 200 Oe to 750 Oe. The power spectral density was measured on the spectrum analyzer. In post processing, we obtain the transmission (S_{21}) characteristics, and plot it against applied magnetic field, to obtain the spectra shown in Fig. 2(a). We observe an SRR mode at 3.17 GHz, which does not change with the field variations. Along with that, we also observe FMR modes whose resonant frequency varies linearly with the applied field. For a field of 435 Oe, we observe the appearance of a small dip at 2.75 GHz, which keeps shifting to the right as we increase the field. In Fig 2(b), we plot the frequencies corresponding to all the dips as observed in Fig. 2(a) apart from those corresponding to SRR dips. We observe a splitting of the spin wave mode resulting from a strong coupling between the microwave photons and magnons. The anti-crossing of the dispersion curves is a consequence of the coupled oscillation of the magnon-photon pair. We are in the process of studying this coupling in other spin wave systems such as magnonic crystals and aim to contribute to the state of the art in the performance of planar microwave devices.

GC-10. Microwave to optical photon conversion by means of travelling-wave magnons in YIG films.

M. Kostylev[1] and A. Stashkevich[2]
1. University of Western Australia, Crawley, WA, Australia; 2. LSPM (CNRS-UPR 3407), Université Paris 13, Villetaneuse, France

The magnon-based microwave-to-light converter is very attractive from the viewpoint of enlarging the potential of the superconducting qubits [1-6]. The first conversion stage of this device is based on coherent coupling between a ferromagnetic magnon and a microwave photon generated by a superconducting qubit. The next stage is up-converting from the microwave domain to the optical one. This proceeds through coupling of the excited microwave magnons to optical photons via magneto-optical interactions. In this way, coherent connection between distant superconducting qubits can be implemented. Currently this research focusses on standing-wave spin wave resonances (the uniform Kittel mode) in yttrium iron garnet (YIG) spheres as the microwave magnons to be coupled to light. In this paper, we investigate theoretically an alternative solution to the problem of magnon-to-light conversion. We consider scattering of guided optical modes from travelling magnetostatic spin waves in a YIG film [7] as a method for the up-conversion. Similar to theroretical treatment of other types of upconverters, we use the classical approach to solve the problem and then apply the standard formula [8] to the obtained result in order to calculate the quantum efficiency. The calculation separates into two stages. The first stage is a calculation of the rate of conversion of microwave photons (which are supposed to be generated by qubits) into travelling magnons. To this end, we develop a very precise self-consistent theory of excitation of spin waves in YIG films with microwave stripline transducers of an arbitrary shape. Our calculations show that excitation of travelling spin waves by asymmetric coplanar transducers can be very efficient – one can reach a conversion rate of microwave photons into magnons of almost 90% (Fig. 1). As a spin-off result of this calculation, we find that the asymmetric coplanar based device represents a very efficient microwave isolator needed for isolating a qubit from noise in the microwave circuit to which it is connected [9]. In the next stage of the calculation, we evaluate the efficiency of magnon to light conversion based on the theoretical approach from [10]. We find that the process of traveling magnon to guided light conversion in YIG films is much more efficient than employing the Kittel mode in a YIG sphere. The potential improvement in the total (both stages together) conversion rate is by four orders of magnitude (Fig. 1). We also speculate that there is plenty of room for further increase in efficiency by recycling light through forming an optical ring resonator from the film. If the length of the ring is larger than the free propagation path for spin waves, no traveling spin wave resonances with a discrete spectrum will be formed in the ring. Our estimation predicts that in this arrangement the microwave to optical photon conversion rate can reach the same record level as achieved with optomechanical systems (10% or so) [11].

Current-driven spin-orbit torque (SOT) has attracted great interest as they can control the magnetization in heavy metal (HM)/ferromagnetic metal (FM) heterostructures with perpendicular magnetic anisotropy (PMA). The polarized spin current will be generated in HM layer with strong SOC due to Spin Hall Effect (SHE), which will diffuse into the adjacent FM layer and exert torques on the moments via spin transfer torque. On the other hand, SOT can also arise from the interfacial Rashba effect, for which the accumulated spins at the interface can force the moments to change its direction by direct exchange coupling [1-7]. In this work, we investigate the magnitude of SOT in perpendicularly magnetized Pt (6)/Co (1)/X trilayers with different capping layers (X=AlO_x, TaO_x, TiO_x, or W) (thickness in nanometer and composition from bottom to top). In these trilayer systems, both the bottom Pt/Co and top Co/X interfaces are utilized to generate SOT via bulk SHE effects and/or Rashba effect. By the selection of capping layer X, one can expect a modulation of these two SOT contributions, which provides an interesting prospect for enhancing strong SOT and the efficient current-induced magnetization switching through a proper combination of materials in the structural engineering. The film was patterned into a Hall bar as shown in Fig. 1(a) using EBL and followed by an Ar ion milling technique. The Hall resistance (R_H) as a function of the out-of-plane magnetic field was presented in Fig. 1(b), which is measured at various DC source current. The changes of a source current cause the coercivity shifts, which are ascribed to the interfacial effect on HMs/FM and/or FM/X, Joule heating effect, and perpendicular anisotropy as well. R_H-I curves were measured with different in-plane magnetic field and presented in Fig. 2. The resistance changes corresponding to the magnetization switching of fully downward and upward state of the films are from 0.2 to 0.5 Ω with the current swept. In conclusion, we investigated the electric current induced SOTs where ultrathin Co is sandwiched between Pt and different capping layers. In these perpendicularly magnetized Pt/Co/X trilayers, we observed strong PMA and SOT effect, which indicate that the effective SOT field can be tuned by using dual interfaces (top and bottom) with different materials.

GD-02. Charge-spin current interconversion in epitaxial systems: symmetric spin-torque ferromagnetic resonance scan but not infinity spin Hall angle.

S. Petit-Watelot[1], C. Guillemard[1], S. Andrieu[1] and *J. Rojas-Sánchez*[1]
1. Institut Jean Lamour - CNRS - Univ. Lorraine, Nancy, France

The conversion of spin current into charge current and vice versa are playing a key role in new research lines in spintronics and related applications. This interconversion can be achieved without any external magnetic field neither magnetic material in 3-Dimensional systems with strong spin-orbit coupling, namely the spin Hall effect (SHE). The quantification of the efficiency of such interconversion is called the spin Hall angle (SHA). The spin Hall angle determination is thus relevant to find out new materials and applications. Large spin Hall angle have been found in heavy metals like Pt [1-3], Ta and W, and alloys like CuBi and AuW. So far the quantification has been evaluated on polycrystalline samples. As soon as a heavy metal or alloys layer is in contact with a layer of different material then we talk about an effective spin Hall angle due to the loss of spin current injection at the interfaces [1]. Here we report on the investigation of epitaxial s//Fe(6 nm)/Pt(5 nm) bilayers grown by molecular beam epitaxy. s stands for the crystalline [001]MgO substrate. We evaluate the spin-charge current conversion by spin pumping- ferromagnetic resonance (SPFMR) [1,2], where at the resonance condition of the Fe layer it is injected a spin current from the Fe into the Pt layer and subsequently converted into a charge current by the inverse spin Hall effect (ISHE). Towards the proper evaluation of the efficiency it is needed a suitable Fe reference sample to account for the effective spin mixing conductivity at the Fe/Pt interface. We have grown simultaneously the Fe layer for the s//Fe/MgO reference sample as for the s//Fe/Pt. We have patterned slabs of 0.005 to 0.4 mm times 4.1 mm along different crystalline directions. The slabs were placed on top of a grounded coplanar waveguide and the spin pumping voltage is measured along the long direction of the slabs and perpendicular to the external in-plane dc magnetic field applied H_{dc}. We have found that the charge current production Ic along the hard axes, [100]MgO || [110] Fe, is more than twice in the slabs patterned along the easy axes, [110]MgO || [100] Fe. This might mean that the effective spin Hall angle is anisotropic along the different crystalline directions. We have found that the effective spin mixing conductance is also anisotropic and depends on the crystalline directions in epitaxial Fe/Pt bilayers. On the other hand, we evaluate the charge-spin current conversion by spin-transfer ferromagnetic resonance (STFMR), which is somehow the reciprocal dynamic effect that SPFMR. We inject direct microwave frequency charge current in the s//Fe/Pt slabs which is converted into spin current inside the Pt layer due to the SHE. Therefore an oscillating spin current is injected from Pt into Fe layer inducing precessing of its magnetization. This in turn lead and oscillatory radiofrequency resistance which mixed with the rf current allows, at the resonance condition, a detectable dc voltage across the slab using a bias tee [3]. The dc voltage is compound by a mixed of a symmetrical lorenztianne and and antisymmetrical one around the resonance field. In the simple model, the quantification of the effective SHA is proportional to the ratio of the symmetrical lorenztianne voltage over the anti-lorenztianne one, V_{symm}/V_{anti}. The sample is from the same batch used for the SPFMR study. Moreover, the slabs for STFMR and SPFMR were patterned simultaneously by standard UV lithography. The slabs for STFMR study have lateral sizes of 20 μm × 90 μm. We show that by STFMR we can also account for the in-plane magnetic anisotropies, i.e, the easy (hard) axes when H_{dc} is parallel to [110]MgO ([100]MgO) as observed in Fig. 1. When the resonance field is large enough to consider uniform precession of the magnetization we found that the effective spin Hall angle (0.055) is similar that previous values reported [1,3]. In this case, we have found similar values when H is applied along different crystallines directions. Let's remember that in this technique the dc voltage is picked up at 45° of the applied H_{dc} instead of 90° as in SPFMR method. Interesting however, we can observe a fully symmetrical lorenztianne curve in STFMR scans when H_{dc} is applied parallel to the hard axes and tuning the microwave frequency. Nevertheless, it does not mean and infinity spin Hall angle of the Pt layer. It is a consequence of the overlapping of the two resonance modes observed when H_{dc} is applied along the hard magnetocrystalline axes. Our results thus highly the importance of taking care of the proper conditions to the estimation of the spin Hall angle as well as the anisotropic spin mixing conductance and effective charge current production in epitaxial FM/HM systems. Therefore it opens a room to exploit epitaxial systems tuning the effective spin-current interconversion by choosing different crystalline directions.

GD-03. Nonvolatile memory devices with magnetic nanowires controlled by spin-transfer and spin-orbit torques.

S. Fukami[1] and H. Ohno[1]
1. Tohoku University, Sendai, Japan

Efficient manipulation of magnetization direction in magnetic nanostructures is of crucial importance for realization of low-power and high-performance nonvolatile spintronics memory devices. Spin-transfer torque (STT) induced magnetization switching in magnetic nanopillars, or magnetic tunnel junctions, has been a leading technology in this field and is about to hit the market as a spin-transfer torque magnetoresistive random access memory (STT-MRAM). In STT-MRAM, the memory element typically has two terminals and magnetization is switched through a spin angular momentum transfer by applying vertical currents. In the meantime, recent researches have opened another possibility of nonvolatile spintronics devices with magnetic nanowires, where the magnetization is controlled by horizontal currents. Such devices typically form a three-terminal architecture [1] and magnetization can be controlled by current-induced domain wall (DW) motion [2,3] or spin-orbit torque (SOT) induced magnetization switching [4,5]. The three-terminal architecture provides a relaxed control of parameters and potential to operate at higher frequency at the cost of cell size compared with the two-terminal counterpart, making the devices an attractive option for integrated-circuits applications [1]. In terms of physics, moreover, the above two schemes complete magnetization switching with characteristic dynamics by torques with a different symmetry from the STT switching, offering unique attributes that are not seen in STT switching. In this presentation, we show recent advances in controlling the magnetization of nanowires via the DW motion and SOT switching. We particularly focus on the characteristic features of the SOT switching and discuss their impact on integrated circuit applications. One of the unique aspects of SOT is an orthogonal relation with the Gilbert damping torque when one utilizes perpendicular easy axis systems. For STT devices, because the damping torque acts in the antiparallel direction to STT, one needs to employ material systems with low damping, which in general has positive correlation with magnetic anisotropy that ensures thermal stability. For SOT devices, on the other hand, due to the orthogonal relation, one can employ high anisotropy materials even with high damping. As a result, electrically controllable memory elements with high thermal stability are expected. We have studied a SOT switching in nanowires with a Co/Pt multilayer having a high magnetic anisotropy and damping [6]. The fabricated nanowire devices show high thermal stability factor, given by a ratio of the energy barrier to the thermal fluctuation energy, of much greater than 100, and magnetization switching driven by current. In addition, we have found that a switching efficiency, defined as an anisotropy energy density divided by switching current density, increases with the stacking number of Co/Pt bilayer. This fact suggests that the SOT is generated in the Co/Pt multilayer despite a structural inversion symmetry, implying an unknown mechanism of SOT generation, as pointed out in a previous work [7]. The obtained results show promise for use in integrated circuits used in wide temperature ranges. The SOT acting in the orthogonal direction to the damping torque also provides a high-speed magnetization switching capability. The STT switching proceeds with a precessional motion and its threshold current is known to increase with an inverse of pulse duration below about a few nanoseconds. In contrast, for the case with SOT, a theory predicts an immediate magnetization switching as soon as the torque is exerted, resulting in a less pulse duration dependence of the switching current [8]. To elucidate this difference experimentally, we have studied a pulse duration dependence of the switching current density for two kinds of in-plane magnetized geometries; one shows switching as in the case for STT switching [5] and the other is expected to show a switching by orthogonal spins [9]. It was found that the latter scheme shows virtually constant switching current density with respect to the pulse duration down to 0.5 ns [10]. This result indicates the potential of SOT switching for high-speed memory operated at GHz class. We have also studied the pulse duration dependence of switching current density for perpendicular easy axis systems with W/CoFeB/MgO stacks [11]. In this experiment, we prepared several devices with various sizes to systematically examine the effect of an incoherent reversal with a DW propagation, which is expected to be significant in perpendicular easy axis systems. It was found that, for micrometer-scaled devices, the switching current density significantly decreases with increasing the pulse duration due to the incoherent reversal. The detailed investigation reveals that the nucleation events take place at various sites inside the magnetic dot or wires, and the switching completes by DW propagation among the sites. For devices with a CoFeB/MgO nanodot formed on a W nanowire, on the other hand, less pulse duration dependence of switching current density was observed as in the case for the in-plane system. Thus, the speed of SOT switching crucially depends on the employed device geometry for perpendicular easy axis systems. The authors thank H. Sato, B. Jinnai, and C. Zhang for technical supports and fruitful discussion. This work was supported in part by ImPACT Program of CSTI, JST-OPERA, and JSPS KAKENHI 17H06093.

In the research community, the coupling of spins with a thermal bath has been widely studied for various applications[Choi 2015, Uchida 2008, Hinzke 2011], for example, in waste energy recovery by converting heat to electricity [Bauer 2012]. Non-homogeneous temperature profiles over a spin system, leads to a spin chemical potential that generates a transfer of spins between regions. The first observation of the Spin Seebeck effect in metallic ferromagnets was made by Uchida and co-workers [Uchida 2008]. It was subsequently demonstrated that the effect was not limited to metallic ferromagnets but also occurs in dilute magnetic semiconductors, due to the collective excitation of localized magnetic moments. Since these initial discoveries, the spin Seebeck effect has been demonstrated in a range of magnetic material classes. In this work, we present numerical evidence for the existence of a magnonic Spin Seebeck effect on the sub-picosecond time-scale. By applying femtosecond laser pulses, the local difference in spin temperatures will produce a fast transfer of spin angular momentum from regions with high to low spin temperature. The simulations are done using an atomistic spin dynamics model and the ultrafast laser pulse is described via the two temperature model, which couples the electron temperature to a phonon bath. The electrons heat up to hundreds of Kelvin and cool down in a few picoseconds. The electron temperature has the role of the thermal bath for the spin system, leading to a change in the spin system configuration, which can be described as a spin temperature. The variation of the spin temperature depends on a combination of factors such as bath coupling, exchange interaction, and material properties. Having a bilayer system, with different properties leads to a different effective spin temperature, thereby creating a spin chemical potential resulting in magnon transport between the two layer layers. On top of this, there is a process of equilibration of each layer of spins with the electron temperature and an equilibration of electron temperature with the phonons. To investigate the energy transfer (magnon transport) between regions just due to the spin temperature difference between the layers, we construct a model system where the two layers are divided in two regions with low and high temperature, generated by the laser. The regions are first equilibrated at the corresponding temperature before coupling at the interface. The two regions will have magnons with different energies, leading to an temperature imbalance. To re-equilibrate there will be a net magnon (energy) transfer via the exchange interaction. The spins from the hot region have a higher angular momentum than the ones from the cold regions and, due to the exchange coupling, there is a net energy transfer. Thus high energy magnons from the hot regions will cross the interface and propagate into the cold region. The propagation can be visualised via the change in the net magnetisation normalised to a constant proportional to the noise in the system. This can be observed in figure 1, where the low magnetisation values develop at interface (Fig. 1 (a)) which then propagates into the cold region (Fig. 1 (b)). The speed of propagation is on the order of several km/s. To calculate the magnon transport through the interface, and the propagation of magnons, we used the expression for the energy flux vector similar to the Poynting vector in electromagnetism: [F = dm(x)/dt]X[m(x)] where m(x) is the net magnetisation as function of x, the direction perpendicular to the interface and dm(x)/dt is the rate of change of magnetisation in time. F gives the net flux through a given plane. The maximum change in F is correlated with the front of magnon propagation. Figure 2 illustrates the magnon spin pumping for the first 20 fs. As the propagation advances into the cold region the amplitude decreases, leading eventually to a small fluctuation around zero. This represents the achievement of equilibrium with equal magnon fluxes in both directions. Our results demonstrate ultra-fast transport of magnons due to inhomogeneous spin temperature as present in ultrafast laser experiments in bilayers systems and also in alloys such as GdFeCo.

GD-05. Enhancement of Gilbert damping in NiFe/Pt bilayers with MgO capping layers.

T. Zhu[1] and F. Chang[1,2]
1. State Key Lab for Magnetism, Institute of Physics, Chinese Academy of Sciences, Beijing, China; 2. Institute of high energy physics, Beijing, China

Spin current possesses the capability to manipulate magnetization, as well as electric transport in metals and insulators, which brings potential to develop the multifunctional spintronic devices. Spin pumping is a widely used method to produce pure spin current, in which a processing ferromagnet (FM) pumps out a spin current into adjacent non-magnetic (NM) conductors. The injected spin current is subsequently converted into a transverse charge current, when large spin-orbit coupling exists in this conductor. The conversion efficiency is governed by spin mixing conductance and diffusion length of spin current in NM, in which spin mixing conductance is a characteristic of FM/NM interface and generally reflected from the enhanced Gilbert damping. Here, we have systematically studied the MgO and Al capping layers effect on damping in NiFe/Pt bilayers, by using coplanar waveguide ferromagnetic resonance and inverse spin Hall effect. The NiFe/Pt bilayers with Al capping layer show clearly magnetic proximity effect, meanwhile a significantly interfacial enhancement of damping, and then spin mixing conductance, has been found in the samples capped by MgO layers with potentially major consequences for applications.

GD-06. Influence of W insertion layer in Ta and CoFeB on antidamping-like effective torque efficiency.

I. Cha[1], Y. Kim[1], G. Kim[1], T. Kim[1], K. Garello[2] and Y.K. Kim[1]
1. Materials Science and Engineering, Korea University, Seoul, The Republic of Korea; 2. Imec, Leuvin, Belgium

Introduction Spin-orbit interaction formed by nonmagnetic (NM) and ferromagnetic (FM) materials have received much attention because of their physical principles and various applications. Recent studies reported more complicated and diverse combinations including antiferromagnets and ferrimagnets to understand the origin of spin-orbit interaction [1], [2]. It is still arguable whether the more dominant effect of spin-orbit interaction is due to bulk or interfacial contribution. It is important to find main effect which control spin-orbit interaction for handling a magnetic and electric properties, for example, magnetic anisotropy, coercivity, antidamping- like effective field, field-like effective field and switching current density. In our study, we investigate the magnetic properties and electric properties depending on the W insertion layer thickness and phase. Experimental All samples were deposited by dc and rf magnetron sputtering under the base pressure below $3x10^{-9}$ Torr. Each sample went through post-annealing at $300^{o}C$ for 1 h in a magnetic field of 6 kOe under $1x10^{-6}$ Torr. We used Ta and W as NMs, which are known to have large spin-orbit coupling and spin Hall angle, CoFeB as an FM. We inserted very thin W layer between Ta and CoFeB to observe electrical and magnetic properties changes. The magnetic properties were measured using a vibrating sample magnetometer (VSM) and the electric properties were measured using second harmonics measurement. All samples are patterned using photolithography and dry etching into Hall bar with a dimension of 5 μm x 35 μm. Results and discussion In Ta/W/CoFeB/MgO structures, all samples have perpendicular magnetic anisotropy after $300^{o}C$ annealing. To inspect the dependence of insertion layer, we changed W insertion layer thickness, CoFeB and MgO layer thickness was fixed as 0.9 nm and 1.0 nm to minimize other influence. We observed change of the antidamping-like effective torque efficiency by insertion layer thickness. In case of Ta/CoFeB/MgO structure, the antidamping-like effective torque efficiency is about 6.6 % and the sign is negative. When W 1.5 nm was inserted between Ta and CoFeB, the antidumping-like effective torque efficiency increased three times and the sign was not changed.

GD-07. Optimize Fe/Pt bilayers as efficient spintronic terahertz emitters by tailoring the thickness of the layers and the interface structural properties.

L. Scheuer[1], S. Keller[1], G. Torosyan[2], M. Battiato[3], R. Beigang[1] and *E. Papaioannou*[1]

1. Physics, TU Kaiserslautern, Kaiserslautern, Germany; 2. Photonic Center Kaiserslautern, Kaiserslautern, Germany; 3. School of Physical and Mathematical Sciences, Nanyang Technological University, Singapore, Singapore

Spin Hall effect and its reciprocal, the inverse spin Hall effect (ISHE), provide the means for conversion between spin and charge currents [1,2]. In particular, the ISHE transforms a pure spin current into a transverse charge current due to spin-orbit coupling. Recently, the decisive role of the ISHE effect on extending the field of spintronics into the terahertz (THz) regime was revealed [3,4]. Here, we demonstrate the generation of pulsed broadband terahertz radiation utilizing the inverse spin hall effect in Fe/Pt bilayers on MgO and sapphire substrates. The emitter was optimized with respect to layer thickness, growth parameters, substrates and geometrical arrangement. The experimentally determined optimum layer thicknesses of Fe (2 nm) / Pt (3 nm) were in qualitative agreement with simulations of the spin current induced in the ferromagnetic layer [5]. Our model takes into account generation of spin polarization, spin diffusion and accumulation in Fe and Pt and electrical as well as optical properties of the bilayer samples. Using the device in a counterintuitive orientation a Si lens was attached to increase the collection efficiency of the emitter. The optimized emitter provided a bandwidth of up to 8 THz which was mainly limited by the low-temperature-grown GaAs (LT-GaAS) photoconductive antenna used as detector and the pulse length of the pump laser. The THz pulse length was as short as 220 fs for a sub 100 fs pulse length of the 800 nm pump laser. Average pump powers as low as 25 mW (at a repetition rate of 75 MHz) have been used for terahertz generation. This and the general performance make the spintronic terahertz emitter compatible with established emitters based on optical rectification in nonlinear crystals. Furthermore, we correlate the interface structural properties with the THz-E-field amplitude and the bandwidth of the THz radiation. By allowing the Pt layers to grow along different crystallographic directions on top of Fe we modify the THz emission characteristics of the optimized emitters. We present a theoretical model which correlates the loss of energy of the hot electrons and the electron-phonon/defect scattering lifetime at the Fe/Pt interface with the ISHE current that causes the THz emission. By taking into account the response function of the THz detector we describe the influence of the crystal structure of Pt onto the THz signal shape and spectrum. The demonstration of the role of the individual layer thicknesses and of the interface quality in the THz emission spectra paves the way for more efficient spintronic THz emitters.

GD-08. Spin Seebeck effect in a polycrystalline bulk-YIG fabricated by the sol-gel synthesis.

M. Jang[1] and K. Lee[1]
1. Materials Science and Engineering, Ulsan National Institute of Science and Technology (UNIST), Ulsan, The Republic of Korea

Introduction Spin-caloritronics, based on the spin Seebeck effect (SSE) hold the promise of future sustainable green energy technologies [1-3]. Since a single crystal $Y_3Fe_5O_{12}$ (YIG) has been believed to generate sufficiently high SSE signal owing to its unique features [4], most of experiments have been performed with a single crystal YIG fabricated by a pulsed laser deposition (PLD) method [5, 6]. However, this method is known to be very difficult to use in mass-production and needs to a high technical skill. In contrast, the sol-gel synthesis can offer a low-cost and mass-production method [7]. Here, we demonstrate that a polycrystalline YIG fabricated by a sol-gel synthesis with proper heat-treatments and a mechanical pressing process [8] can generate enough SSE signal. Experiments We prepared the YIG precursor by mixing yttrium nitrate ($Y(NO_3)_3.6H_2O$, 99.99%) and iron nitrate ($Fe(NO_3)_3.9H_2O$, 99.99%) powders in a stoichiometric ratio of 3:5, and adding citric acid ($C_6H_8O_7.H_2O$). The precursor mixture was dissolved in distilled water (100 mL) by stirring (300 rpm) at 27 °C for 18 hours. The solution of the citric acid was maintained at 1pH. The resulting solution (sol) was then stirred for 24 hours at 80 °C to obtain a homogenous gel. Next, a form a dry material (gel) was obtained from the sol by drying the solution, which was decomposed at 100 °C for 5 hours. The YIG powder was obtained by grinding the completely dried gel for 30 minutes. The calcination process was carried out at 850 °C in the air for 2 hours at a heating rate of the 7.7 °C /min to get rid of residual impurities and the crystallization. After, we did the pressing process 150 MPa for 5 minutes not only to produce the substrate-free disk-shaped YIG sample with 1.8 mm-thickness and 14 mm-diameter but also to enhance saturation magnetization (M_S). Lastly, sintering has been done at 1400 °C for 4 hours. To measure the longitudinal-SSE (LSSE), the 15 nm-Pt layer was deposited by an electron-beam evaporation on the surface of a YIG disk. To form temperature gradient along -z direction, bottom surface was heated, and top surface was air cooled as shown in Fig. 1(a). By applying 400-Oe magnetic field parallel to the disk plane (+y direction), magnetization in a bulk YIG aligned along +y direction and thus, it gives rise to the thermoelectric (TE) voltage along x direction through the inverse spin-Hall effect (ISHE) in a Pt layer. Results & Discussion From X-ray diffractometer (XRD), X-ray photoelectron spectroscopy (XPS), and the field-emission scanning electron microscopy (FE-SEM) measurements, we identified complete crystallization with large grain size of 5.4 μm diameter and a remarkable reduction of impurities in the microstructure after the pressing and sintering process. This provides significant enhancement of the M_S value of a YIG as shown in Fig. 1(b), which is 70 % of the ideal M_S value of a YIG. Figure 1(c) indicates a TE voltage induce by LSSE versus temperature difference between top and bottom surfaces of a bulk YIG. We found that the TE voltage is proportional to the temperature gradient and its values are comparable to the TE voltage of single crystal YIG. Our results enabling one to start paving the ways for the use of SSE for practical energy harvesting devices.

GD-09. Anomalous Nernst and Hall effects in ferromagnetic multilayers.

M. Mizuguchi[1,2], H. Suzuki[1], H. Sharma[1,2] and K. Takanashi[1]
1. Tohoku University, Sendai, Japan; 2. JST-CREST, Kawaguchi, Japan

I. INTRODUCTION The interaction between a spin current and a heat current has been studied in a new field of spin caloritoronics since the discovery of the spin Seebeck effect, and a number of thermomagnetic effects related to spin current have been investigated [1,2]. The Nernst effect is a common thermomagnetic effect, that has been known for a long time. When a temperature gradient is applied on a material with spontaneous magnetization, an electric field is induced in the perpendicular direction to both the temperature gradient and the magnetization, which is called the anomalous Nernst effect (ANE) [3,4]. In a previous paper, we reported material dependence of ANE in perpendicularly magnetized ordered-alloy thin films such as $L1_0$-FePt, $L1_0$-FePd, $L1_0$-MnGa, and $D0_{22}$-MnGa[5], and the relation between ANE and uniaxial magnetic anisotropy in the ordered-alloy systems has been clarified. We also reported strong anisotropy in ANE for highly ordered γ'-Fe_4N[6]. Recently, the enhancements of ANE in paramagnet / ferromagnet multilayers have been reported[7-11], though the ANE in ferromagnet / ferromagnet multilayer films with the interface magnetic anisotropy was not investigated systematically so far. In this contribution, ANE in Co / Ni epitaxial multilayer films with various stacking thicknesses was measured and discussed in relation to the interface magnetic anisotropy. Besides, the relation between ANE and the anomalous Hall effect (AHE) was also investigated systematically to clarify the role of spin current in both effects in ferromagnetic multilayers. II. EXPERIMENTALS Epitaxial Co / Ni multilayers were fabricated by molecular beam epitaxy on MgO(111) substrates at room temperature. Total thickness was fixed to 12 nm and each thickness of Co and Ni (Co : Ni = 1 : 2) was varied. ANE and AHE were measured in a physical properties measurement system (PPMS), and the Seebeck effect, the Nernst effect, and the Hall effect were measured at temperatures between 10 and 300 K. A magnetic field perpendicular to the sample plane was applied. Magnetic properties were measured at 300 K using a superconducting quantum interference device (SQUID), and magnetic anisotropy (K_u) for each thin film was evaluated from magnetization curves. III. RESULTS AND DISCUSSION Figure 1 shows magnetization curves for epitaxial Co / Ni multilayer films (each thicknesses Co and Ni are 0.8 and 6.0 nm) measured at room temperature. Co / Ni: 0.8 nm showed the perpendicular magnetization whereas Co / Ni: 6.0 nm showed in-plane magnetization. It was clarified that magnetic anisotropy was successfully varied by changing the each thickness. Figure 2 shows layer thickness dependence of the transverse Seebeck coefficients (S_{xy}) for epitaxial Co / Ni multilayer films measured with out-of-plane magnetic field at room temperature. S_{xy} is derived from the following equation. $S_{xy} = E_y / \nabla T_x$, (1) where E_y and ∇T_x express the Nernst electric field and the temperature gradient, respectively. With increasing the layer thickness, S_{xy} increased till 2.4 nm and decreased for multilayers with in-plane magnetization (6 and 12 nm). As shown in the figure, all Co / Ni multilayers showed larger S_{xy} values than that estimated for bulk $CoNi_2$, implying that interface magnetic anisotropy strongly contributed to ANE. More precise mechanism of ANE in ferromagnetic multilayer systems and the relation between ANE, AHE and magnetic anisotropy will be discussed. IV. CONCLUSIONS ANE and AHE in Co / Ni epitaxial multilayer films with various stacking thicknesses were measured and discussed in relation to the interface magnetic anisotropy. Total thickness was fixed to 12 nm and each thickness of Co and Ni (Co : Ni = 1 : 2) was varied. With increasing the layer thickness, S_{xy} increased till 2.4 nm and decreased for multilayers with in-plane magnetization (6 and 12 nm). All Co / Ni multilayers showed larger S_{xy} values than that estimated for bulk $CoNi_2$, implying that interface magnetic anisotropy strongly contributed to ANE.

GD-10. Thermal contribution to the spin-orbit torque in metallic/ ferrimagnetic systems: the switching temperature.

J. Rojas-Sánchez[1], T. Pham[1], S. Je[2,1], P. Vallobra[1], T. Fache[1], D. Lacour[1], G. Malinowski[1], M. Cyrille[3], G. Gaudin[2], O. Boulle[2], M. Hehn[1] and S. Mangin[1]
1. Institut Jean Lamour - CNRS - Univ. Lorraine, Nancy, France; 2. CNRS, SPINTEC, Grenoble, France; 3. Leti, technology research institute, CEA, Grenoble, France

The spin Hall effect and the electrical manipulation of magnetization, namely spin-orbit torque, are at the core of spin-orbitronic applications. Thus, the possibility to reduce the current density and the external in-plane applied field to switch a perpendicular magnetization are the most important goals towards applications exploiting charge to spin current conversion [1-3]. So far however, the thermal contribution to this phenomenon has been neglected. On the other hand, the use of ferrimagnetic materials starts to draw attention due to the possibility to tune the net magnetization with composition or temperature and even reach zero magnetization at the compensation point [4,5]. Our study [4,5] presents experimental results about the current-induced magnetization switching considering a model W/ Co_xTb_{1-x} as heavy metal/ferrimagnetic bilayer for various compositions and temperatures. We demonstrate that i) the current density is not a minimum at the nominal magnetic composition point, ii) there is a strong thermal contribution which we have quantified, iii) although the sample shows strong perpendicular magnetic anisotropy the external in-plane magnetic field needed for the switching is quite small (i.e 2 mT), iv) the devices has to reach a characteristic switching temperature before the current generate the reversal, T_{switch}(x), and v) T_{switch}(x) increases with increasing Co-concentration x and consequently scales with the Curie temperature T_C(x). Thus, we believe that our discovery of the major importance of T_{switch}(x) which scale with T_C(x) is significance and opens new road for the exploitation of thermal contribution using highly resistivity heavy metal to reduce both the critical current and external magnetic field to achieve the current-switching.

GD-11. Anamalous hall effect in Ultrathin FePt ferromagnetic layer.

J. Yu[1,2], L. Liu[1], J. Deng[1], H. Yoong[1], W. Lin[1], H. Wang[1], H. Liu[2], F. Poh[2], D. Shum[2] and J. Chen[1]
1. Material Science and Engineering, National University of Singapore, Singapore; 2. GLOBALFOUNDRIES Singapore Pte Ltd., Singapore 738406, Singapore, Singapore

The study of anomalous hall effect (AHE) has paved a road to study the origins of spin orbit interactions in materials for spinorbitronics application. Theoretically, the origins of AHE are widely believed to be (1) intrinsic contribution from Berry curvature of the occupied Bloch states($\rho_{xy}\alpha\rho_{xx}^2$), (2) extrinsic contribution from skew scattering ($\rho_{xy}\alpha\rho_{xx}$) and side jump ($\rho_{xy}\alpha\rho_{xx}^2$)[1]. Experimentally, by scaling anomalous hall resistivity with normal resistivity, the origins of spin orbit interaction of many materials were revealed[2, 3]. Recent few years, FePt thin film has attracted a lot of attention in spintronics due to its large intrinsic dominant mechanism [4]. However, only films with substantial thickness were studied because ultra-thin film on MgO substrate contains strain induced grain boundaries [5], making the film non-conductive of electricity. Thus, there is a need to evaluate the origins of spin orbit interaction in thinner FePt on another substrate for its future spintronics application. In this paper of SiO_2(2)/FePt (6, 8, 12 and 20nm)/STO were prepared by using AJA Orion 8 sputtering system with a base pressure lower than 2×10^{-8} Torr. The deposition temperature of FePt was 380 C. The samples were cooled down to room temperature and 2nm of SiO_2 was grown *in situ* as a protection layer against the chemical and physical attack in the device fabrication process. XRD spectrum and VSM loops were measured to ensure good epitaxy growth and good perpendicular magnetic anisotropy (PMA). Then the films were patterned into hall bars with 10um width using laser writer. Transport property were measured using Quantum Design Physical Properties Measurement System. Both VSM and AHE loops shown in Fig 1 testify good PMA of the samples. As shown in Fig 2 (a), (b) anomalous hall resistivity and normal resistivity decreases simultaneously with decreasing temperature shows that anomalous hall resistivity is mainly influenced by normal resistivity. $\rho_{xy}= a\rho_{xx,0}+a'\rho_{xx}+b\rho_{xx}^2$[3] was deployed to fit the data as it can obtain best fit line among all the possible fitting equations. The first term *a* reveals the contribution from extrinsic skew scattering, the second *a′* term is the contribution from phonon scattering and the last term *b* is the combined contribution from extrinsic side jump and intrinsic Berry curvature. The fitting curves are shown in Fig 2 (c). The fitting results of *a′* and *b* are shown in Fig 2 (d). increases with decreasing thickness of FePt reveals that at lower thicknesses, the phonon scattering contributes significantly in the mechanism of AHE. When FePt is with substantial thickness (8nm), the anomalous conductivity *b* remained at 800-900S/cm. This is consistent with the theoretical calculations [4, 6]. However, when the film is thin, *b* decreases significantly. This shows that the intrinsic contribution is suppressed while the extrinsic origins plays an important role in AHE of ultra-thin FePt.

GE-01. Chiral Majorana Fermion Modes in a Quantum Anomalous Hall insulator-Superconductor Structure for Topological Quantum Computing.

K. Wang[1]
1. Departments of ECE, Physics and Astronomy, and MSE, University of California, Los Angeles, Los Angeles, CA, United States

In 1937, Ettore Majorana proposed a particle being its antiparticle. Since its inception, Majorana has been under intensive pursuit both theoretically and in experiments. Recent interest in robust topologically protected quantum computing has accelerated the experimental quest of Majorana. Among various proposals, I will discuss the scenario when a topological insulator meets a superconductor. This system offers a possible host for Majorana. The talk will begin from the experimental efforts of the quest of dissipationless transport: quantum Hall without magnetic field, quantum spin Hall to quantum anomalous Hall (QAH). The latter was enabled by a long term effort in the materials growth of topological insulator - magnetic (Cr) doped BiSbTe to achieve reliably QAH. I will discuss the topological transitions of Dirac electrons of TI in QAH as illustrated in Fig. 1, in which a zero plateau is illustrate due to the gap by the hybridization of two surfaces of TI. The material structure is illustrated in high resolution TEM shown in Fig. 2. When the QAH edge states interface with a superconductor, the Dirac electron space is transformed to the Nambu space, hosting Majorana fermions via pairing energy of the superconductor (Fig. 3). We will describe our experimental efforts to show the convincing evidence of quantized signature of the one-dimensional chiral Majorana fermion. A half-integer quantized conductance plateau (0.5 e^2/h) gives a firm signature of the elusive Majorana fermion for the first time by scanning topological phase transitions under the reversal of the magnetization as shown in Fig. 4 [1]. This finding gives a new direction for robust topological quantum computing to minimize the de-coherence challenge. I will discuss several possible pathways for realizing the elemental qubits and operations. The use of QAH is of critical importance as the dissipationless edge state of QAH offers a long coherent length in mm length scales; this is the key for scaling to a large number of quantum bits. One of these approaches is to pattern a 2-dimensional structure into nanowires, which make the Majorana Chiral modes into zero modes, for which quantum bits may be coded. *The work was in part supported by DoE ERFC-SHINES, ARO MURI, FAME, CEGN and NSF.

GE-02. Superconducting exchange coupling and spin currents between ferromagnets.

M.G. Blamire[1]
1. Materials Science, University of Cambridge, Cambridge, United Kingdom

Conventional spintronics research aims to achieve active electronic control of the magnetic state of a device – for example via non-equilibrium spin current flow generating spin transfer torque switching [1] or the movements of magnetic domain structures [2]. Underpinning the function of such devices is passive exchange coupling between magnetic layers: for example, exchange bias between an antiferromagnet and a ferromagnet which prevents the low-field reversal of one magnetic layer and hence underpins the operation of the spin valve [3], and the Ruderman-Kittel-Kasuya-Yosida (RKKY) coupling between ferromagnets which is required for the observation of giant magnetoresistance in magnetic multilayers [4,5]. The field of superconducting spintronics[6,7] has followed the same path as conventional spintronics with primary attention being focused on the generation and propagation of spin currents (triplet [8,9] or quasiparticle [10]) and the active effects of such currents on magnetic elements. The founding paper in superconductor / ferromagnet field was published in 1966 by de Gennes [11] who predicted that a trilayer ferromagnetic insulator / superconductor / ferromagnetic insulator (FI/S/FI) device, later called a superconducting spin switch, should have a much lower critical temperature (T_c) when the FI magnetisations are parallel (P) compared with the antiparallel (AP) configuration. This prediction of a controllable T_c was experimentally realised quickly [12,13], but it was only recently that large changes (~1 K) in T_c (ΔT_c) could be achieved [14]. De Gennes made a second prediction in his paper[11] which has been largely overlooked: the control of T_c by the magnetic configuration implies that the superconductor condensation energy depends on the relative alignment of the ferromagnetic layers. If the ferromagnet layers are AP and T_c is maximised, then the total free energy is minimised. Thus there is an antiferromagnetic coupling between the FI layers mediated by the superconductivity of the interlayer (the superconducting exchange coupling which is the primary research focus for this proposal). Our experiments [15] are based on GdN/Nb/GdN superconducting spin switches (see Fig. 1). GdN is a FI which we have studied extensively as a barrier in S/FI/S superconducting tunnel junctions [16-19]. As shown in Fig. 1a these devices show both the largest values of ΔT_c ever recorded (which can exceed 1.5 K) and infinite magnetoresistance – i.e. a complete switch between zero and full resistance over an extended temperature range (Fig. 1b). However, the key discovery is the observation of a significantly enhanced coercive field for the harder GdN layer (see Fig. 1c) which increases as the temperature is reduced below T_c which implies the onset of an antiferromagnetic exchange coupling which is in quantitative agreement with the original prediction [11]. This paper will explain the results and discuss the significance of superconducting exchange coupling in the development of practical superconducting spintronic devices. It will also report recent results which demonstrate triplet pair mediated spin current transport through superconductors – another essential ingredient for superconducting spintronics.

GE-03. Domain Imaging Across the Magneto-Structural Phase Transition in $Fe_{1+y}Te$.

J. Warmuth[3], M. Bremholm[1], P. Hofmann[2], J. Wiebe[3] and R. Wiesendanger[3]
1. Department of Chemistry, Aarhus University, Aarhus, Denmark;
2. Department of Physics and Astronomy, Interdisciplinary Nanoscience Center (iNANO), Aarhus University, Aarhus, Denmark; 3. Department of Physics, Hamburg University, Hamburg, Germany

$Fe_{1+y}Te$ is the non-superconducting parent compound of $Fe_{1+y}Se_xTe_{1-x}$, in which superconductivity is induced by the substitution of Te with Se [1]. Such Fe-chalcogenides form the structurally simplest material group of all Fe-based superconductors and they are therefore the ideal compound for a fundamental investigation of the complex mechanisms leading to superconductivity in these materials [2, 3, 4, 5,6]. So far, the complex interplay of magnetic and structural phase transitions in $Fe_{1+y}Te$, which crucially depends on the amount of excess Fe, *y*, has been mostly investigated by spatially averaging techniques such as neutron diffraction, magnetic susceptibility, and resistivity measurements [4, 7, 8]. Our specially and spin-resolved scanning tunneling microscopy (STM) study presents, with respect to previous investigations, a major advancement simultaneously revealing the local structural and spin order at the surface of $Fe_{1+y}Te$ compounds with atomic resolution. For low values of excess Fe, $y < 0.11$, a simultaneous magnetic and structural, so-called magneto-structural, transition from a high-temperature paramagnetic tetragonal to a low-temperature monoclinic phase with a diagonal double-stripe antiferromagnetic spin structure [9] was observed. The transition temperature T_N of this phase transition decreases with increasing *y*. For $y > 0.13$ there is a magneto-structural transition from the tetragonal phase into an incommensurate antiferromagnetic orthorhombic phase upon cooling [10, 11]. Most notably, for $0.12<y<0.13$, it was suggested that, upon cooling, the system first transforms from the tetragonal phase into an intermediate incommensurate antiferromagnetic orthorhombic phase and consecutively into a mixture of the incommensurate antiferromagnetic orthorhombic and the monoclinic phase, suggesting a tricritical point at y=0.11 [4]. However, a detailed understanding of the proposed mixed phase and its evolution on a microscopic level were so far lacking. Here, we present a real space spin-resolved STM investigation of the surface of $Fe_{1+y}Te$ single crystals with different excess Fe content, *y*, which are continuously driven through the magneto-structural phase transition. For $Fe_{1.08}Te$, the low-temperature monoclinic commensurate antiferromagnetic phase [9] exhibits a well-defined three-dimensional surface corrugation upon cooling below T_N, clearly visible in the three-dimensional representation of a large-scale STM image shown in Fig 1 (a). The magneto-structural phase transition is mapped by STM images continuously acquired while crossing T_N revealing the emergence and annihilation of the surface corrugation Fig. 1 (b). The STM investigation reveals that four types of surface domains are formed at the surface of $Fe_{1.08}Te$ in the monoclinic phase. These domains exhibit four different orientations of the same surface inclination and form two types of domain boundaries. The spin-resolved STM image displayed in Fig. 2 (a) shows that the four domains (red, blue, green, and yellow) exhibit different orientations of the monoclinic lattice and of the antiferromagnetic order at the surface (Fig. 2 (b)) indicated by the red and blue arrows. This depicts how structural and magnetic order are intertwined within this compound. In the low-temperature phase of $Fe_{1.12}Te$, one type of the domain boundaries disappears, and the transition into the paramagnetic phase gets rather broad, which is assigned to the formation of a mixture of orthorhombic and monoclinic phases below T_N [4]. Our investigation presents the first atomic-scale real-space observation of the simultaneous evolution of spin and structural order in the parent compound of the simplest Fe-based superconductors across the magneto-structural phase transition. The study reveals subtle atomic scale effects in the complex interplay of magnetism and lattice structure and possible ways to manipulate these structures by the Fe content and thermal cycling. One major advancement is the continuous observation of the magneto-structural phase transition resolving the structural and spin order transition at the atomic level. This technique reveals the nature of the investigated phase transition and its application can be transferred to the investigation of other parent compounds of high-temperature superconductors beyond the Fe-chalcogenide family. This work is submitted for publication in a peer-reviewed journal and available as a preprint [12].

GE-04. Coexistence of Ferromagnetism and Superconductivity in Zn-ion implanted and buffer-free InN films.

W. Xie[1], Q. Xie[2], F. Duan[1], K. Wang[1], H. Tian[1] and X. Wu[1]
1. Physics, Nanjing Unversity, Nanjing, China; 2. Nanjing University of Posts and Telecommunications, Nanjing, China

We report the coexistence of superconducting and magnetic behaviors in Zn-ion implanted and buffer-free InN films at low temperature. The ferromagnetism persists up to 300K, and the superconducting transition temperature locates around 3.5K. Based on the experiment and the fisrt principle calculations, we attribute the superconductivity and ferromagnetism to specific structures, individually, i.e., the well-crystallized lattice, and the defects of Zn replacing In or In vacancies, individually. The coexistence scenario would provide the possibilities to study their interplay coupling.

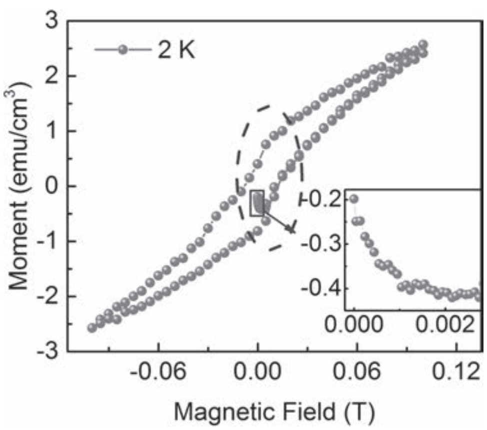

Fig. 1. shows the magnetization vs. magnetic field curves for sample Zn doped InN film at 2 K, exhibiting ferromagnetic signal. The inset is the enlargement of data marked with rectangles, indicating the antiferromagnetic behavior at very low magnetic field due to the superconductivity.

Iron borate $FeBO_3$ is an excellent example of the materials called "transparent magnets" [1], associating room temperature magnetic ordering (weak ferromagnetism) with transmission windows in visible spectral range [2]. The persisting research interest in iron borate is stimulated by its outstanding magnetic, magneto-acoustical, optical, magneto-optical, resonance, etc. characteristics [3-7]. Recently, new iron borate-based materials - $Fe_xGa_{1-x}BO_3$ crystals - have been synthesized by the solution in the melt technique [8] and studied by Electron Paramagnetic Resonance (EPR) [9], Nuclear Magnetic Resonance [10, 11] as well as by optical and magnetooptical techniques [12]. These crystals: (i) *per se* possess extraordinary physical characteristics suitable for practical applications, and these characteristics can be monitored in the synthesis process; (ii) allow comprehensive studies of diamagnetic dilution - isomorphous substitution of iron by gallium - effect on the properties of magnetic materials, viz., gradual transition from magnetically ordered to paramagnetic state; (iii) allow understanding the nature of various mechanisms responsible for magnetic properties of iron borate, e.g., magnetocrystalline anisotropy, the former having different concentration and temperature dependences. Different types of Electron Magnetic Resonance (EMR) have been observed in $Fe_xGa_{1-x}BO_3$ crystals depending on iron contents and the temperature. Figure 1 (a) shows the spectra transformation with x. At $x = 1$ (pure iron borate), only a low-field resonance is observed, earlier identified as Antiferromagnetic Resonance (AFMR) [7]. At a lower iron content, $x = 0.75$, besides the low-field line a new broad resonance emerges at higher magnetic fields, with the effective g-factor $g\approx 2$. Since iron substitution for gallium occurs more or less randomly, such crystals are expected to contain regions with different local iron concentrations, implying different magnetic ordering. The low-field line observed in the mixed crystals, by analogy with iron borate [7], can be identified as AFMR line arising from magnetically ordered regions, whereas the high-field line can be ascribed to Cluster Magnetic Resonance (CMR), i.e., EMR arising from only partially magnetically ordered regions. Both the low- and high-field EMR lines are present in all crystals with $0.35 \le x < 1$; thus, one can conclude that in such crystals both long-range and short-range (cluster-type) magnetic ordering coexist. Figure 1 (b) shows the temperature dependence of the CMR line intensity for $x = 0.65$. With decreasing temperature this line considerably broadens and its intensity does not follow the T^{-1} Curie law, confirming its attribution to magnetic clusters. At still lower iron contents, $x = 0.2$, the AFMR line disappears and the high-field line increases in intensity. The EMR spectra for $x = 0.2$ crystal consist of a single line at $g\approx 2$, quite similar to the high-field line observed for higher x, consequently, in this case the antiferromagnetic regions are absent in the whole temperature range. The temperature dependence of the intensity of this line shown in Figure 1 (c), confirms that the Curie law for this resonance is not respected. For $x = 0.04$, the latter line also disappears and the EPR spectrum of diluted Fe^{3+} ions, broadened by dipole-dipole interactions, comes into view. At a still lower iron content, $x = 0.003$, this spectrum is spectacularly narrowed. A detailed account of the EPR studies of these crystals has been recently carried out using laboratory-developed codes [9]. In order to confirm or infirm the existence of magnetic clusters in the mixed iron-gallium borates, we have carried out SQUID measurements. The temperature dependence of the magnetic susceptibility in crystals with intermediate x-values, e.g., see Figure 2, reveals the presence of a strong out-of-phase component, thereby confirming the existence of magnetic clusters at intermediate x values. GE-06. Theory of Mn-containing high-magnetization permanent magnets.

A. Kashyap[1], D. Sellmyer[2] and R. Skomski[2]
1. School of Basic Sciences, IIT Mandi, Mandi, India; 2. Department of Physics and Astronomy, NCMN, University of Nebraska-Lincoln, Lincoln, NE, United States

1. INTRODUCTION Isolated manganese atoms have half-filled 3*d* shells and a magnetic moment of 5 μ_B. If this moment could be realized in permanent magnets, it would revolutionize technology. The present-day room-temperature record is about 2.43 μ_B in $Fe_{65}Co_{35}$, and the maximum energy product of permanent magnets is quadratic in the magnetization. Furthermore, the crystal structure of $Fe_{65}Co_{35}$ is cubic and not suitable for permanent magnets, and it may be possible to create noncubic Mn magnets with substantial magnetocrystalline anisotropy. Known Mn-based permanent magnets, such as MnAl, MnBi, and Mn_2Ga, exhibit modest energy products. The main reason is the low net magnetic moment, of the order of 0.5 μ_B per atom, which means that 99% of the energy product are wasted. The focus of our presentation is the theoretical explanation of the low moment of Mn-based permanent magnets and the search for crystal structures with improved net magnetization. Analytical quantum mechanics and density functional (DFT) calculations [1] will be used to tackle the problem. Since the magnetization is equal to the moment per volume, the Mn atoms need to be compacted into solids, and the resulting interatomic hybridization tends to reduce the atomic moments. However, moments of about 3 μ_B are rather easy to realize in solids, and up to about 3.7 μ_B per atoms are not unrealistic even in metals [2]. Another factor is the dilution of the magnetization due to the presence of nonmagnetic atoms, e.g., Mn moments approaching 5 μ_B can be realized in oxides, but the large volume of the O^{2-} ions severely limits the magnetization. II. FERRO- AND ANTIFERROMAGNETIC Mn ALLOYS The biggest concern with respect to the Mn magnetization is the element's trend towards antiferromagnetic (AFM) spin alignment. This trend is often rationalized in terms of the Bethe-Slater-Néel curve which predicts AFM order for small interatomic distances and ferromagnetic (FM) order for large interatomic distances. However, the curve conflates antiferromagnetism with Pauli paramagnetism, does not distinguish between different crystal structures, and ignores that the number of 3*d* electrons is an important parameter. For example, AFM order is particularly widespread in nearly half-filled 3*d* shells, and Mn is the most affected element. The reason for the AFM interatomic coupling of half-filled shells is that interatomic hopping reduces the energy through the formation of bonding states. Interatomic hopping is pronounced in ferromagnetic and paramagnetic metals, where it yields relatively broad bands. It is much less effective in antiferromagnets, because neighboring ↓ atoms act as energy barriers for traveling ↑ spins, and *vice versa* [3]. One may thus expect all magnetically ordered metals to be FM in lowest order. However, half-filled FM bands mean that all available orbitals are filled by ↑ electrons, both bonding and antibonding orbitals, so the net hybridization energy gain is zero. The AFM state has both ↑ and ↓ electrons in the bonding orbitals and therefore the lower energy in for half-filled shells. III. ROLE OF CRYSTAL STRUCTURE The number of Mn 3*d* electrons can be somewhat varied through alloying, but to create ferromagnetism in Mn alloys, one needs suitable crystal structures. There is a big difference between fcc-type dense-packed alloys, where nearest neighbors form equilateral triangles, and bcc-type less-dense-packed alloys, which do not contain such nearest-neighbor triangles. Elements in the middle of the 3*d* series, such as Fe and Mn, require structures of the second type, as opposed to the late 3*d* elements Co and Ni, where ferromagnetism is supported by fcc-type structures. The reason is the Stoner criterion, which requires a high density of states (DOS) at the Fermi level: otherwise, the only choice is between paramagnetism and AFM (or a complicated spin structure). We will show DFT calculations to verify this rule, but the underlying nearest-neighbor physics, is easily seen from the two-cluster shown in Fig. 1. Equilateral triangles create a strongly asymmetric DOS, with the highest DOS near the upper edge of the level distribution. This is the reason for the frequent occurrence of ferromagnetism in dense-packed late 3d magnets. In the absence of such triangles, the level distribution is symmetric and reaches its highest density for half-filled shells. Structures of type of Fig. 1(a) are most promising for new Mn-based ferromagnets. This analysis is partially based on existing Mn-based magnets, e.g, MnAl exhibits strong Mn-Mn exchange, in spite of a very short Mn-Mn nearest neighbor distance. The reason is that the atoms in the Mn layers of the $L1_0$-ordered alloy form a square lattice. A class of Mn alloys of current interest in several areas of magnetism are bcc derivatives, including Heusler alloys. Ferromagnetic order in these alloys is important for spin electronics applications, and some of them are presently investigated as potential high-magnetization permanent magnets. As we will discuss, the individual site occupancies are of crucial importance in these systems.

1. The University of Tokyo, Bunkyo-ku, Japan; 2. Kyoto Institute of Technology, Kyoto, Japan; 3. Tokyo Institute of Technology, Yokohama, Japan

Ultrathin Co/Pd multilayers are artificial nanomaterials that exhibit perpendicular magnetic anisotropy (PMA), due to the spin-orbit interactions, achieved through interfacial chemical bonding. Regarding applications, after the development of artificially synthesised PMA, researchers have pointed out the expectation of ultra-high density recording media [1]. Extensive efforts have been made for studying interfaces of ultra-thin magnetic multilayers and nanostructures. Studies on Co atoms performed using x-ray magnetic circular dichroism (XMCD) have suggested the enhancement of orbital magnetic moments at the interfacial Co that is adjacent to Pd [2]. It has been reported that the PMA emerges due to the cooperative effects between spin moments in 3*d* transition metals (TMs) and large spin-orbit interactions in the non-magnetic 4*d* TMs. The Co/Pd interfaces and multilayers have also been employed to demonstrate the photo-induced precession of magnetisation [3] and the creation of skyrmions using the interfacial Dzyaloshinskii-Moriya interaction [4], and magnetisation reversal using the spin-orbit torque phenomena [5]. Despite the abovementioned promising studies on Co/Pd interfaces, the interfacial PMA, including the anisotropic orbital magnetic moments, has not been fully understood for both Co and Pd sites. Bruno and van der Laan theoretically proposed an orbital moment anisotropy in 3*d* TMs within the second-order perturbation of the spin-orbit interaction for more than half-occupied electrons [6, 7]. However, in the case of strong spin-orbit coupling in 4*d* (Pd) or 5*d* (Pt) TMs, the validity of this perturbative formula has been debated [8]. In order to study the mechanisms of PMA in Co/Pd multilayers, the orbital magnetic moments contributions of each element have to be explicitly considered. It is challenging to study the anisotropy of the orbital magnetic moments of both Co *L*-edge and Pd *M*-edge elements using one specific experiment, due to the challenges in detection of the induced magnetic moments, of Pd in particular. For the interfacial Pd, the magnetic dipole contribution through the quadrupole interactions between dipoles is assessed quantitatively. We focus on the anisotropy of orbital moments at the Co/Pd interfaces using XMCD and first-principles density functional theory (DFT) calculations, which provide the element- and layer-resolved contributions that reveal the mechanism of PMA. In this study, we discuss the anisotropies of both spin and orbital moments of Co and Pd using angle-dependent XMCD data and DFT calculations. We prepared two kinds of samples of Co/Pd multilayered structures: Co (0.69 nm)/Pd (1.62 nm) for PMA and Co (1.03 nm)/Pd (1.62 nm) for in-plane anisotropy with stacking five periods on the Si substrates [3]. Sample surfaces were sputtered by Ar ions before the XMCD measurements in order to remove the oxygen contamination. We performed XMCD experiments in the total electron yield mode. A magnetic field of ±5 T was applied along the direction of the incident polarized soft x-ray. We successfully observed clear XMCD signals in Pd *M*-edges after the removal of surface contamination as shown in Fig. 1. Although the x-ray absorption spectroscopy (XAS) line shapes overlap with those of O *K*-edge absorption, clear XMCD signals induced by the proximity with Co layers are observed. The Pd *M*-edge XMCD line shapes in both PMA and in-plane samples are almost identical, which suggests isotropic orbital moments in Pd, within the detection limits. On the other hand, clear Co *L*-edge XAS and XMCD with angular dependence reveal the enhancement of orbital moments in the surface normal direction because of PMA. Next, we can discuss the magnetic dipole moments m_T through quadrupole-like spin-flipped contribution of the interfacial Pd layer using the angular-dependence of spin magnetic moments. We found that the m_T is an order of magnitude smaller than the orbital moments, i.e., *0.005 mu*$_B$, comparable with the detectable limits. Therefore, the relatively large spin-orbit coupling constant and small Pd exchange splitting contribute to the appearance of PMA by means of quadrupole-like interactions through the interfacial proximity effects. Figure 2 represents the contributions of the crystalline magnetic anisotropy at each atomic site by DFT calculations. Four types of spin transition processes occur between the occupied and unoccupied states within the second order perturbation of the spin-orbit interaction. For Co sites, the transition between down-down spin states is dominant, suggesting the conservation of spin states in the transition, which can be explained using the Bruno model assuming a large spin splitting. In contrast, for Pd, the spin-flipped transitions between up-down and down-up states become dominant due to the small band splitting, hence both spin-preserved and spin-flipped processes occur near the Fermi level. These results are consistent with the angular-dependent XMCD in Co and Pd sites. In the presentation, we will discuss the orbital-resolved interfacial electronic structures in Co/Pd system with the estimations of spin, orbital, and magnetic dipole moments.

GE-08. Perpendicular exchange bias in CoPt/FeMn bilayers.

C. Pan[1,2], T. Gao[3], T. Harumoto[2], Z. Zhang[1], Y. Nakamura[2] and J. Shi[2]
1. School of Materials Science and Engineering, Tsinghua University, Beijing, China; 2. School of Materials and Chemical Technology, Tokyo Institute of Technology, Tokyo, Japan; 3. Department of Applied Physics and Physicoinformat, Keio University, Yokohama, Japan

Two series of samples, CoPt single layers (SL) and CoPt/FeMn bilayers (BL), were fabricated by DC magnetron sputtering on MgO (111) substrates to investigate magnetization anisotropy and exchange bias effect in CoPt/FeMn hetero structure. It is proposed that perpendicular magnetization anisotropy (PMA) in magnetic films mainly originates from the anisotropy of phase ordering (such as $L1_1$ or $L1_0$), shape anisotropy and strain anisotropy trigged by magnetostriction strain imposed on the film by the substrate. [1] In this work, PMA in CoPt/FeMn films was systematically investigated. Fig.1 (a-e) shows hysteresis loops of CoPt single-layered films with different thicknesses. It is clearly that magnetization easy axis switches from out-of-plane direction to the in-plane direction with the increase of thickness of CoPt layer. From the area enclosed between the in-plane and out-of-plane magnetization loops, the effective magnetic anisotropy (K_{eff}) [2] can be readily obtained and shown in the inset of Fig.1 (f). Fig.1(f) shows the product of K_{eff} and t_{CoPt} as a function of t_{CoPt}. $K_{eff}\, t_{CoPt} = K_V\, t_{CoPt} + 2K_s$ (1) In this combining equation, Kv is the volume anisotropy deduced by the slop of fitting line, and Ks is the interface anisotropy obtained from the intercept. [2] A positive (negative) Keff describes the preferential magnetization direction is along the out of plane (in plane) direction. The signs of K_{eff} from positive to negative is coincident with the alternation of magnetization curves from out-of-plane to the in-plane direction. Moreover, the careful characterization on structure by XRD has also been conducted on the two series of samples (not shown here). For SL, CoPt (111) peaks at around 41^o shift to higher angle till 3nm, indicating shrink of interplanar distince and in-plane tensile stress. The magnetic anisotropy of thin film can be correlated with equation (2) [3] between internal stress σ_{in} and magnetoelastic energy $K_{me,}$ $K_{me} = - 3/2\, \lambda\sigma_{in}$ (2) where λ is the magnetoelstic constant, and CoPt alloy has a negative magnetostriction constant along <111> direction, an in-plane tensile stress (σ_{in}〉0) identified from shift of peaks in XRD profile results in a positive magnetoelastic energy and the PMA is favoured. Therefore, PMA observed in thinner CoPt films is believed due to internal stress. Fig.2a shows typical magnetization curves of CoPt/FeMn bilayer films prepared at 350 ^oC, the as deposited (A.D) film shows PMA. Meantime, distinctive perpendicular exchange bias (PEB) appears after cooling samples from 500K down to 80K with a 5kOe external field applied perpendicular to the film plane, and the measurement was conducted at 80K. Fig2b shows the dependence of coercivity and exchange bias on the FeMn thickness measured at T=80K. When the thickness of FeMn is smaller than 2nm, exchange bias is almost 0, because at this thickness, FeMn is probably not AFM [4]. EB field increase drastically as FeMn thickness increases to 8nm and then decrease to a constant value in the subsequent thicker thickness. Coercivity was found to depend strongly on the thickness of FeMn layer. It is known that spin configuration of FeMn plays a critical role in determining the direction and strength of the exchange coupling at the interface. FeMn has a 3Q spin structure, with spins pointing to the [111] directions.[5] The spin orientation has a vector component projection along the normal direction of the thin film plane and would contribute to PEB in CoPt/FeMn hetero structure, so pinning effect can be enhanced till to peak at 8nm. The fascinating point is the peak at 8nm in Fig. 2(b). In this work, one model proposed by Binek et,al (equation (3)) [6], based on a generalized Meiklejohn and Bean approach, $H_{EB} = a + b/t_{AF} + c/t^2_{AF}$ (3) is the most possible one for this dependence. The peak at 8nm observed in the AF thickness dependence of exchange bias is considered due to the frozen magnetization of the AF, which is generally assumed to be 0 in most models. The special alignment of spins at the CoPt-FeMn interface need further investigation.

Abstract: Compositionally graded $FeNiAlCo_xCr_{1-x}$ ($0 \leq x \leq 1$) high entropy alloys (HEA) as well as the related Fe-Ni and Fe-Ni-V, Fe-Ni-Mo alloys have been processed by laser additive manufacturing. The graded composition and processing conditions result in interesting non-monotonic saturation magnetization (M_S), coercivity (H_C) and Curie temperature (T_C) behavior. Such tunable functionally graded magnetic properties offer unique potential for permeability engineering applications, such as electrical machines. Introduction: Soft magnetic alloys, e.g., Fe-Ni based alloys, are extensively used in numerous applications, such as sensors, power conversion devices, e.g., transformers, inductive devices, electrical machines etc. The emerging field of high entropy magnetic materials based on these Fe-Ni alloys has also revealed interesting, widely tunable magnetic properties. High-temperature processing of such alloys by conventional techniques, e.g., casting, melt spinning can result in undesirable magnetic properties. Hence, it is essential to investigate novel additive manufacturing techniques. Additive manufacturing, e.g., by laser engineering net shape (LENS) processing, allows near-net shaping of dense metallic objects via introduction of pre-alloyed or blended elemental powders into a melt pool produced by a high-power laser. It can produce functionally graded materials that are difficult to process using conventional techniques. The composition and microstructure can be tuned along the sample length in functionally graded materials, resulting in a systematic variation in their properties. The microstructure and magnetic properties of several LENS deposited alloys were investigated and compared to those of conventionally processed alloys. Experimental: $FeNiAlCo_xC_{1-x}$ alloys with varying Co/Cr ratios were deposited using a LENS system with two powder feeders, one containing an elemental blend of FeNiAlCo and the other containing a blend of FeNiAlCr. The composition variation was achieved by varying powder flow rate from both powder feeders during deposition. The compositionally graded sample is cylindrical (10 mm diameter × 25 mm height). The powders used for depositing these alloys consisted of commercial near spherical Al, Co, Cr, Fe, and Ni powders (purity at least > 99%). A range of processing conditions was used, and optimized, to produce a homogenous LENS^{TM} deposit with minimal defects. Cylindrical deposits (10 mm diameter, 12–15 mm height) of the Fe-30at.%Ni alloy were deposited using three nominal laser powers (300W, 400W, and 500W) and two travel speeds (8 inch per minute (IPM) and 13 IPM). Cylindrical deposits of nominal compositions of Ni-15Fe-5 V and Ni-15Fe-5Mo were deposited using 400W laser power and a vector speed of 20 IPM. For compositional, microstructural and magnetic property measurements several sophisticated characterization techniques, e.g., XRD, SEM, EDX, TEM, APT, VSM have been used. More details can be found in the references[1-4]. Results: The graded $FeNiAlCo_xCr_{1-x}$ ($0 \leq x \leq 1$) HEA samples were deposited using the LENS process. All the alloy compositions exhibited a mixture of BCC and B2 (ordered BCC) phases. FeNiAlCo (x=1) alloys exhibited, coarse equiaxed grains and at a finer length scales, early stages of phase separation into Ni-Al rich and Fe-Co rich regions. As Cr content increases, more pronounced spinodal decomposition was observed within the BCC grains. Both TEM and APT analysis show that FeNiAlCr (x=0) alloys exhibit spinodal decomposition within BCC grains. The M_S rises monotonically upon Co addition, from 20.6 emu/g at x=0 (FeNiAlCr) to 123 emu/g at x=1 (FeNiAlCo) (Fig 1a). In contrast, the composition dependence of H_C is non-monotonic: H_C is low for x=0, but increases dramatically at x£0.4 and then falls again for x>0.4, reaching a low value at x=1 (Fig 1b). Fig 2 show the M_S and H_C for six selected deposition conditions, i.e., 300 W, 400 W and 500 W, for travel speeds of 8-IPM and 13-IPM. The M_S and H_C were found to be in the range of 96-114 emu/g and 21-30 Oe, respectively (Fig 2). For the 8-IPM LENS deposition, the magnetization values decrease and coercivity increases with decreasing laser power, while for the case of 13-IPM LENS deposition, M_S values increase, and H_C decreases with decreasing laser power. The M_S for the 13-IPM/300 W samples is highest due to the largest content of the bcc phase, as confirmed by XRD and TEM analyses. The change in saturation magnetization can be attributed to a change in total magnetic moment, from 1.15 μB/atom for the pure *fcc* phase to 1.87 μB/atom for the pure *bcc* phase[5]. The M_S and H_C values for the Ni-15Fe-5V sample are 72 emu/g and 6 Oe, respectively, while the values for the Ni-15Fe-5Mo sample are 82 emu/g and 4.9 Oe, respectively. Conclusions: Graded $FeNiAlCo_xCr_{1-x}$ ($0 \leq x \leq 1$) HEA and related Fe-Ni, Fe-Ni-V, Fe-Ni-Mo alloys were prepared using additive manufacturing. The microstructure and magnetic properties of these additively processed alloys were found to be promising for permeability engineered near net shape magnetic components.

GF-01. Crossover to subthermal magnons spin conductance in open YIG films driven by large spin-orbit torque.

O. Klein[1], N. Thiery[1], L. Vila[1], G. de Loubens[2], V. Naletov[2], V.E. Demidov[3] and S.O. Demokritov[3]
1. CEA-SPINTEC, GRENOBLE, France; 2. CEA-SPEC, Gif-Sur-Yvette, France; 3. Physics department, University of Muenster, Muenster, Germany

The recent demonstrations that spin orbit torques (SOT) allow one to generate and detect pure spin currents has triggered a renewed effort to study magnons transport in extended magnetic films. A large effort has concentrated so far on yttrium iron garnet (YIG), which is famous for having the lowest known magnetic damping parameter. From a fundamental point of view, these studies of magnon transport in YIG by means of the direct and inverse spin Hall effects (ISHE) [1–6] are very interesting, as they provide new means to alter strongly the energy distribution of magnons up to thermal energies, and the interplay between these non-equilibrium populations is expected to lead to new collective phenomena, even potentially, to trigger condensation [7]. In contrast to spin transfer process in closed geometries (lateral size of the system smaller than the spin- wave propagation distance), very little is known about spin transfer in open geometries, which have continuous spin-wave spectra containing many modes which can take part in the magnon-magnon interactions. While magnons excited coherently, e.g. by means of a ferromagnetic resonance or parametric pumping, when the frequencies of the excited magnons are fully determined by the frequencies of the external signals, the excitation of magnons by means of spin transfer process lacks frequency selectivity, and, therefore, can lead to their excitation in a broad frequency range. This poses a challenge for the identification of the nature of magnons modes excited by SOT. It has been already shown, that it is convenient and useful to introduce the concepts of subthermal (having energy close to the bottom of the spin wave spectrum) and thermal (having energy close to k_BT) magnons. On one hand, it has been well established [8] that subther- mal magnons can be very efficiently thermalized near the spectral bottom (region of so-called magnetostatic waves) by the intensive magnon-magnon interaction, whose decay rate between quasi-degenerate modes increases with power, to reach a quasi-equlibrium state by a non-zero chemical potential [8] and an effective temperature. Under spin transfer process, whose efficiency is known to increase with decreasing magnon frequency, in closed geometries with localized spin-current injection (i.e. when there are no quasi-degenerate modes), it has been shown, that one can reach current induced coherent GHz- frequency magnon dynamics in YIG [4, 5, 9]). In open geometries, the recently discovered non-local magnon transport [2, 3] suggests that the magnon transport properties of YIG films subjected to small SOT are dominated by thermal magnons, whose number overwhelmingly exceeds the number of other modes at any non-zero temperature. The interesting challenge is to elucidate what will happen to this spectrum (in particular the interplay between the thermal and subthermal part when one applies large SOT to a magnon continuum. We report herein measurements of the room temperature spin conductance of YIG films when the driving current is varied in a wide range magnitudes creating, first, a quasi- equilibrium transport regime, and, then, driving the system to a strongly out-of-equilibrium state. To reach this goal the spin current injected in the YIG by SOT shall be increased by more than one order of magnitude compared to previous works, while simultaneously reducing the film thickness by also an order of magnitude, using ultra-thin films of YIG grown by liquid phase epitaxy (LPE). We show that at large current the spin conductance is dominated by magnetostatic magnons, which are low-damping non-equilibrium magnons thermalized near the spectral bottom by magnon-magnon interaction, with consequent a sensitivity to the applied magnetic field. This picture is supported by microfocus Brillouin Light Scattering spectroscopy. We believe that our current findings are not only important from the from the fundamental point of view, but might be also useful for future applications. While transport of thermal magnons are difficult to control due to their relatively high energies, the subthermal magnons could be efficiently controlled by variation of relatively weak magnetic fields.

Ferromagnetic semiconductor (Ga,Mn)As has emerged as the most thoroughly studied material for spintronic applications [1]. An important property of this ferromagnetic material is its magnetic anisotropy [2]. However, the origins of this anisotropy have not yet been entirely explained. Full understanding of magnetic anisotropy in (Ga,Mn)As is especially important for its use in prospective applications as memory devices, and is being intensively investigated by various experimental techniques, such as ferromagnetic resonance (FMR) and spin-wave resonance (SWR) [3]. Most of these methods have been used to obtain information on volume characteristics of this material, such as bulk anisotropy fields and exchange constants. Recently, it has also been proposed [4] that one can employ the full potential of SWR to probe information on magnetic characteristics of the surface, such as surface anisotropy and surface pinning energy, and their dependence on the orientation of magnetization in the material. Our early attempts [5] have successfully determined the surface pinning parameters of (Ga,Mn)As from SWR spectra using the surface inhomogeneity model [6,7] obtained for different angular configurations (θ_H, ϕ_H) of the external static magnetic field H_{dc} with respect to the surface of the studied (Ga,Mn)As thin film. Although the obtained surface pinning parameter A as a function of the field (or magnetization) polar and azimuthal angles was obtained in only limited ranges of both angles, these results have stimulated fruitful theoretical discussion and insight [8,9]. Recent theoretical development in this area [4] focuses specifically on the spherical surface pinning (SSP) model, in which the surface spin pinning energy is expressed by configuration angles (the out-of-plane polar angle θ and the in-plane azimuthal angle ϕ). The model is based on a series expansion of the surface spin pinning energy, where the terms in the series represent respective pinning contributions from the cubic as well as the uniaxial anisotropies. In particular, the model has predicted the existence of double critical polar angle phenomenon in SWR measurements performed in specific out-of-plane configurations, not been observed in earlier studies. Stimulated by these predictions, we have conducted detailed SWR measurements on a 120 nm thick annealed $Ga_{0.92}Mn_{0.08}As$ film. SWR measurements were carried out using three basic geometries. In Geometry 1, the [110] edge of the specimen was oriented vertically. This configuration allows measurements with the dc field in any arbitrary direction in the (110) crystal plane, from [-110] to [001]. In Geometry 2, the sample was mounted with the [1-10] edge of the specimen oriented vertically. This configuration allows measurements with the dc field in any arbitrary direction in the (1-10) plane, from [110] to [001]. In Geometry 3, the sample was mounted with the [010] edge of the film oriented vertically. This configuration allows measurements with the dc field in any arbitrary direction in the (010) plane, from [100] to [001]. In Fig. 1, the spectrum clearly evolves as the applied field H_{dc} is rotated from the out-of-plane orientation ($\theta_H = 0^o$) to the in-plane orientation ($\theta_H = 90^o$, $\phi_H = -45^o$). In particular, for H||[001] a resonance spectrum consists of at least five well resolved Portis-type SWR lines. As one rotates H away from the perpendicular orientation, the SWR modes successively disappear, and eventually – at some critical angle θ_c (24° in Fig. 1) – the multi-SW spectrum vanishes except for a single narrow resonance line, which corresponds to the uniform FMR mode. For angles $\theta_H > \theta_c$, the multi-mode nature of the SW spectrum re-emerges, generally containing two or three broad resonances. The spectra obtained in Geometry 2 are similar to those shown in Fig. 1. As predicted in Ref. [4], the spectra obtained in Geometry 3 show a new phenomenon: here we observe *two* critical angles (20° and 38° in Fig. 2). Specifically, as one rotates H away from the perpendicular orientation, the SWR modes disappear at the first critical angle θ_{c1}. As θ_H increases, the multi-mode nature of the SW spectrum re-emerges; the peak on the high-field side is identified as an exchange-dominated non-propagating surface mode. However, at the second critical angle θ_{c2}, the multi-SW spectrum again vanishes, collapsing to a single narrow resonance line. For angles $\theta_H > \theta_c$ (*i.e.,* as one approaches the easy axis, H||[100]), the spectrum consists of at least three SWR lines, which are believed to be bulk modes. In summary, we have observed the double polar critical angle phenomenon in SWR, as predicted from the recent theoretical model for specific experimental configurations. This observation verifies the surface pinning model of SWR, thus bringing new insights to surface anisotropy phenomena in (Ga,Mn)As thin films, and providing new information relevant to spintronic applications.

1. S. N. Bose National Centre for Basic Sciences, Kolkata, India

In the light of increasing demand for computational resources, the electronic circuits are reaching their limits in terms of miniaturization, performance and energy consumption. Spin waves (SWs), the coherent oscillations of magnetization, are among the potential candidates for replacement of electric charges as information carriers which may satisfy those demands. The control and functionality of SW based logic is expected from the so-called magnonic crystal (MC)[1], which is formed by periodic modulation of magnetic properties in one- or two- dimensions, resulting in allowed and partially or fully forbidden SW modes which can be manipulated via a wide range of structural, geometric and magnetic parameters. Here we have studied by experimental and theoretical methods the magnonic characteristics in an array of nanoscale asymmetric sawtooth shaped width modulated ferromagnetic waveguides (ASW) with average width: 350 nm, forming a novel pseudo one-dimensional MC (See Fig. 1a)[2]. The interesting aspect of this system is that it features the periodic modulation of two different magnetic parameters in two perpendicular directions: in the z-direction there is a periodic distribution of magnetic dipolar field whereas the y-direction posses a periodic modulation of internal magnetic field. Using Brillouin Light Scattering (BLS) technique we measured the magnonic band diagram of this structure by varying the angle (ϕ) between the wave vector (directed along ASW axes) and magnetic field, which is compared with the calculated frequency dispersion using plane-wave method. The measurement geometry is shown in Fig. 1b. The change in the magnetic field direction gives rise to a modulation in the profile of periodically varying SW channel, which eventually determines the SW frequency dispersion. Consequently, the band structure for ϕ = 90° features propagating SW modes and is characterized by a pronounced magnonic bandgap. The frequency and size of the gap is effectively modified upon varying ϕ to 70°. The band structures are presented in Fig. 2 (Fig. 2a and 2b for ϕ = 90° and ϕ = 70°, respectively), where the blue lines denote the calculated band structure and the bold green lines signify the bands with predicted large scattering cross sections. The experimental data (red solid circles) are overlaid on the calculated dispersion, which is in good agreement with the latter. Further calculations of the spatial mode profiles reveal that the edge potential well modes can be effectively engineered by manipulating the edge corrugation. Overall, selective control on SW propagation is presented which asserts that this system may serve as a possible prototype for SW waveguide and SW filter operating in the GHz frequency regime.

GF-04. Field Controlled Modulation of Magnetization Dynamics and Spin-Wave Mode Conversion in Two-Dimensional Nanoscale Antidot Lattices.

A. De[1], S. Mondal[1], S. Sahoo[1], S. Barman[2], Y. Otani[3] and A. Barman[1]
1. S. N. Bose National Centre for Basic Sciences, Kolkata, India; 2. Institute of Engineering and Management, Kolkata, India; 3. The University of Tokyo, Chiba, Japan

Introduction Ferromagnetic antidot lattices (ADLs) have emerged as a strongt candidates for reconfigurable effective media for spin-wave (SW) propagation, the so-called magnonic crystal [1]. They also find potential applications in magneto-photonic crystals and ultrahigh density data storage media. Hitherto, significant research has been devoted to study the magnetization precession, damping, switching and SW dynamics in ferromagnetic ADLs with circular and square shaped holes. Here we report, field controlled modulation of ultrafast magnetization dynamics and SW mode conversion in a new type of $Ni_{80}Fe_{20}$ (Py) antidot lattice with triangular shaped holes arranged in hexagonal lattice. In these ADLs, the sharp edges of the triangular holes creates inhomogeneous internal magnetic fields due to the effective pinning centers for SWs created by the asym metric demagnetized regions between the neighboring antidots, which is mainly responsible for the observed tunability of the magnetization and SW dynamics. *Results and Discussion* Two 25 μm × 25 μm arrays of Py antidots with triangular holes arranged in hexagonal lattice have been fabricated by a combination of electron-beam lithography, electron-beam evaporation and ion milling. The edge length of the triangular hole is about 200 nm and the separation between the nearest edges of the antidots for the two samples is about 200 nm and 500 nm, respectively (lattice constants are 400 nm (S1) and 700 nm (S2), respectively). The ultrafast magnetization dynamics is measured by using a time-resolved magneto-optical Kerr effect (TRMOKE) microscope based upon a two-colour collinear pump-probe setup [2]. The second harmonic (λ = 400 nm, pulse width ~100 fs) of a Ti:sapphire laser was used to pump the samples, while the time-delayed fundamental (λ = 800 nm, pulse width ~80 fs) laser beam was used to probe the dynamics by measuring the polar Kerr rotation with an optical bridge detector. Figure 1a shows the scanning electron micrograph of sample S1 with the schematic of the bias field geometry. The azimuthal angle of the bias field ϕ is varied during the experiment. The experimental SW spectra for S1 show three modes for ϕ = 0°, 30°, 60° and 90° at H = 1 kOe. The spectra for 0° and 60° are qualitatively similar in nature (though the mode frequencies are not same). Also there is qualitative matching between the spectra for 30° and 90°. But the SW spectra are remarkably different for 15°, 45° and 75° with drastic increase in the number of modes at 45° and 75°. These indicate a change in the collective nature of the spin dynamics with varying ϕ values. For S2, instead of a large number of modes we get only two modes (one dominant mode with a low power shoulder) for almost all the angles. Micromagnetic simulations qualitatively reproduce the experimental results and reveal a transformation of fully extended standing SW modes to quantized ones and vice versa (mode conversion) simply by changing the in-plane orientation of the bias field. For S1 channels for SW propagation are found to be opened at ϕ = 0° (horizontally extended channel) and 60° (diagonally extended channel). For ϕ = 45° we get pseudo extended nature of SW modes along the diagonally extended channel. For the other angles due to unavailability of the channels, the powers of SWs are found to be concentrated at specific edges of the triangular holes. For ϕ = 15° and 30°, the powers of SWs are concentrated at the top and left most vertex of the triangular holes, respectively. At ϕ = 75°, each mode splits into two which are parallely running through the diagonally extended channel of the array. Interestingly for S2, due to the increased lattice constant, an additional SW propagation channel at ϕ = 90° gets opened and fully extended modes in DE geometry are obtained through the horizontal, diagonal and vertical channels for ϕ = 0°, 60° and 90° respectively. It is also observed that the domain structure and the internal fields change considerably with the variation of in-plane bias field orientation leading towards the variation in the SW mode structures as well as the mode frequencies. *Conclusion* We have successfully investigated the influence of the orientation of bias field and lattice constant to the ultrafast magnetization dynamics, SW mode conversion and magnetostatic field distribution in a two-dimensional array of triangular nanoholes forming a hexagonal antidot lattice in a thin Py film by using time-resolved Kerr microscopy and numerical simulations. The observed tunability of the magnetization dynamics with the change in the orientation of the bias field and lattice constant is significant for future magnonic and spintronic devices. *Acknowledgement* We gratefully acknowledge the financial support from S. Magnonic crystals are magnetic structures with periodically modulated magnetic properties, thus, enabling modification of the magnonic band structure to feature allowed and forbidden frequency bands in the spin wave (SW) spectrum [1]. Moreover, the spectrum can be influenced by using an external magnetic field to change the local magnetization structures. These features offer fine tuning and reprogrammability, which are desirable for applications [2]. Quasicrystals have long-range order, but no periodicity. Introducing such quasiperiodicity in magnonic structures yields an additional degree of freedom for SW manipulation. In comparison to periodic systems, magnonic quasicrystals are characterized by a more complex dispersion relation with an increased number of band gaps and narrow allowed bands, and localized excitations which can be concentrated in various parts of the structure [3]. In this work, we investigate one-dimensional magnonic quasicrystals consisting of 10 μm long nanowires (NWs) from 30 nm thick permalloy (Py – $Ni_{80}Fe_{20}$). These NWs are either wide (1400 nm) or narrow (700 nm) and dipolarly coupled over 80 nm wide air gaps. The NWs are arranged using the Fibonacci inflation rule, according to which, analogously to the creation of the Fibonacci sequence, the structure of higher order consists of the sum of the two previous structures, and structure of the 1st and 2nd order is a single narrow or wide NW, respectively. Spin waves are excited with a coplanar waveguide that is integrated on top of the structure and aligned parallel to the NWs. The external magnetic field is applied perpendicular to that direction, along the NWs. Spin waves excited by coplanar waveguide (CPW) are imaged using scanning transmission X-ray microscopy (STXM) at the MPI IS operated MAXYMUS end station at the UE46-PGM2 beam line at the BESSY II synchrotron radiation facility. This technique allows imaging of the magnetization dynamics with spatial and temporal resolution down to 18 nm and 35 ps, respectively, while providing phase resolution and spectral sensitivity. In the images, the gradual variation of phase in the direction perpendicular to the NWs is observed, which indicates the propagating character of these SW resonances. Modes from the 1st and 2nd bands are detected and can be distinguished by the presence of a node in the excitation profile along the width of the wider NWs for modes from the 2nd band. Additionally, evanescent SWs are measured at frequencies inside of the band gap. Furthermore, mini band gaps in the spectrum are observed that also efficiently forbid SWs propagation. These findings directly prove the influence of collective effects of the quasiperiodic order on the SW dispersion relation. Additionally, reprogrammability of the Fibonacci structures is demonstrated to showcase the utility of magnonic quasicrystals for future applications. Figure 1 shows the SW spectra obtained from numerical calculations at 5 mT for ferromagnetic (FO, neighboring NWs parallel) and antiferromagnetic (AFO, neighboring NWs antiparallel) order of the NWs magnetization. It becomes evident, that the change in magnetization configuration has a significant influence on the SW band structure. To elucidate the microscopic origin of this change in the SW spectrum, selected modes A-C where captured by STXM and are shown in Figure 2. Frequency A lies in the 1st band and strong excitations for the FO and AFO order are visible. However, for the AFO case, there is a phase jump between wide and narrow NWs, which means that the magnetization precession in these two NWs types has opposite sign. Frequency B lies in the band gap for FO order but is close to the 2nd band for AFO order. Thus, a propagating SW is only observed for the latter. For frequency C the opposite is true: it is close to the 2nd band for FO order and lies in the band gap for AFO order. Hence, propagating SW can only be observed for FO order here. These observations indicate that by switching the magnetic structure between these two states, it is possible to reprogram the dispersion and, thus, control the transmission of the SWs. The interpretation of experimental results are aided by numerical calculations. Excellent agreement between measurement and simulation is found and the SW mode profiles could be matched (*cf.* Figure 2). In summary, we show that quasiperiodicity provides an additional degree of freedom in tuning SW dispersion relations and typical features of quasicrystals are reproduced for the magnonic band structure as directly imaged by STXM. Furthermore, the reprogrammability of 1D magnonic quasicrystals, that is demonstrated here, allows advanced tailoring of the SW spectrum, which opens up new pathways for the potential applications.

Magnetic micro- and nanostructures are extensively investigated due to their potentials as candidates for future spintronic and magnonic devices [1-4]. Main carriers of signals used for information processing in such structures are magnons and, in particular, magnetostatic spin waves (MSW). They are also possible candidates for beyond-CMOS (complementary metal-oxide semiconductor) technologies [5], as they are free of Joule heating and, respectively, free of power loss associated with traditional electronics [6,7]. Here, the concept of three-dimensional (3D) magnonic crystals is discussed for the first time. A meander type ferromagnetic film which can be grown at the top of the structured substrate can be a candidate for such 3D crystal (see Fig.1). Propagating wave dispersion and band structure in such crystals are calculated using finite elements method and by the means of micromagnetic simulation. Amplitudes of magnetostatic potentials as functions of frequencies are also deduced. Wave reflections and transmissions at the corners of parts of the meander waveguide are discussed and estimated within the model of transfer matrix method [8]. Furthermore, the properties of coupled 3D magnonic crystals are also considered. We considered the meander type structure with isotropic ferromagnetic layer saturated by in-plane magnetic field. We restrict ourselves by dipole approximation eliminating the exchange interactions. The calculation of the magnetic field within one cell of the periodic structure was provided using magnetostatic equations as well as periodic boundary conditions using finite elements method (FEM) [9]. In order to calculate dispersion of the propagating MSW in such structures we used Maxwell's equations in a magnetostatic approximations with electrodynamic boundary conditions. It has been shown that the band gaps have clearly appeared in dispersion of magnetostatic surface spin waves (MSSW) propagating in such 3D structures. They were at the frequencies of Bragg resonances when the MSSW wavelength is equal to two periods of the periodic structure. Dispersion characteristics of MSSW are shown in Fig. 2 at various meander depths. Two main conclusions can be made based on the results of this Figure. Namely, as the depth of the groove is increased the width of the band gap is also increased. Second conclusion concerns that fact at fixed wavenumbers (or wave lenghts) the dispersion curves are shifted in the lower frequencies and this is due to decrease of the MSSW phase velocities. Authors acknowledge the financial support from RFBR through the grant 18-57-76001.

GF-07. Magnetization Dynamics of $Ni_{80}Fe_{20}$ Nanowires with Continuous Width Modulation.

L. Xiong[1], M. Kostylev[2] and A. Adeyeye[1]

1. National University of Singapore, Singapore; 2. University of Western Australia, Crawley, WA, Australia

INTRODUCTION The static and dynamic behaviors of ferromagnetic nanowires (NWs), have been subject to extensive explorations in the last few decades due to their great promise for applications in spintronic devices[1] and tunable magnonic filters[2]. Researches have shown that notches can be used either to locate DW positions or to boost the propagation of DWs. It has also been published that geometrical constrictions on micron-scale NWs can be used to tune resonant frequencies of NWs[3]. Recently, works on tuning the band structures of one-dimensional width modulated magnonic crystals (MCs)[4] have shown that two or more band gaps appear due to the NW modulation. However, most of the studies of NWs with modulation reported so far are theoretical with very few detailed experimental results. Thus, it would be interesting to investigate the magnetization reversal and dynamic behaviors of NWs with continuous width modulation. EXPERIMENTAL AND SIMULATION DETAILS Two sets of $Ni_{80}Fe_{20}$ NW arrays, homogeneous NWs (NWHs) for reference and NWs with continuous width modulation (NWMs), were fabricated over an area of 4x4 mm^2 on top of a silicon substrate for direct comparison. Typical scanning electron microscope (SEM) images are shown in Fig. 1. The thickness t of the wires is varied in the range from 5 to 70 nm. The collective magnetization reversal processes of the arrays were characterized at room temperature using vibrating sample magnetometer (VSM) by sweeping the magnetic field along the easy axis of the NWs. The dynamic behaviors of the NWS were investigated using broadband ferromagnetic resonance spectroscopy (FMR). In order to understand the dynamic response of the wires, micromagnetic simulations were performed using the LLG micromagnetic simulator, which computes the equilibrium magnetization distribution of the NWs based on the Landau-Lifshitz-Gilbert (LLG) equation: $\partial_m/\partial_t = -\gamma m \times H_{eff} + \alpha m \times \partial_m/\partial_t$ (1) The resonant mode profiles were extracted using spatially and frequency-resolved Fast-Fourier-Transform (FFT) imaging method. In all the simulations, periodic boundary condition was used to mimic the wire arrays. RESULTS A systematic investigation of the magnetization reversal and the dynamic behaviors of uncoupled $Ni_{80}Fe_{20}$ NWs with artificial continuous width modulation is presented. In contrast with the single resonance mode observed in the NWHs from the FMR, the NWMs display three to five distinct resonance modes with increasing wire thickness in the range from 5 to 70 nm due to the non-uniform demagnetizing field as shown in Figs. 2(a)-(b). The highest frequency mode and the frequency difference between the two distinct highest modes are shown to be markedly sensitive to the NW thickness. Interestingly, we found that these modes can be described in terms of the quantization of the standing spin waves due to confined varied width. Typical simulated mode profiles for the NWMs with 30-nm $Ni_{80}Fe_{20}$ are shown in Fig. 2(c). In addition, the easy axis coercive field for the width modulated NWs is much higher than homogeneous NWs of the same thickness when less than 70 nm. Our experimental results are in good qualitative agreement with the micromagnetic simulations.[5] The results may find potential applications in the design and optimization of tunable magnonic filters.

GF-08. Efficient Modulation of Spin Wave Dynamics in two-dimensional Quasiperiodic magnonic crystals.

S. Choudhury[1], S. Barman[2], Y. Otani[3,4] and A. Barman[1]
1. S. N. Bose National Centre for Basic Sciences, Kolkata, India; 2. Institute of Engineering and Management, Kolkata, India; 3. Institute for Solid State Physics, University of Tokyo, Kashiwa, Japan; 4. RIKEN-CEMS, Wako, Japan

I. INTRODUCTION Magnonic crystals [1] (MCs) are artificial crystals, fabricated by the periodic arrangements of magnetic nanostructures which form magnonic band structures with allowed and forbidden frequency bands. For such MCs, spin waves (SWs) are the transmission waves. Since the wavelengths of SWs are in the nanoscale at gigahertz frequency regime, MCs offer great prospects for on-chip communication devices. In addition, due to the anisotropic propagation of the SWs, the frequency position and width of the band gap can also be tuned by varying various physical and geometrical properties of the MCs. Ferromagnetic antidot lattices (ADLs) [2] belong to a unique class of MCs where antidots (holes) are periodically patterned on a ferromagnetic thin film and they are strongly dipole-exchange coupled media with larger propagation velocities of SWs as opposed to dipolar coupled nanodot or nanowire arrays. In such ADLs, magnonic band structures can be efficiently modified by tuning the packing density of antidots in the lattice as well as the lattice symmetry due to the large modulation of the demagnetization regions around the antidots. The large tunability of magnonic band structures and modulation of SW velocities with the periodicity of the lattice make two-dimensional (2D) ADLs an interesting topic in magnetism, for controlling the SW propagation and also for other kinds of applications. II. EXPERIMENTS AND ANALYSIS Here, we report the investigation of the high-frequency magnetization dynamics of 2-dimensional arrays of $Ni_{80}Fe_{20}$ (NiFe) antidots of 20 nm thickness (t) with circular shape of diameter (d) 140 nm arranged in octagonal lattices which may be considered as magnonic quasiperiodic crystal with varying lattice spacing (a) of 300, 400, 500, 600 and 700 nm. For the dynamical measurement, we used a broadband ferromagnetic resonance (FMR) spectrometer [3] based on vector network analyzer (VNA) under the application of an in-plane bias magnetic field (H_{ext}), whose magnitude is varied from 0.2 to 1.56 kOe during the measurements at a fixed value of in-plane angle $\Phi = 0°$. We observed a significant tunability in the SW spectra with the increase in lattice spacing (a). For $a = 300$ nm, seven SW modes are observed as shown in Fig. 1(c), which converge into two modes for $a = 700$ nm. The experimental results have been well reproduced by micromagnetic simulation and different types of extended and localized standing SW modes with varying quantization numbers are observed. The configurational anisotropy of the samples is investigated by varying the azimuthal angle (Φ) of the bias field from 0° to 360° at $H_{ext} = 800$ Oe. We have observed a significant eight-fold rotational symmetry superposed with a four-fold and two-fold anisotropies in these octagonal crystals with the orientation of the bias magnetic field as shown in Fig. 1(d) for $a = 300$ nm, while the value of this anisotropy is reduced with the increase in the lattice spacing (a). The magnetostatic field distribution within the octagonal unit cell is mainly responsible for the origin of the eight-fold anisotropy, whereas the rhombus-like cell present between two octagonal unit cell is mainly responsible for the four-fold anisotropy. In addition to this, the phase profile shows a mode conversion from extended SW mode to quantized standing SW mode for these samples with the rotation of the bias field direction. III. CONCLUSION In summary, we have fabricated high-quality arrays of circular shaped NiFe antidots arranged in an octagonal lattice with diameter 140 nm and the lattice constant is varied from 300 nm to 700 nm. The magnetization dynamics of these samples are investigated with the help of broadband FMR spectroscopy by varying the strength and orientation of the applied magnetic field. The experimental results showed a remarkable variation in the SW spectra with the variation of lattice constants. The experimental results have been well reproduced by micromagnetic simulation and the magnetostatic fields including the demagnetization field distributions are calculated to interpret the origin of the observed SW modes. The configurational anisotropy of the samples shows the presence of an eight-fold rotational anisotropy superposed with four-fold and two-fold rotational anisotropies. These observations open more opportunities in the engineering of quasiperiodic arrays for magnonic and spintronic devices. IV. ACKNOWLEDGEMENT The authors gratefully acknowledge financial support from Department of Science and Technology, Government of India under grant no. SR/NM/NS-09/2011. S. C. acknowledges S. N. Bose National Centre for Basic Sciences for the senior research fellowship.

GF-09. Low losses YIG based nano-magnonic crystals for tunable frequency filtering.

H.P. Merbouche[1], M. Collet[1], L. Soumah[1], S. Xavier[2], V. Cros[1], P. Bortolotti[2] and A. Anane[1,3]
1. Unité Mixte de Physique CNRS/THALES, Palaiseau, France; 2. Thales Research & Technology, Palaiseau, France; 3. Université Paris-Sud, Orsay, France

Spin waves based devices are promising for next generation analog signal processing systems as they display small wavelength (μm) and easily tunable frequencies in the radiofrequency regime. For instance, by propagating spin waves through a periodic magnetic structure, i.e., a magnonic crystal (MC), one can achieve filtering in the GHz regime at the micro-scale [1]. For a long time, YIG-based magnonic crystals could not be downscaled to the sub-micrometer range as standard liquid phase epitaxy growth techniques yield relatively thick films (>1μm) incompatible with nanolithography. In the last few years, the advent of nanometer-thick YIG films of high quality either grown using pulsed laser deposition (PLD [2]) or sputtering ([3]) has open new perspective to adapt the knowledge that has been developed for metallic magnonic crystals ([4]) to YIG. Recently, using phase resolved μ-BLS microscopy on a width-modulated YIG waveguide, frequency filtering has been reported [5];indeed, the spin-wave propagation length was decreased by a factor of 4 inside a 15MHz band gap. However, this filtering came at the cost of increased propagation losses. Here we report on S-parameter characterization of a series of ultrathin YIG MC waveguides using Propagating Spin Wave Spectroscopy (PSWS). The MC obtained by etching 150 nm wide, periodically spaced grooves. Thickness modulation is expected to improve the filtering efficiency and insertion losses compared to width-modulated MC. The studied system is composed of 50 parallel wave-guides that are each 2.5μm-wide. These guides are designed using e-beam lithography and laser lithography and etched off 20nm thick YIG film PLD grown film with a Gilbert damping of $4x10^4$ [6]. Two U-asymmetric gold antennas are deposited on top, 30μm apart (see figure 1.a). The 150nm wide periodic grooves, orthogonal to the waveguides principal axis (see fig.1.b) corresponds to a Bragg k-vector of $1\mu m^{-1}$, the depth of the grooves is incremented from 0 to 20nm in 6 successive steps. The spectrum of mutual inductance due to the propagation of the spin waves is recorded over a frequency range between 0.5 and 2.5GHz, at various magnetic fields. A first measure of these spectra is performed on the waveguide without grooves (un-etched) and is found to be in good agreement with theoretical expectations for magnetic fields up to 20 mT. Within the same field range, we then measure the mutual inductance after etching for the same magnonic crystals having now grooves depth greater than 5nm. An example of successful filtering at 1.3GHz obtained for a field μ_0H=9mT is shown in figure 2. A 20MHz transmission gap is observed corresponding to a decrease by a factor of 4 of the spin wave intensity at 30μm from the antenna when compared to the reference waveguide. Importantly, we also find that the transmission outside the frequency gap is unaffected by the presence of the periodic grooves, even until an etching depth of about 10nm (not shown) in the 20 nm thick YIG film. In summary, we demonstrate a microscopic magnonic crystal based on ultra-thin YIG films suitable for implementation of nano-scale magnonic circuits with smaller dissipation than its width-modulated counterpart. Furthermore, the attenuation length of our films being of the order of 150μm in this frequency range, we expect to obtain much higher frequency selectivity by increasing the distance between our antennas up to 100μm, thus increasing the number of periods of our magnetic crystal while preserving our moderate propagation losses.

GF-10. Integrated magnonic networks based on the lateral magnonic stripes and magnonic crystals.

A.V. Sadovnikov[1,2], Y. Sharaevsky[1], S. Sheshukova[1], E. Beginin[1] and S. Nikitov[2,1]
1. Nonlinear Physics, Saratov State University, Saratov, Russian Federation; 2. Kotel'nikov Institute of Radioengineering and Electronics, Russian Academy of Sciences, Moscow, Russian Federation

In recent years much research has been directed towards the use of spin waves (SWs) for signal processing at microwave and subterahertz frequencies due to the possibility to carry the information signal without the transmission of a charge current[1,2]. Magnonic crystal (MCs)[1,2] have attracted a significant attention due to their wide range of application and numerous ways to fabrication. MCs are used in linear and nonlinear magnonics as a building block of magnonic networks. In the majority of the previously realized devices the MCs have been used as the high-Q tunable rejection filter due to the most important features of the MCs – the magnonic forbidden (rejection) band or magnonic band gap in the spin-wave spectra. However, the possible use of the magnonic forbidden band to fabricate the drop filters in magnonic integrated circuits can extend the application of MCs, in particular, for the magnonic logic[1,2,3]. In the asymmetric MC the spin waves have non-equal propagation constants and thus the phase-matching condition is violated. While phase mismatch might seem on the surface to decrease the coupling efficiency, the unusual increase of the spin-wave coupling can be observed at the frequencies in the vicinity of the magnonic band gap. This idea can underpin the experimental and theoretical studies regarding the side-coupled magnonic crystals, which can also act as frequency selective multiplexers. Here we report the experimental observation of the spin-wave coupling in the asymmetric adjacent magnonic crystals based on multimode yttrium iron garnet (YIG) waveguides[4-8]. We show, that the combination of frequency and spatial filtering features of the MC and spin-wave coupling in the adjacent magnetic waveguide leads to the realization of the magnonic drop filter (Fig.1). We also identify the mechanism of the efficient spin-wave power transmission between the magnonic crystals. As a major result, we have demonstrated by the means of the space-resolved Brillouin light scattering (BLS) technique, that non-identical MCs within close proximity demonstrates the efficient spin-wave coupling at the frequency of the magnonic forbidden gap of one of the MCs. Thus MCs can be used not only to achieve the spatial and frequency filtering of spin-wave signal but also to provide the phase condition with an efficient spin-wave power transfer from the input to drop port of magnonic coupler. The obtained results open new perspectives for the future-generation electronics using integrated magnonic networks. This work was supported partially by the grant from Russian Science Foundation (No. 16-19-10283).

GF-11. Tunable microwave properties of rhomboid shaped nanomagnet pairs.

C. Tian[1] and A. Adeyeye[1]
1. Electrical and Computer Engineering, National University of Singapore, Singapore

INTRODUCTION Nanomagnet-based memory and logic operations have attracted great technological interest in recent years due to their nonvolatility, low-power logic operations, ultrahigh density, and high endurance [1,2]. They are regarded as potential candidates for the next generation of non-volatile, low power logic devices beyond conventional CMOS technology. Recently, reconfigurable microwave responses have been shown based on in-plane dipolar coupled rhomboid shaped nanomagnets (RNMs) which do not require any stand-by power once initialized [3]. To optimize the frequency difference between ferromagnetic (FM) and antiferromagnetic (AFM) ground states, multilayer RNMs with a relatively thin nonmagnetic spacer layer have been investigated in which the nanomagnets are strongly out-of-plane dipolar coupled, and therefore a distinct frequency difference ($\Delta f \sim 1.9$ GHz) is achieved [4]. We may obtain a more complex relation of the magnetic ground state with the initialization field and intriguing magnetization dynamics at remanence by incorporating both in-plane and out-of-plane dipolar coupling in RNM-based structures. Thus, an understanding of the static and dynamic magnetic properties of the multilayer RNM pair in which the nanomagnets are both in-plane and out-of-plane dipolar coupled would be of great interest. EXPERIMENTAL DETAILS To probe the dynamic responses of the multilayer PQ-RNM pair experimentally using micro-focused Brillouin light scattering (micro-BLS) spectroscopy, a shorted ground-signal-ground (GSG) coplanar waveguide (CPW) made up of Cr (5 nm)/Pt (200 nm) was fabricated on a SiO_2/Si substrate using optical lithography and a liftoff process. Subsequently, PQ-RNM pairs were patterned using the electron beam lithography technique on top of the signal line of the shorted CPW as shown in the schematic representation in Fig. 1(a). The multilayer of $Ni_{80}Fe_{20}$ (25 nm)/Cr (15 nm)/$Ni_{80}Fe_{20}$ (20 nm) was deposited using electron beam evaporation followed by a lift-off process. A single-layer 45 nm thick $Ni_{80}Fe_{20}$ PQ-RNM of identical dimensions was also deposited as a control sample. In the micro-BLS technique, a monochromatic green laser (wavelength, 532 nm) with a focused spot size of ~250 nm was used to probe the dynamic response of a single RNM pair. RESULTS For the single-layer PQ-RNM pair, the BLS spectra for the two magnetic ground states (FM and AFM) are shown in Fig. 1(b). FM and AFM ground states were obtained by applying H_{ini} along the long and short axes, respectively. The AFM ground state has a higher resonance frequency because each nanomagnet experiences a larger effective field due to the stray field from its coupled neighbor. The multilayer PQ-RNM pair displays multiple magnetic ground states (FM, AFM1, and AFM2) upon different initialization fields [insets in Fig. 1(c)] due to the presence of both in-plane and out-of-plane dipolar coupling. The dynamic response as a function of initialization field has been systematically investigated. Distinct microwave absorption behavior and resonance frequency shift are observed when the nanomagnet pair is switched into different magnetic ground states as shown in Fig. 1(c). The observed resonance frequency shift can be understood in the context of a nanomagnet in the multilayer PQ-RNM pair experiences different stray fields depending on the magnetization orientations of its in-plane and out-of-plane coupled neighbors. Micromagnetic simulations validate our experimental observations [5].

GG-01. High-order methods applied to electrical machine modeling.

L. Friedrich[1], M. Curti[1], B. Gysen[1], J. Jansen[1] and E. Lomonova[1]
1. EPE, TU/e, Eindhoven, Netherlands

Introduction High-order methods have been subject of research over the last years to replace the time-consuming meshing operation of Finite Elements Method (FEM) by a structured grid, which is exploiting the tensor product. The problem formulation in these methods is generally the same, i.e. weak form implemented through the Bubnov-Galerkin method. First and second order polynomials functions used in FEM are replaced by high arbitrary-order polynomial functions because of their overall excellent accuracy and fast computation time. The Spectral Element Method (SEM) and Isogeometric Analysis (IGA) among others, are exploiting high order basis with established mathematical framework [1], [2], and available numerical tools [3]. In this paper, the solution for elliptic Laplace equation formulated with SEM and IGA are applied to 2D magnetostatic problems, including both linear and nonlinear materials. The obtained magnetic field distributions and post-processed parameters such as flux linkage, forces, and inductances are validated with FEM. A very low discrepancy is achieved which demonstrates the applicability of the proposed high-order methods, and enables integrated design-through-analysis of electrical machines. In this paper, SEM and IGA are applied to the analysis of two electrical machine benchmarks, in which a nonlinear iron characteristic is considered. Each of these methods uses different basis functions, quadrature rules, and space discretization, although both are based on the same Galerkin method. Modeling Solutions obtained from FEM are known to be very dependent on the quality of the triangular mesh [4]. Moreover, in FEM a curved geometry is approximated by linear elements which influences the accuracy, or comes at the cost of a high number of mesh elements. SEM divides the geometry into elements or patches, as exemplified in Fig. 1. Each patch is mapped to a unique square parent element, where calculations and matrix assembly are conducted. Legendre polynomials are used as basis functions. Lagrangian interpolation subsequently allows the computation of the solution on the Lobatto-Gauss-Legendre roots [1], and obtains the functional coefficients on the grid. IGA basis-functions are formed by the tensor-product of B-splines or NURBS (non-uniform rational B-splines), which is the industry-standard geometrical description used in computer aided design (CAD). The same basis functions allow to represent complex geometrical shapes [2], compute and visualize the solution. The physical domain is mapped to a rectangular computational domain, on which the basis functions and their gradients are known and where the calculations are conducted through numerical Gaussian quadratures. In both proposed methods, the geometry is discretized into 2D conforming patches where continuity is strongly imposed, forcing each basis function on the interface to match one-to-one. The formulation suited for 2D magnetostatic electrical machine modeling is further extended to include nonlinear material properties, such as soft-magnetic iron. The spatial distribution of the remanent magnetization and the magnetic incremental permeability are updated iteratively, according to the considered BH-curve, interpolated by means of a spline. The developed high-order methods allow for modeling curved topologies such as slots in a simpler manner than generally considered in analytical methods [5], in the same time, ensuring both flexibility and accuracy. Results and conclusion FEM reference results are obtained from a very dense second-order mesh and the accuracy threshold of the Newton-Raphson solver is reduced. A convergence comparison between the methods is conducted for the L2-norm. The first benchmark is used to compare magnetic forces, obtained by means of Virtual Work in FEM and Maxwell's Stress Tensor in both IGA and SEM. Moreover, two different integration paths are compared, and the influence of the quadrature rule and nodes is discussed. Magnetic vector potential distribution and discrepancies between FEM, IGA and SEM are displayed in Fig. 2. Additionally, the apparent and incremental inductance for the second benchmark are compared. The magnetic flux linkage is obtained through integration of the vector potential, consequently the apparent inductance is deducted. Spline interpolation of the flux linkage is conducted, from which the incremental inductance is computed with differentiation. Another method for calculating the incremental inductance is proposed, based on the magnetic potential generated by the remanent magnetization of the iron, while switching off the current density. The method has similar approach to frozen permeability [6]. Significant improvement of the incremental inductance prediction in terms of both accuracy and computational effort is achieved in comparison with the FEM results, obtained by means of local linearization. This aspect is specifically important for the control algorithms and power converters design. Concerning the calculation of the force and flux linkage, discrepancies are below one percent, which demonstrates the accuracy and applicability of the developed high-order methods for electrical machine modeling.

GG-02. Reluctance Network Model of Permanent Magnet Synchronous Motor Considering Magnetic Hysteresis Behavior.

Y. Hane[1] and K. Nakamura[1]
1. Tohoku University, Sendai, Japan

In recent years, the demand for high-efficiency electric machines is increasing from the viewpoint of global environmental issues and energy saving. In order to further improve the efficiency of the electric machines, it is necessary to establish a method for quantitatively calculating iron loss including magnetic hysteresis behavior. To solve the above problem, we have focused on a play model [1], which is one of the phenomenological models of magnetic hysteresis behavior. We embedded the play model in the magnetic circuit model, and calculated iron loss including minor loops with high accuracy and speed [2]. However, this method was applied only for the objects with simple shapes such as a ring core. The authors proposed a reluctance network analysis (RNA), which expresses an analysis object by one reluctance network. All the reluctances can be determined by *B-H* curve of the material and dimensions [3]. The RNA has been applied to the calculation of characteristics of various electric machines including transformers and motors. However, a method for expressing magnetic hysteresis is not established for RNA. This paper describes that the play model is applied to the RNA by using a permanent magnet (PM) motor as a consideration target, in order to estimate the iron loss including the magnetic hysteresis behavior. As shown in Fig. 1 (a), the play model can express an arbitrary hysteresis loop by multiplying play hysterons $p_N(x)$ with different widths by shape functions $f_N(p_N(x))$. Although a large number of measured dc hysteresis loops with different maximum flux densities are required to derive the play model in general, the proposed method requires only one or two measured dc hysteresis loops because the Landau–Lifshitz–Gilbert (LLG) equation is used to calculate the dc hysteresis loops [2]. Fig. 1 (b) shows the hysteresis loops calculated by the LLG equation. As shown in this figure, a large number of hysteresis loops which are used to derive the play model can be obtained without experiments. In the following, we describe a method for deriving the RNA model of surface permanent magnet (SPM) motor, which has 6-slots and 4-poles. The stator is divided into 12, which is twice the number of slots, in the circumferential direction so that the leakage flux between the slots is taken into consideration. On the other hand, the tip of stator pole, air gap, permanent magnet on the rotor surface, and rotor yoke where the flux distribution is more complicated, are divided into 180 in increments of 2 degrees in the circumferential direction. Each divided element is replaced with reluctances. Among them, the reluctances in the rolling direction are needed to be determined in consideration of nonlinear magnetic property. In the conventional RNA model, the magnetic nonlinearity is given by dc *B-H* curve of the material. However, the magnetic hysteresis is not taken into consideration. In this paper, each reluctance of the RNA model is replaced with the play model and two circuit elements, one is inductance denoting the eddy current loss, and the other is controlled-source denoting the anomalous eddy current loss as shown in Fig. 2(a) [2]. The figure shows the schematic circuit diagram of the proposed RNA model of one pole of the SPM motor. The MMF at the stator pole in the figure is one generated by the winding current. In the RNA model, the MMF F_c of the magnet is expressed by the following equation using the coercive force H_c and the average magnet length l_m. $F_c=H_c l_m$ (1) The reluctance R_p of the magnet is given by the following equation using the relative recoil permeability μ_r and the average cross sectional area S_m. $R_p=l_m/\mu_r\mu_0 S_m$ (2) The reluctances in an air space surrounding the magnetic core are simply given by the following equation using the average cross sectional area S and length l of divided elements, and the vacuum permeability μ_0, $R_{air}=l/\mu_0 S$ (3) Fig. 2 (b) shows each loss calculated by the proposed RNA model when a rotational speed is 1000 r/min, torque is 0.65 Nm, and winding rms current is 1.3 A, respectively. The copper loss is obtained from the product of the winding resistance and the square of the winding rms current. The eddy current loss of the magnet is obtained from an electric network model of the magnet [4], which consists of electromotive forces induced by the flux flowing through the magnet and electric resistances determined by the resistivity of the magnet and dimensions. Accordingly, the iron loss is obtained by subtracting machine output, copper loss, and magnet eddy current loss from electrical input. In the near future, we will verify the validity of the proposed model by comparing the results with the prototype machine. In addition, Fig. 2 (c) shows calculated hysteresis loop of a certain divided element of the RNA model. As shown in the figure, using the proposed model, the magnetic hysteresis inside the iron core, which is generally difficult to measure, can be drawn.

I. INTRODUCTION The interior permanent magnet synchronous motor (IPMSM) and blushless DC (BLDC) motor can be controlled by either the pulse-width modulation (PWM) inverter excitation or pulse-amplitude modulation (PAM) inverter excitation [1-5]. The authors in [2] evaluated losses of the PMSM in high-speed drive of 50 krpm to 200 krpm, where the carrier frequency is from 25 kHz to 200 kHz. Motor drive system used in electric vehicles (EV) requires the variable voltage and variable frequency operation for motor velocity control. Although the PWM inverter can make variable voltage and frequency, its output waveform is usually complicated. The PAM inverter requires an additional DC-DC converter for variable voltage, but it has simple output waveform as the 120-degree commutation technique [3]. Besides, the low carrier frequency and rotational speed affects the total core loss of IPMSM considerably. Our study focuses on this issue with the PWM and PAM inverter excitations in both no-load and load operational cases of the motor; the evaluation is conducted with computational analysis and experiments. Moreover, response of the magnetic flux density in stator and distribution contours of motor core losses with the two inverters are analyzed in computational simulation. II. STRUCTURES OF PWM AND PAM INVERTER EXCITATIONS FOR IPMSM In this study, structures of PWM and PAM inverter excitations are shown in Fig. 1 panels (a) and (b), respectively. In the case of no-load operation, the torque meter SS-020, BLDC motor and resistor load are disconnected to the IPMSM. With the PWM inverter excitation in Fig. 1 panel (a), the DC-link voltage V_{dc} is a fixed value. Whereas, the PAM method controls the inverter with 120-degree commutation and automatically adjusts amplitude of the changeable DC-link voltage as shown in Fig. 1 panel (b). In addition to experiments, numerical calculation is done for evaluating the motor core loss. III. COMPUTATIONAL ANALYSIS AND EXPERIMENTAL MEASUREMENT METHODS The total core loss of IPMSM can be computed as given in (1). $P_{core} = P_{3\Phi} - R_s(I_u^2 + I_v^2 + I_w^2) - P_f - \omega T$ (1) Where P_{core} : total core loss of IPMSM, $P_{3\Phi}$: total input active electrical power, R_s : phase resistance, 0.6 Ω, I_u, I_v, I_w : phase currents in rms, P_f : IPMSM and encoder mechanical losses, 0.628 W, ω : rotational speed, 750 rpm, T : output torque. The stator and rotor are made of a non-oriented material, named as 35H300, and the permanent magnet in the rotor is sintered NdFeB. The nominal power of the motor is 400 W. The software for computational analysis is JMAG. In simulation, the torque in the load test case is fixed as T = 0.497 Nm, while the torque value in experiments is measured and often in the range of T = 0.5 Nm (at the starting time) to 0.497 Nm (from the time t = 90 minute). Operational parameters for PWM inverter are as follows; the fixed DC-link voltage is V_{dc} = 205 V, the fundamental frequency is f_0 = 50 Hz, the carrier frequency is f_C = 1 kHz, and the dead-time of inverter is 3500 ns. Operational parameters for PAM inverter are as follows; the fundamental frequency is f_0 = 50 Hz, the inverter is controlled with the 120-degree commutation, and the dead-time of the inverter is 3500 ns. Firstly, the experimental system is operated to warm up the IPMSM for ninety minutes. Then, from the time t = 90 minute to 115 minute, and from t = 170 minute to 195 minute, we perform six to twelve measurements; each measurement has forty samples. In total, there are 240 to 480 data samples for all measurement times of each experiment. For each the operational case, we perform at least four independent times of experiment; the result is the average value of all the times of experiment. IV. COMPUTATIONAL AND EXPERIMENTAL RESULTS As described in Fig. 2, the PAM inverter excitation can diminish the total core loss of the IPMSM significantly in both the no-load and load operational cases. As compared to the PWM inverter, the PAM inverter has the much better efficacy of reducing the motor core loss in calculation and experiments. In the no-load operational case, the total motor core loss with PWM inverter are 5.9 W and 5.87 W, while the ones with PAM inverter are 2.11 W and 2.243 W, respectively; the reduction is about 62%. In the load test case, the motor core loss with PWM inverter are 6.365 W and 6.61 W, while the ones with PAM inverter are 2.415 W and 2.766 W, respectively; the reduction is about 60%. The computational and experimental results are relatively consistent. In both computational and experimental results, harmonics in voltage and current waveforms in stator of the IPMSM is substantially mitigated with the PAM inverter as compared to the one with the PWM inverter. In simulation results, the response of magnetic flux density in stator with the PAM inverter is also smoother than the one with the PWM inverter. V. CONCLUSION This paper has shown the superior effectiveness of the PAM inverter excitation in decreasing the total core loss of IPMSM as compared to the PWM inverter excitation. The computational analysis and experimental results have been conducted and examined carefully to confirm the salient advantages of the PAM inverter excitation. In future work, an experimental system, including a silicon carbide (SiC) MOSFET inverter with the PAM excitation and an IPMSM, will be developed to assess motor core losses in wide range of speed.

GG-04. Unity Power Factor Control Method for Permanent Magnet Synchronous Generator Based on Flux-Weakening Current Injection.

Y. Xu[1], Z. Zhang[1], Y. Jiang[1], J. Huang[1] and Z. Miao[1]
1. Nanjing University of Aeronautics and Astronautics, Nanjing, China

I. INTRODUCTION The permanent magnet synchronous generator (PMSG) has been gaining interest for aircraft starter/generator (S/G) system application over the last few years due to its high power density, high efficiency and wide operation speed range [1]. Higher power density PMSG generation system is demanded due to the growing generation power capacity. High power factor (PF) operation or even the unity power factor (UPF) operation of the PMSG always means the reduction of converter weight, leading to the higher-power-density and higher-performance SG system [2]. In this paper, the feasibility of the PMSG UPF control based on flux-weakening current injection is demonstrated. Analytic model under UPF operation condition is established to analyze relationship of the d-axis current (i_d) and q-axis current (i_q). Comparison between the proposed method and i_d =0 control method is made to illustrate the advantages of the proposed method. Finite element analysis (FEA) and experiments are conducted on the 24/16 interior permanent magnet (IPM) PMSG and 12/10 surface permanent magnet (SPM) PMSG to verify the effectiveness of the proposed method. II. UPF CONTROL OF THE PMSG Phasor diagram of the PMSG under d-q axis reference frame is illustrated in Fig.1, where α_u and α_i are angles between the d-axis and voltage and current vector, respectively. The d-axis voltage (u_d) and q-axis voltage (u_q) are computed as equation (1) and (2). When the PMSG operates under UPF condition, the PF angle ϕ equals zero, thus α_u equals α_i, which can be illustrated in equation (3)-(6). The solution to the formula (6) is shown in equation (7). It reveals the relationship of i_d and i_q to achieve UPF operation. FEA is conducted on the 24/16 IPM generator and 12/10 SPM generator to verify the deduction. The cross section views of the PMSGs are shown in Fig.2 and the main parameters is shown in Tab.I. Fig.4 and Fig. 5 show PF and loss of the two machines under different i_d in the rated condition. From Fig.4, it can be seen that when i_d is -6A, the PF reaches the maximum value (unity) and the total loss is minimum. As for the SPM, when i_d is -165A, PF is unity but the total loss is not the minimum. This is because the operating speed is relatively high and the PM loss dominates the total loss, which is not relevant to the demagnetization current. Tab.II shows the calculated and simulated i_d values when the machines operate under UPF condition. It can be referred that, the calculated result agrees with the FEA results generally, but is a slightly lower. This is because the core saturation is neglected in the analytical model. The UPF control is proposed based on the flux-weakening current injection, as illustrated in Fig.2. The control structure contains voltage outer loop, current inner loop, space vector pulse width modulation (SVPWM) module, three-phase bridge converter and the PMSG. The command value of i_q (i_q^*) is determined by the voltage loop to output command dc voltage. The command value of i_d (i_d^*) is determined by i_q, back electromotive force (E_0), d-axis inductance and q-axis inductance according to equation (7). SVPWM module generates the PWM signals to drive the IGBTs in the rectifier. Such arrangement ensures the UPF operation of the PMSG. III. COMPARISON OF UPF CONTROL AND ID=0 CONTROL METHOD To further clarify advantages of the UPF control method, FEA is carried on the 24/16 IPM. UPF control method and i_d =0 control method are conducted on the machine with different axis lengths in the rated condition. Results are illustrated in Fig.6. Fig. 6(a) and (b) explain the relationship between the i_d, i_q, i_a and the axis length under the UPF control and the i_d=0 control respectively. The maximum armature current is almost the same under the two control methods. Fig.6 (c) shows the PF under the i_d=0 control. When the axis length is longer than 100mm, PF starts to saturate, the maximum value is around 0.8. Fig.6 (d) illustrates the loss of the two control methods. It can be seen that the total loss of the PMSG is reduced by employing the UPF control method. The comparison shows that the proposed method could raise PF greatly within the same current constraint. The converter capacity could be reduced compared to that of the i_d=0 control method. It is beneficial to raising the power density of the whole generation system. IV. EXPERIMENT VERIFICATION Experiments are carried on the 24/16 IPM prototype. The stator and rotor laminations are shown as Fig. 7(a) and (b). The experiment platform is shown in Fig.7 (c). The operating speed is 1000 rpm and the output power is 3.6 kW. UPF control method is taken. The voltage waveform and current waveform of phase A are shown as Fig.7. From the result, it can be seen that the phase voltage and the phase current share the same phase angle, which verifies the effectiveness of the control method. V. CONCLUSION In this paper, the feasibility of the PMSG UPF control based on flux-weakening current injection is demonstrated. The control law is analyzed by mathematic model and FEA. The comparison between the proposed method and i_d=0 control method is presented. The proposed method can reduce reactive power of the generation system, thus reducing the capacity of the converter. The proposed method could also reduce the total loss in the low speed operation. Experiments are carried on a 24-slot, 16-pole IPM PMSG to verify the effectiveness of the proposed method. A simple and effective UPF control method is provided, improving the power density and reducing the loss of the PMSG.

GG-05. Virtual Flux Direct Power and Voltage Balance Control of Dual-Stator Linear and Rotary Permanent Magnet Generator.

C. Zhang[1], L. Xu[1] and X. Hu[1]
1. School of Electrical and Information Engneering, Jiangsu University, Zhenjiang, China

I. Introduction Dual-stator Linear and rotary permanent magnet generators (DSLRPMG) features high efficiency and high power density. The two stator windings with a variety of connections can realize wide voltage output range. Therefore, it has important application value in the starter / generator of the hybrid electric vehicle [1], two degree of freedom generator [2], and the wind generator [3]. In this paper, a novel strategy of virtual flux direct power and voltage balance control (VFDPVBC) is proposed to improve the dynamic performances of DSLRPMSG system. Based on the two three phase PWM rectifiers and two extra parallel selection switch, the direct power control without any AC voltage sensors and the output DC voltage balance control are investigated. Meanwhile, space vector modulation (SVM) is also utilized to fix the switching frequency. The simulation and experimental results show the validity and correctness of the method. II. DSLRPMG and Circuit Topology A. DSLRPMG Topology The topologies of the DSLRPMG are shown in Fig. 1. There are three structures named series structure, parallel structure, and half & half structure for the DSLRPMG. Due to the two stators and one mover, the generator can obtain double energies than that of the conventional one. However, when the coil turns of the two stators are unequal or the two stators are in 2-DOF energy input, the energy conversion from the two stators to the load is coupled. This may cause unbalanced output voltages and the dynamic performances reduction of the generation system. B. Circuit of the DSLRPMG System Fig.2 shows the main circuit of the DSLRPMG system. The R and L are considered as the stator resistance and leakage inductance of the DSLRPMG, respectively. III. VFDPVBC and Decoupling Principle The VFDPVBC consists of DC voltage outer loop, DC voltage inner loop, and power loop, as shown in Fig. 3. The internal voltage loop is regulated by two PI controllers separately. When reference power P^{*}_{ref} changes, the interaction between active and reactive power makes the steady and dynamic performances deteriorating. Moreover, by controlling of the two parallel switch (S_{d1} and S_{d2}), the load bus voltage can keep a constant. The voltage equation of the DSLRPMG in the stationary reference frame can be expressed as $u = Ldi/dt + Ri + u_{conv}$ (1) where $u = [u_{a1}, u_{b1}, u_{a2}, u_{b2}]^{T}$ and $i = [i_{a1}, i_{b1}, i_{a2}, i_{b2}]^{T}$, the u_{conv} can be obtained from the dc-link voltage u_{dc1} and u_{dc2}, and the states of rectifier switching (S_{a1}, S_{b1}, S_{c1}, S_{a2}, S_{b2}, S_{c2}) as follows: $u_{conv} = [u_{conva1}, u_{convb1}, u_{conva2}, u_{convb2}]^{T}$ (2) The virtual flux $\psi = [\psi_{a1}, \psi_{b1}, \psi_{a2}, \psi_{b2}]^{T}$ can be induced as $\psi = \int u dt = \int (Ldi/dt + u_{conv}) dt$ (3) According to the instantaneous power theory, the instantaneous active power p and reactive power q can be calculated by $P = Re(ui^{*})$, $q = Im(ui^{*})$ (4) The voltage space vector can be obtained from (3): $u = d(\psi_{m} e^{jwt}) / dt = (\psi_{m} / dt) e^{jwt} + jwy$ (5) When the input mechanical is unstable, the voltage balance estimator works to keep the stable of the outer output voltage, as well as the direct power control works to keep the stable of the inner output voltage. IV. Simulation and Experiment In order to verify the correctness of the proposed VFDPVBC, a 1.5kW-rated power of DSPMG model is established by the Matlab/Simulink software. The DSLRPPMG is a double stator linear and rotary permanent magnet machine (DSLRPMM) which is proposed in [2]. The basic waveforms of the control strategies are given. Furthermore, a prototype is established and tested. Fig. 4 shows the experimental prototype, which includes DSLRPM utilized as a generator, inductance, power circuit, DSP control board and the resistance load. The experimental results are analyzed and compared with that obtained by the simulation. V. Conclusion This paper proposed a novel strategy of direct power control coupled with voltage balance control. Based on the utilization of the power loop, inner voltage loop, and outer voltage loop, the dynamic performances of the generation system is improved. The simulation and experimental results show the validity and correctness of the strategy.

GG-06. Computation of Cogging Force of a Linear Tubular Flux switching Permanent Magnet Machine Using a Hybrid Analytical Modeling.

D. Lo[1], H. Lawali Ali[1], *Y. Amara*[1], G. Barakat[1] and F. Chabour[1]
1. GREAH, University of Le Havre, France, Le Havre, France

I. Introduction Permanent magnet flux switching machines are gaining more and more interest due to their relatively good characteristics. Indeed, the presence of all magnetic field sources in the stator (armature windings, permanent magnets and/or field windings), which implies a completely passive rotor, makes it suitable for a large variety of applications [1] [2]. Different flux switching machines topologies have been studied in scientific literature. In this contribution, a relatively new modeling approach [3] based on the coupling of mesh based generated reluctance networks (MBGRN) and analytical models (AM), based on the formal solution of Maxwell's equations, is used for the accurate prediction of cogging force of a linear tubular flux switching machine. This type of machines could be favorably used in oceanic renewable energy conversion. Figure 1(a) illustrates how the two approaches are combined for the case of a tubular linear flux switching structure. In this example the analytical solution is used for modeling the mechanical air-gap, and inner and outer airs, and the RN method is used to model the moving and static armatures. In order to have a more generic approach, the stator and moving armatures are modeled using mesh based generated reluctance network (MBGRN) technique [3]. This technique, as classical RN method, can be used with a minimum number of reluctances for regions where flux tubes are not highly affected by topology changes. As for finite elements analyses (FEA), the studied domain in MBGRN should be finely meshed in some regions (air-gap for example) and coarsely meshed in other regions. However, in contrast to FEA, the mesh relaxation in MBGRN can be done more easily conducting to reduced system matrix dimensions, and consequently reduced computation time. Indeed, while in FEA two adjacent elements should share an edge, it is no more necessary for RN method, as illustrated in Fig. 1(b). This new modeling approach has been used to analyze the performance of different electromagnetics devices (2D and 3D) [3]–[7]. In this contribution, this technique is used for the computation of cogging force of a linear tubular flux switching permanent magnet structure, something which has never been reported yet, to the best of our knowledge, in scientific literature. The goal is to further extend the investigation of this technique for the computation of relatively sensitive quantities, such as the cogging force, in more complex structures. Another goal is to highlight advantages of HAM as compared to other modeling techniques, and more particularly FEA, in order to obtain reduced order equations system [8] [9]. II. Hybrid Analytical Model (HAM) The coupling between the AM and the RN model is done at the boundary between both models by equalising the tangential components of magnetic field H, and normal components of magnetic flux density B. The coupling will be more thoroughly described in the full version of the contribution. Analytical solutions in the three regions: internal air, air-gap and external air, will be presented and equations system construction will be detailed. Figures 2(a) and 2(b) compare the air-gap flux density components obtained using both FEA and HAM in the middle of the air-gap. As can be seen relatively good agreement is obtained. The number of nodes of RN used for the modelling of the moving and static armatures is the same and equal to 15120. The number of considered harmonics in all regions modelled using the AM is set to 300. Geometric dimensions and physical characteristics of studied machine along with details about the finite element analysis will be provided in the full version of the contribution. III. Cogging Force Analysis The HAM has been applied to analyse the cogging force in a tubular linear flux switching permanent machine. In order to assess accuracy of developed model, results from HAM are compared to corresponding results from a FE analysis. The cogging torque waveform is very sensitive to computation accuracy of air-gap magnetic field components, in particular when Maxwell's stress tensor method is used, and constitutes therefore a good quantity to assess the accuracy of the HAM as compared to FEA. Figure 2(c) shows comparison of cogging force waveforms obtained from both methods. The results from both methods (FEA and HAM) are in relatively good agreement, which demonstrates the effectiveness of the HAM model to handle more complex structures. In the full version of the contribution, effect of mesh density, in both techniques FEA and HAM, on cogging force computation will be addressed. Along with the effect of mesh density, the use of virtual work method in order to estimate the cogging force will also be investigated.

GG-07. A fully magnetic multi-scale model dedicated to power grid planning.

V.G. Mazauric[1,2] and N. Maïzi[2]
1. Strategy & Technology, Schneider Electric, Grenoble, France; 2. Centre for Applied Mathematics, MINES ParisTech, PSL Research University, Sophia-Antipolis, France

Free current density occurring within a power grid exhibits well-split scales allowing mean-field procedures, *i.e.* the global trend toward reversibility [1] is replaced by embedded minimizations on the relevant scales involved by the power transmission. Various scales were already successfully explored from the material to the device scale [2-4]. At the power management level, the exchange of the magnetic Helmoltz free-energy provided by the so-called reactive power acts to enforce synchronism, usually 50 or 60Hz, between all generation plants supplying the power grid. An X-Y lattice model [5] is adopted to describe the interaction between the magnetic momentum carried by the rotor of a given generator and the mean-field resulting from all the others. The question of ordering stability of two-dimensional systems was extensively studied in the context of phase transitions and critical phenomena. Whereas no long-range order exists in two-dimensional lattices with short range interaction between Heisenberg magnets, Onsager provided an exact resolution of the Ising model with first neighbor interactions. Hence, the X-Y model appears as a marginal case where the long-range ordering may vanish through a weak singularity under an external perturbation [6]. In the context of power system, the synchronism between rotors may be jeopardized by long-range modes and it is convenient to study this problem within the Kuramoto's model [7]. For keeping a stable solution – *i.e.* backing locally and exponentially to a synchronous steady-state after any small disturbance – the indicator expressing the ratio between (i) the algebraic connectivity of the graph of admittances underlying the power flow of the grid; and (ii) than the maximal rate of congestion expected on the grid must be higher than 1 [8]. Besides, magnetic Helmoltz free-energy embedded in the power grid is derived from the Kuramoto's Hamiltonian, showing the critical role of the reactive power to maintain the synchronism and the grid operation. In other words, the stability of the power grid is kept thanks to a strong enough correlated lattice – or actually a suitable voltage plan on the grid – which provides large enough resistant electrodynamic torques to the generators therefore able to face to any admissible fluctuation. Then, the kinetic energy embedded in the whole power system may be aggregated to act as a global and huge inertia to prevent abrupt frequency deviations which therefore may only occur on several periods under a linear regime. By enforcing over time (i) the embedded kinetic energy to be higher than a minimal level typically given by its current value; and (ii) the synchronism indicator to be higher than 1, the previous approach provides a minimal set of technical requirements to ensure reliable operations in a long-term planning exercise addressing both space-aggregation and time-reconciliation of all scales involved in the power management. To that end, the technical optimal TIMES model [9] was adapted to provide, beyond the strict system adequacy, future generation mixes according to different scenarios which obey operation constraints. This issue is addressed for the Reunion Island, which aims to reach energy independence by 2030 using 100% renewables (Fig. 1), this methodology draws the following conclusions: (i) to achieve the 100% renewables target, the capacity to invest in the energy sector is doubled, and the level of reliability decreases considerably; (ii) the loss of reliability induced by higher intermittency— typically 50% —in the power mix can be counter balanced and leveraged by implementing flexibility solutions (demand response and storage) and reinforcing the grid (Fig. 2).

GG-08. Electromechanical Analysis in Electromagnetic Rail Launcher With Different Cross Section Rails.

X. Wan[1], J. Lou[1], J. Lu[2] and D. Liang[1]
1. School of Electrical Engineering, Xi'an Jiaotong University, Xi'an, China; 2. School of Electrical Engineering, Naval University of Engineering, China, Wuhan, China

Abstract Electromagnetic rail launcher is essentially a high-speed linear motor. It can accelerate projectiles in the range from milligrams to several kilograms to velocities more than several kilometers per second. Electromechanical characteristics in electromagnetic launcher with the cross section of plane, convex, and concave rails were investigated with/without friction under the channel cooling condition. The Kinematic characteristics of armatures and Von Mises stress of three type rails were studied. The velocity and acceleration of armature in electromagnetic rail launcher with convex rail are the highest. The peak stress in plane rail during one shot period is the largest. In light of obtaining higher velocity and acceleration of armature and moderate stress in rail, convex rail is better than the other two type rails. Keywords: Electromagnetic rail launcher, cooling channel, kinematic characteristics, Von Mises stress. A.Introduction The electromagnetic rail launcher (ERL) is composed of two parallel rails and armature. When ERL works, the current flowing from one rail, across the armature, then to the other one will produce strong magnetic field. The Lorentz force induced by the interaction between magnetic field and current will push the armature to high speed. During this process, there is much thermal and strong electromagnetic force in rails. It is a multi-field coupled system. Repetitively-shot is a prerequisite of the practical application of a utility ERL. In multiple shot mode, channel cooling approach is used to remove thermal generated by current flowing through rails. The cooling channels are very beneficial for taking away thermal in rails. But they directly influence the mechanical performance of the rails, thus affect the structure stability of the whole system. So it is a meaningful topic how to keep structure stability in ERL under channel cooling condition. When armature slides along the rails, as the muzzle velocity of armature is more than 2 km/s, the larger armature velocity leads to an increase in Peclet number, which will seriously influence the convergence and accuracy of the model. To avoid the oscillation caused by the higher Peclet value, Zhang [1] and Huang [2] used the moving co-ordinate frame to solve the problem of eddy current in the moving conductors. Yamazaki [3] and Rapetti [4] employed mortar method to handle the staggered meshes on the moving boundary in each time step. Hsieh [5] developed EMAP 3-D code with Lagrangian description to simulate the dynamic launching process of the launcher. However, the mechanical characteristics of ERL with plane, convex, and concave rails by active cooling condition have not seen in literatures. The results in this paper are very important for structure optimization design of electromagnetic rail launcher with cooling channels. They are also significant for eventually realizing efficient repetitively-shot in the electromagnetic rail launcher. B.Model of ERL And Applied Pulse Current To compare the electromechanical performances under identical conditions, the cross section area, a, R, h, L1, and L2 are kept constant. The ERL in this paper is composed of two parallel copper rails which are 7m long and aluminum armature. The armature mass is 3709.72g. Owing to the symmetry, only a quarter of the armature and rails will be considered. The pulse current used is a trapezoidal wave current. The peak value of the current is 3.0MA.FEM simulations of EM-structure coupled field are carried out to compare the mechanical performances of three type rails under same condition. C. Analysis Results The kinetic characteristics of the armatures gained by simulations are shown in Fig.1. As shown in it, the velocity and displacement of armature in ERL under friction/no friction condition with convex rail are the highest. And the velocity and displacement of armature in ERL with plane rail are the lowest. As shown in Fig.2, at the max stress moment during one shot cycle, peak stress all occurs around cooling channels in three type rail. They are all less than the yield strength of copper. In zero friction/ friction condition, peak stress in plane rail during one shot period both is the largest in three type rails. And the max stress in concave rail is the lowest in three type rails. D.Conclusions In this paper, electromechanical characteristics were analyzed for the cross section of plane, convex, and concave rails with active cooling conditions. Coupled EM-structure simulations were implemented for the three types of ERL respectively. The velocity and acceleration of armature in ERL with convex rail are the highest. The deformation and stress in plane rail is the largest. At the max stress moment during one shot cycle, peak stress all occurs around cooling channels in three type rail. Peak stress in plane rail during one shot period is the largest in three type rails. In terms of gaining better electromechanical characteristics in ERL, the ERL with convex rails is the best one.

GG-09. Reduced Order Modeling of Axially Laminated Synchronous Reluctance Motors Based on Numerical Field Solutions.

D. Lin[1], P. Zhou[1] and *M. Rahman*[2]
1. Ansys Inc., Pittsburgh, PA, United States; 2. Memorial University of Newfoundland, St. John's, NL, Canada

Axially laminated synchronous reluctance motors (ALA-SynRM), which possess relative high torque density owing to their high saliency ratio, have received growing interest in recent years [1]-[3]. Since ALA-SynRMs have characteristics suitable for mass production and easy manufacturing processes, they are viable candidates for various domestic and industrial applications [2], [3]. In many applications of ALA-SynRMs, what system designers want to know is the transient response to various electrical and mechanical inputs. Although finite-element analysis (FEA) can simulate this transient process accurately, it usually requires very long processing time. In such numerical simulations, where the magnetic field distribution inside the machine is not the main concern, reduced order modeling [4] is an efficient technique. A key advantage of reduced order modeling is its capability for significantly reducing the computational burden and cost of numerical simulations, while maintaining a sufficient accuracy for the concerned performance from the engineering point of view. A reduced order model (ROM) could be a parameter based model in which the electromechanical coupled state equations are represented with some linear or nonlinear electrical and mechanical parameters, or a look-up-table based model in which all electrical and mechanical outputs, such as winding flux linkages and rotor torque, are expressed as functions of some electrical and mechanical inputs, such as winding currents and rotor position, via interpolation from a discrete look-up table. The former which uses less memory is more suitable for hardware-in-the-loop controls, and the later which is more accurate in system simulation can be used in circuit design and optimization. This paper presents both parameter and look-up-table based ROMs of ALA-SynRMs, derived from FEA solutions. The axially laminated rotor is treated as a core with nonlinear anisotropic material [5]. The anisotropic magnetic property in the easy direction is derived from the parallel connection of steel lamination layers with inter-laminar insulation layers, and that in the hard direction is derived from the series connection. The circuit realization of parameter based ROM for ALA-SynRMs is shown in Fig. 1, where *d*- and *q*-axis inductances (L_d and L_q), assumed to be independent of rotor position θ, are expressed as non-linear functions of *d*- and *q*-axis currents (i_d and i_q), and the zero-sequence inductance L_0 is assumed to be constant. The output torque is directly computed from the *d*- and *q*-axis inductances and currents. Two pins of the rotational mechanical port are denoted as ROT1 and ROT2. Fig. 2 shows the circuit realization of look-up-table based ROM for ALA-SynRMs, where λ denotes flux linkage. Based on a sweeping set of *d*- and *q*-axis currents and rotor position, three-phase winding currents for FEA excitations are obtained from the *dq*0 to *abc* transformation without the need to sweep the zero-sequence current component. After FEA simulation, we obtain three-phase flux linkages, as well as rotor torque, from the FEA solutions. The flux linkages in the *dq*0 system, used as outputs of look-up table, are transferred from the flux linkages in the *abc* system. In this paper, we will also introduce some advanced techniques to reduce computational time at specified density of the sampling points by taking advantage of the symmetric conditions of three-phase windings and the periodic condition of rotor position. Since a reluctance rotor has repeatable pole geometry, the flux linkage in one phase generated by three-phase currents will be negatively repeatable in 180 electrical degrees of rotor position even though the three-phase windings may be of the fractional-slot type. As long as three-phase windings are symmetric, the flux linkage in one phase can be obtained from another phase by shifting the waveform by 120 electrical degrees. As the results, in the *dq*0 system, the *d*- and *q*-axis flux linkages, as well as the rotor torque, are repeatable in 60 electrical degrees due to absence of the zero-sequence flux linkage component. Therefore, the rotor position is required to be swept for only 60 electrical degrees, instead of 360 electrical degrees. This technique, together with the algorithm not to sweep the zero-sequence current, is able to reduce the computational time significantly. A 5.5kW, 380V, 4-pole, 1500rpm ALA-SynRM design is presented as an application example. Solutions from the system simulation with look-up-table based ROM are compared with the solutions directly from the FEA transient simulation. To illustrate the difference between the parameter and look-up-table based ROMs, the solutions from the system simulation with parameter based ROM are also presented.

GG-10. Development of a New Approach to Core Quality Assessment of Modern Electrical Machines.

H. Bahmani[1]
1. Ulster University, Londonderry, United Kingdom

I. Introduction Mechanical, magnetic and electric properties of electrical steels can be deteriorated by manufacturing process, e.g. welding and cutting, which has a direct impact on normal operation of the magnetic cores [1-3]. Quality of the magnetic cores is an important consideration for the designers, manufacturers and users of the magnetic devices. Core quality mainly depends on electrical and magnetic properties of the magnetic material, quality of the insulation material, clamping pressure, magnetising condition, etc. Key amongst these are inter-laminar faults, which have been identified as a major threat for normal operation of electrical machines and transformers [3-4]. Whereas, a large number of inter-laminar faults can lead to catastrophic failure, the machine can still operate with a limited number of faults, but with elevated power loss. Local power loss results in hot spots in the core, which accelerate the degradation of the insulation coating of the laminations and can cause premature aging of the magnetic cores. Therefore, core quality assessment, should be performed at an early stage before it progress to machine failure [5]. This is an essential criterion for efficient and reliable operation of the electrical machines and transforms. Hysteresis behaviour of the magnetic materials is an important characteristic in characterisation of the material under different magnetisation conditions. All types of magnetic materials can be characterised and interpreted by means of particular aspects of hysteresis phenomenon. The area enclosed by the hysteresis loop represents the amount of energy dissipated into heat during one magnetisation cycle. This is an important aspect of hysteresis phenomenon, to characterise the magnetic material and has found many applications in physics and engineering [6]. Accurate measurements of Static Hysteresis Loop (SHL) and Dynamic Hysteresis Loop (DHL), is an adequate technique of loss evaluation. In this respect, analytical methods have been developed to reproduce DHL of the material for power loss prediction and separation [7-10]. In this paper, a new approach based on the DHL is developed for core quality assessment purposes. The developed method can be implemented to detect inter-laminar fault between laminations of the clamped magnetic cores, over a wide range of magnetisation. II. Experimental Results The experimental work were carried out on stacks of four Epstein size laminations of 0.3 mm thick CGO 3 % *SiFe*, with standard grades of M105-30P. Similar to the previous work [4], partial artificial short circuits of 10 mm wide and different configuration were introduced between the laminations, as described below: Pack # 1: *Inter-laminar faults at three step-like points* Pack # 2: *Inter-laminar faults at one set point* Pack # 3: *Inter-laminar faults at three set points* Each pack of lamination was magnetised separately using a single strip tester at peak flux densities of 1.1 T to 1.7 T and magnetising frequencies from 50 Hz up to 1000 Hz. Magnetic properties of the samples including bulk power loss and DHL were measured individually. DHL of the specimens at measured frequencies and peak flux density of 1.7 T are shown in Fig 1. The most evident feature of Fig 1 is the significant increase of the hysteresis loop area and change in the loop shape, for different types of fault. This result reflects a unique property of the DHL in power loss evaluation, which can be implemented in the characterisation of the magnetic cores subjected to different types of faults. This concept is a powerful technique in core quality assessment of the electrical machines, and can provide a meaningful comparison between magnetic properties of the magnetic cores subjected to different types of inter-laminar fault. An approach was developed to calculate power loss of each stack from the measured DHL, for each flux density and frequency. The results were then compared with the bulk power loss of the samples. Fig 2 shows a comparison between the power loss of the samples calculated from the measured DHL, and bulk measurement for the measured frequencies and peak flux density of B_{pk}=1.7 T. The results show a close agreement between the calculated power loss and bulk measurements, with the maximum difference of less than 4 %. Therefore, it can be concluded that inter-laminar faults in the magnetic cores, that increase the core loss, can be effectively detected by observing the DHL of the core. The results show high sensitivity in fault detection and core quality assessment, even for low frequencies and low flux densities. III. Conclusion A new approach was developed to evaluate quality of the magnetic core of the electrical machines and transformers. Accuracy of the method was validated on stacks of laminations subjected to different types of inter-laminar faults, over a range of frequency and flux density. Therefore, the developed approach can be effectively implemented to characterise magnetic properties of the magnetic cores, and condition monitoring of magnetic cores of electrical machines and transformers. IV. Acknowledgment The author is grateful to Cogent Power Ltd. for providing the electrical steel sheets, and Wolfson centre for magnetics at Cardiff University for the experimental work.

GG-11. Memory Efficient Harmonic Method for Electromagnetic Models Using Scattering Matrices.

C. Custers[1], J. Jansen[1] and E. Lomonova[1]
1. Department of Electrical Engineering, Eindhoven University of Technology, Eindhoven, Netherlands

I. INTRODUCTION In design and optimization of electrical machines, accurate models of the electromagnetic fields are important to predict the performance of the machine. The finite element method (FEM) is often used, because of its ability to produce accurate results when it is correctly utilized. However, the method can be demanding in terms of memory and relatively slow in terms of computation time. Therefore, semi-analytical models have been proposed over the years for increasingly complex structures in both 2D and 3D. One of the semi-analytical models is the harmonic modeling technique [1], [2], [3], which uses a Fourier bases to describe the solutions to electromagnetic field quantities. In many electromagnetic configurations, accurate results are obtained using a relatively low number of harmonics. However, for more complex structures, the number of harmonics has to be increased to retain accuracy. This leads to a proportional increase in the required memory. As a result, especially in 3D models, the advantage in terms of memory of the harmonic model in comparison to FEM is reducing. In this paper an alternative solving method for 3D harmonic models with position dependent material properties is presented. Using the scattering matrix approach, the memory required to obtain the solutions of the model is significantly reduced. II. METHOD In Fig. 1 a configuration consisting of a coil and a conducting plate above in the 3D Cartesian coordinate system is shown. The model is periodic in both the *x*- and *y*- direction. Because of this periodicity, all solutions have a double Fourier series bases. The number of harmonics considered in the *x*-direction is denoted by $N+1$ and in the *y*-direction by $M+1$. In the *z*-direction, the model is divided into regions. For each region, expressions are obtained for the magnetic flux density and magnetic field strength as explained in [3]. These expressions contain unknowns per region. In non-conducting regions there are $2*(N+1)*(M+1)$ unknowns and in conducting regions $4*(N+1)*(M+1)$. To obtain the unknowns, boundary conditions are applied between the regions. The boundary conditions force the continuity of the tangential magnetic field strength components (H_x *and* H_y) and normal magnetic flux density component (B_z) between regions. Typically, in harmonic models, the boundary conditions are listed in one single matrix. By inversion of this square matrix (A) and multiplication with a vector containing the source terms (y) of the regions, the vector of unknowns (c) is obtained, e.g. $c=A^{-1}y$. (1) The drawback of this direct solving method is that matrix A can become large and will as a consequence occupy a large amount of the available memory. As for each region $2*(N+1)*(M+1)$ or $4*(N+1)*(M+1)$ (depending on the type of region) unknowns are added, the number of considered harmonics has to be decreased when a region is added to the model. As a solution to the inefficient memory usage of the direct solving method, the scattering matrix method [4] has been implemented. First, by rewriting the boundary conditions on both sides of a region denoted by *k*, a scattering matrix S can be determined, which relates the coefficients of the neighboring regions, $k-1$ and $k+1$. The matrix equation linking the coefficients is given by $c^-_{k-1} = S_{11,k} \bullet c^+_{k-1} + S_{12,k} \bullet c^-_{k+1} + y_{1,k}$ $c^+_{k+1} = S_{21,k} \bullet c^+_{k-1} + S_{22,k} \bullet c^-_{k+1} + y_{2,k}$ (2) where S_{11}, S_{12}, S_{21} and S_{22} are submatrices of S. A representation of (2) is depicted in Fig. 2. The vector denoted by y represents the rewritten source terms of a region. A scattering matrix S is calculated for each region in the model. With the total number of regions denoted by K, the total scattering matrix S_{model} of the model can be calculated by $S_{model} = S_0 \blacksquare S_1 \blacksquare \ldots \blacksquare S_K$, (3) where $\blacksquare$ is the Redheffer star product [5]. This product multiplies the matrices S_k in such a way that the total scattering matrix S_{model} gives the same relation as in (2) between the coefficients of the top and bottom region of the model. The source terms y_k are also multiplied according to the Redheffer star product to obtain the vector containing the source terms for the total model y_{model}. It is assumed that the top region of the model extends to infinity and the bottom region to minus infinity. As a result, one of the vectors of unknowns in these regions is zero. The non-zero vector of unknowns of the top and bottom region are determined by $(c^+_0\ c^-_K)^T = (S_{model})^{-1}\, y_{model}$ (4) The matrix S_{model} which is inverted to obtain the unknowns of the top and bottom regions is of size $2*(N+1)*(M+1)$, independent of the number of regions in the model. For the model in Fig. 1, this means that the matrix that has be inverted is now 5 times smaller compared to the classical solving method. The unknowns for all other regions can be determined using the scattering matrices. In the full paper, the classical solving method and the proposed method are compared in terms of memory occupation, accuracy and computation time for the configuration shown in Fig.1. III. CONCLUSIONS In this paper a method is implemented to solve electromagnetic harmonic problems in a memory efficient manner. Due to the use of scattering matrices, a reduced size matrix is solved to obtain the unknowns per region. Moreover, this matrix is independent of number of regions that are in the model. As a result, more harmonics can be used with the same available memory, leading to more accurate results.

GG-12. Analysis of Temperature Field of High Power Permanent Magnet Driving Motor for Special Vehicle.

C. Li[1] and J. Gao[1]
1. Hunan University, Chang Sha, China

I. INTRODUCTION In recent years, with the development of automobile technology, the vehicle electrical motor needs higher power density and higher pull-in torque. However, the performance of the motor will increase the loss of the motor and raise the temperature. Therefore, it is necessary to analyze the temperature field of the motor to ensure its reliable operation. The temperature field of low power motors has been studied and simulated by many scholars at home and abroad[1]Including water-cooling system design and thermal analysis[2-3] However, the analysis of temperature field of special high-power drive motor is less. This paper take the 350 kW permanent magnet drive motor on as the object II. LOSS MODEL OF MOTOR The characteristics of 350kW permanent magnet drive motor: the rated power is 350kW; the rated speed is 3000r/min; the peak power is 450kW; the DC bus voltage is 900V;Cooling method is water-cooling (The inlet temperature of the cooling water is 85°C; the flow rate is 60L/min and the velocity of water is about 3.5m/s). The root cause of motor heating is various losses. According to the conventional method of loss solving[4] the stator iron loss is 2.39kW; the rotor iron loss is 0.297kW; the stator copper loss is 5.97kW; the mechanical loss is 2.8kW; the total loss is 14.75kW. III. Simulation and analysis of finite element temperature The heat transfer of the motor is mainly heat conduction and convection heat transfer, which is directly related to the thermal conductivity and the surface heat transfer coefficient of the medium. The cooling structure of the stator is designed as follows: Both sides of the stator core are provided with the stator outer retaining plate and the stator inner retaining plate, the inlet and outlet of the generator connected to the pressure pump on motor housing. The circular channel between the outer circle of the stator core and the casing which is formed to cool the stator core. In a stable state, the total energy is constant. $\lambda(\partial^2T/\partial^2X+\partial^2T/\partial^2Y+\partial^2T/\partial^2Z)+q_v=0$ Convective heat transfer mainly occurs between the bottom of the channel and the cooling water. The following expression is the basic law to describe the convection heat transfer process. $q=\alpha(T_{t1}-T_{t2})$ As shown in Fig. 1. It can be seen from the chromaticity, the stator core highest temperature is 156.3°C, the minimum temperature is 92.26°C, reduce the ambient temperature(85°C), the highest temperature rise of the stator core is 71.3K. The maximum temperature of the stator winding is 172.3°C, at the end of the winding, the minimum temperature is 136.7°C, the highest temperature rise of the stator windings is 87.3K. The maximum temperature of the rotor is 162.5°C, the minimum temperature is 149.3°C, the highest temperature rise of the rotor is 77.5K. The inlet temperature of water channel is 85°C and the outlet is 90.3°C. IV. parison and analysis of experimental data The temperature rise experimental data are as follows:Stator current is 557A; The input power is 350.1kW; The electronic voltage is 470.5V; The power factor is 0.91;The cooling water is room temperature and flow rate is 60L/min. Temperature rise curve of stator winding and bearing is shown in Fig. 2. As you can see from the Fig.2. The steady state temperature of the stator windings is about 174°C, minus the ambient temperature 85°C, The temperature rise of the stator windings is about 89K. The maximum temperature rise of simulated stator windings is 87.3 K and the temperature of stator core is about 155°C, minus the ambient temperature 85°C, The temperature rise of the stator core is about 70K. The maximum temperature rise of simulated stator core is 71.3 K. The correctness and accuracy of this model and the simulation method are verified from stator winding and stator core.

GH-01. Exciting Force and Vibration Analysis of Stator Permanent Magnet Synchronous Motor.

J. Hong[1], S. Wang[1], Y. Sun[1], J. Li[1] and H. Cao[1]
1. Tsinghua University, Beijing, China

ABSTRACT: This paper presents the detail analysis of the radial force and bending moment responsible for vibration in the stator permanent magnet synchronous motors (SPMSM). Firstly, the air gap flux density distribution and radial force density distribution are derived in detail. In addition, the relationships between these two vibrations and pole width, pole number and slot number are analyzed. The multi-probe mode-included test method of vibration acceleration is proposed and the experimental results on a 6-pole/36-slot SPMSM match well with the simulation results. 0 Introduction With the advancement of the electrical vehicles such as hybrid-electric and electric vehicles, improving the noise and vibration characteristics of rotating electric machines is becoming important consideration issues for the development of vehicles [1-4]. Electrical vehicles make use of permanent magnet synchronous traction motors for their high torque density and efficiency compared with other types of motors [5-9]. The stator permanent magnet synchronous motors (SPMSM) have good advantages and are widely applied in the industry. Few papers reported to focus on the vibration characteristics of this type of motor[10-12]. So, this paper investigates the vibration mode and frequencies in the stator permanent magnet synchronous motor, which is shown in Fig.1. 1The magnetic field and exciting force 1.1 analysis of Magnetic field When ignoring magnetic saturation, the flux density distribution in the air gap under no load can be expressed as $b(\theta,t)=\pm(B_\delta\Lambda_0+\sum B_\delta\Lambda_k\cos kZ(\theta-\omega_r t))$ $\theta\epsilon[-\alpha\pi/(2p)+j2\pi/(2p),\alpha\pi/(2p)+j2\pi/(2p)]$(1) Where Z is the number of rotor slots, Λ_0 and Λ_k are the amplitude of average and k-th harmonic magnetic permeability. α is the pole arc coefficient. When j=2m,m=0,1,2,3..., the sign in the equation takes a positive value; When j=2m+1, the sign is negative. 1.2 Force analysis The force on ferromagnetic substance in the electromagnetic field can be described by Maxwell stress tensor method. Radial force wave generated by magnetic field is $p_n=1/(2\mu_0)\{(B_\delta\Lambda_0)^2+\sum[B_\delta\Lambda_k\cos kZ(\theta-\omega_r t)]^2+2B_\delta^2\Lambda_0\Lambda_k\cos kZ(\theta-\omega_r t)\}$(2) The third term indicates radial force which changes with time generated by interaction of the not time-varying magnetic field and the periodic magnetic field, which causes a considerable vibration. The vibration frequencies are the integral multiples of the product of the slot number and the rotation frequency. 2 Two vibration sources In the motor, the radial force P_n on one pole can be equivalent to one equivalent pulsating force P_{np} varied with time on the center line of the pole and equivalent bending moment m_{np} varied with time on the pole. The general expression of pulsating force is $P_{np}(t)=2l_pRB_\delta^2\Lambda_0\Lambda_1\sin(\alpha_1\pi/(2p))\cos(jZ2\pi/(2p)-Z\omega_r t)/(Z\mu_0)$(3) Where R is the radius of the inner surface of the pole, α_1 is pole arc width expressed by rotor number. Because the uneven distribution of the force density, the corresponding bending moment is $m_{np}(t)=l_pR^2B_\delta^2\Lambda_0\Lambda_1\cos(\alpha_1\pi)\sin(\alpha\pi/(2p))\sin(jZ2\pi/(2p)-Z\omega_r t)/(Z\mu_0)$(4) From the equation(3) and (4), we can know that: If $2\pi Z/(2p)=2n\pi$, n is integral, the radial forces and the bending moment on the two adjacent poles are in the same phase. When α_1 is n, radial force reaches minimum, bending moment reaches maximum, and the mode number equal to the pole number. When α_1 is n+1/2, radial force reaches maximum, bending moment reaches minimum, and the vibration mode equal to 0. If $2\pi Z/(2p)=(2n+1)\pi$, the phases of the forces on the two adjacent poles are opposite, and so do the bending moment. When α_1 is n, radial force reaches minimum, bending moment reaches maximum, and the mode number equal to the pole pairs. When α_1 is n+1/2, radial force reaches maximum, bending moment reaches minimum. The vibration mode equal to pole pairs. 3 simulation analysis In the simulation, a harmonic response analysis has been performed by using the mode-superposition method. the motor is constrained by elastic support through the end face. A damping ratios of 4.4% extracted from the modal test is used. The harmonic forces are projected on the structure mesh of the stator in order to calculate the deformation, and the vibration mode. 4 Experiment test In order to verify the validity of analytical model studied in this paper, the Operational Deflection Shapes experiment is performed. The designed motor with 6-pole, 36-slot, α_1-5 is hanged on the bracket by elastic rope, and seven accelerometer sensors are evenly attached on the stator in the circumferential direction. The motor run at 1500rpm. Fig.2(a) compares the measured acceleration with those FEM at five frequencies associated with slot frequency. It clearly reveals that the acceleration components at the harmonic frequencies of 36fr, 72fr, 108fr, 144fr, etc.. Vibration shape at slot frequency is measured seen in Fig.2(b). It can be seen clearly that the vibration mode at slot frequency is six order, consistent with the analytical results. 5 Conclusions In this paper, a detailed analysis of vibration in stator permanent magnet synchronous motor (SPMSM) is presented. Some conclusions can be summarized from the paper: The frequencies of the exciting radial force and vibration of the SPMSMs mainly are integral multiples of the product of the slot number and the rotation frequency, which is different from the frequencies related about the pole number in the rotor permanent magnet motors. The vibration mode is decided by the radial force, which causes the pulsating mode, and the bending moment, which causes the bending mode.

GH-02. Loss Calculation and Thermal Analysis of a High Speed Permanent Magnet Synchronous Motor with an Amorphous Metal Stator Core.

W. Tong[1], R. Sun[1], C. Zhang[1], S. Wu[1] and X. Ma[1]
1. School of Electrical Engineering, Shenyang University of Technology, Shenyang, China

Electric motors are the single biggest consumer of electricity. They account for about two thirds of industrial power consumption and about 45% of global power consumption. Therefore, high-efficiency motors can make an outstanding contribution to energy conservation. The techniques on decreasing iron loss of motors with conventional magnetic material have already reached a breaking point. With the development of new magnetic materials, employing low loss magnetic materials instead of traditional counterpart becomes a feasible way to improve the efficiency of high speed motors. Amorphous metal is characterized by extremely low losses. The disordered atomic structure of amorphous metal leads to electrical resistivity 2 times higher than that of conventional silicon steel sheet (SSS). The high resistivity and only one twentieth the thickness of conventional SSS help minimize iron loss when the metal is subjected to an alternating magnetic field [1-2]. Therefore, the excellent properties offer some possibilities to increase efficiency of high speed motors in using amorphous metal. In this paper, a 15kW, 30000 rpm amorphous metal permanent magnet synchronous motor (PMSM) with surface-mounted permanent magnets and a titanium alloy retaining sleeve is chosen as the research object to analyze the no load losses, on load losses and thermal behaviors in the conditions of converter supply by using finite element method. The configuration of the motor prototype and the experimental platform are shown in Fig. 1. 4-pole and 18-slot is adopted to develop the motor prototype. The advantages of the high speed PMSM with a amorphous metal stator core are demonstrated by both the finite element method calculation results and the no load loss and efficiency experiment results. In order to analyze the loss properties of the high speed motor, it is necessary to obtain the magnetization curves and the loss curves at different operation frequencies. Therefore, a experimental platform is built up to measure the magnetic properties of the yoke of amorphous metal stator cores at different frequencies according to the international standard measurement method IEC 60404-6 [3]. In the test, the yoke of the amorphous metal stator core is recognized as a ring-shaped core specimen. The experimental platform and the test results of the amorphous metal stator core are shown in Fig. 2. As can be seen from the figure, the magnetization curves are almost the same at different frequencies, and the loss of amorphous metal stator core is much smaller than that of conventional SSS. The no load losses, including the loss of amorphous metal stator core, the losses of surface-mounted permanent magnets and the titanium alloy retaining sleeve, are analyzed at several different frequencies by finite element method. The corresponding experiment is also carried out according to the calculation condition to verify the feasibility of the calculation. As a comparison, the no load losses of another motor with a carbon fiber sleeve are also analyzed, and some conclusions of the no load rotor losses are obtained. The temperature rise of high speed motors is one of the most import issues that affecting the reliable operation of the motor. The on load losses as the heat resource of the motor are analyzed, and then, the air flow condition inside the motor and the temperature distribution of each part of the motor are calculated by using computational fluid dynamics method. The frictional loss between the rotor surface and the air inside the motor is taken into consideration during the thermal analysis. The temperature rise test is proceed to verify the accuracy of the analysis. In the experiment, two identical amorphous metal PMSMs are connected to each other, one of which is used as an electric motor and the other as a generator. The load of the generator is a resistance box as shown in Fig. 1. The efficiency of the prototype is also obtained by the experiment platform.

1.INTRODUCTION In recent years, the use and interest of synchronous reluctance motors has increased with the development of software tools, magnetic materials, power electronics and control techniques. Synchronous reluctance motors (SRMs) are quite low cost compared to other types of permanent magnet (PM) motors and relatively easy to manufacture. SRMs can be used for high-speed applications due to their robust construction. Permanent magnet-assisted synchronous reluctance machines (PMaSRMs) can be designed by adding magnets in the rotor cavities so that quite wide field weakening region could be achieved. The aim of this study is to investigate motor performance considering the high speed losses of an unconventional PM assisted synchronous reluctance motor. Motor performance including torque ripple and torque speed characteristics will also be covered in the paper. This will be the first paper for washing machine application that covers all of these issues for concentrated winding PMaSRMs. 2.DESIGN OF PMaSRM A. Design Specifications In this study, a concentrated winding PM assisted synchronous reluctance motor with 9-slot and 8-pole is designed by using Flux 2D package. Fig.1 (a) shows motor design specifications. Fig.1 (b) shows the FEA model, mesh structure, flux density and flux lines of the proposed PMaSRM. It can be noted that maximum flux density at no-load is obtained as 1.3 T on the teeth. Due to the belt driven system and limited area, the application requires wide flux weakening range which is up to 14000rpm. Therefore, the motor is designed with a constant speed power ratio (CSPR) of 4.3 providing torque even at 12500rpm. The torque-speed curve obtained by FEA considering the voltage limits is shown in Fig. 2(a). More detail for the FEA studies will be provided in the final version of the paper. B. Investigation of Torque Output In white goods applications, the quality of the output torque is crucial and it is one of the most critical components in the motor performance since unwanted torque pulsations cause undesirable noises. Therefore, special attention should be given in order to reduce torque pulsations during the motor design. Average torque, reluctance torque and cogging torque components of the designed motor are shown in Fig. 2(b) and Fig. 2(c), respectively. The cogging torque is extremely low and the magnet torque is higher than the reluctance torque. Since the magnet is located on q-axis of the synchronous reluctance motor, the amount of magnet increases the torque output by decreasing q-axis inductance. In this way, there is no need to weaken the magnet flux in the field weakening zone. C. Investigation of Iron Losses Cost and efficiency as well as better motor performance are quite critical parameters for appliance industry. Iron losses especially at high speeds are the most important design criteria which determine the efficiency of the motor. Therefore, losses should be optimized based on cost-efficiency values. Since the motor is designed for low cost and wide speed range applications, the influence of the increased frequency on the motor performance has also been investigated in the paper. Iron loss-speed graph of the designed motor are shown in Fig. 2(d). In addition, skin and proximity effect losses at the maximum operating speed will be calculated and the results will be given in the final paper. 3.CONCLUSION In conclusion, design and investigation of losses for a concentrated winding PM assisted synchronous reluctance motor with 9 slot / 8 poles has been carried out in this study. It is shown that wider constant power region can be obtained with this structure. Iron losses especially at high speeds have been investigated. It has also been studied on minimizing the torque ripple to increase the output torque quality. The average torque was found to be roughly 28.2% in reluctance torque and 71.8% in magnet torque. It is also shown that wide CPSR could be obtained using the magnet configuration and fractional slot structure. The suitability of the designed motor for washing machine application has been evaluated and prototype motor has been built. More details including the test data will be provided in the final version of the paper. The FEA results will also be supported with the test data in the final paper.

GH-04. Design and Analysis of Halbach Array Flywheel Motor/Generators.

M. Yin[1], K. Liu[1], Y. Kong[1] and M. Lin[1]
1. Southeast University, Nanjing, China

Abstract-Halbach array permanent magnet machine has a number of attractive features in comparsion with the conventional permanent magnetic machines. In this paper, electromagnetic design and analysis equations for external rotor ironless brushless DC machine (BLDCM) which is used in flywheel energy storage system (FESS) are presented. The Halbach array permanent magnet machine is studied compared with the radial magnet array. The relationship between the air gap field distribution and the magnet array is discussed. At last, the eddy current loss of the external rotor ironless brushless DC machine (BLDCM) is analyzed between Halbach permanent magnet machine and conventional permanent magnet machine. I.INTRODUCTION The external rotor ironless brushless DC machine (BLDCM) is commonly suitable for use in flywheel energy storage system (FESS) in the space field. This type of BLDCM which used in FESS has the following advantages: (1) the operation efficiency is higher than the normal type of BLDCM ;(2) the space volume of FESS is greatly reduced;(3) the torque fluctuation is relatively smaller than the normal BLDCM.(4) the structure of the external rotor ironless brushless DC machine is simple and reliable. Though the external rotor ironless brushless DC machine has small torque fluctuation and iron losses, magnetic density of air gap is too small. So it is difficult to effectively play the advantage of high power density and high torque density of BLDCM. Compared to the conventional magnetization method, a high air gap flux density can be obtained by using the Halbach magnetic array. This paper studied the air gap magnetic density and eddy current loss of permanent magnet of the external rotor ironless BLDCM in different magnetic methods through finite element analysis. II.ELECTROMAGNETIC DESIGH Fig.1 illustrates the structure of the external rotor ironless BLDCM. The design process started from the calculation of the size of rotor. The number of stator-slots and rotor-poles is chosen after comprehensively consideration of loss and the efficiency goal. The winding turns are calculated under the requirements of the speed range and the power supply voltage limit. The material of permanent magnets is SmCo as per the temperature and operation environment. III.COMPARISON OF TWO MAGNETION METHODS Fig.2 shows the air gap magnetic density distribution of normal permanent magnets array. It includes radial magnetization and parallel magnetization.Fig3 shows that the air gap magnetic density distribution of Halbach permanent magnets which has 3 segments per pole. The magnetization of each permanent magnet can be expressed by the following equation: $M_x(i)=M\cos[360(1-p)(i-1)/(2pn)]$ $M_y(i)=M\sin[360(1-p)(i-1)/(2pn)]$ i indicates the magnetization of each segment, P is the polar logarithm of the motor, and n is the number of segments per pole. Fig.4 shows the two air gap magnetic density distribution in different magnetic arrays. The Halbach array permanent magnetic machine provides a better sine waveform than the normal array one. The Halbach array permanent magnetic machine exhibit less eddy current loss compared to the conventional external rotor permanent machine. The simulation and experiment results based on the different magnetization will be showed in the full paper. IV.CONCLUSION The basic design equations for external rotor permanent magnet machines using Halbach cylinders have been presented, especially for slotless and ironless machine topologies. It has been shown that such machines may offer significant advantages over conventional permanent magnet machines, particularly for high-speed applications when the eddy current losses can be significant.

GH-05. Eddy-Current Loss Measurement of Permanent Magnet Material at Different Frequency.

C. Zhang[1], B. Jiang[1], R. Chen[1], Y. Li[1] and Q. Yang[2]
1. Hebei University of Technology, Tianjin, China; 2. Tianjin Polytechnic University, Tianjin, China

I Introduction Permanent magnets have been widely used in rotating electrical machines. The eddy current loss induced by the fundamental air-gap field is usually neglected, since it rotates in synchronism with the rotor[1]. To improve torque density and torque ripple, a new class of PM machines is emerging in which stator coils are wound on consecutive or alternate teeth with a fraction number of tooth per pole [2]. However, the large number of harmonics caused by slot ripple, inverter [3] will lead to significant eddy current loss in the magnets, which makes the temperature of magnet increase and may cause the thermal demagnetization [4]. As a result, it is necessary and important to study the eddy current loss in the permanent magnets. Many analytical models are developed to predict induced eddy current loss, but few are verified by experiments until now. In this paper, the eddy current loss of NeFeB sintered magnet is measured by using a newly developed closed-circuit measuring equipment, meantime the same size simulation model is established by Ansoft to compare with the experiment results. The behavior of the eddy current loss of permanent magnet is investigated at different frequency. II Measurement System Setup (A) The Excitation Structure Fig.1 shows the novel dynamic hysteresis loop measurement apparatus of permanent magnet material with the frequency up to 1 kHz. The alternating flux density inside the magnet material is up to 0.2 T, which is large enough for the rotor of various AC machines. The closed-loop magnetic circuit is composed of the double C-shaped core, flexible excitation windings and the permanent sample. The excitation C-shaped cores are made of ultra-thin 0.1mm silicon steel, which can work up to 1 kHz. The permanent samples are made into the cylinder-shaped, which is located in the air-gap between the double C-shaped cores. And the air-gap between the magnet poles can be adjusted according to the length of the sample, for the C-shapes is placed on the slide rail. The four multi-layer excitation windings were separately wound on the C-shaped cores. And the windings were made of 12-turns Litz wire, which can work up to 10 kHz. The power amplifier for the excitation windings is PA500 made by Brockhause Company with the frequency from DC to 20 kHz. (B) The Sensing Structure The coil of magnetic flux density is directly wounded on the permanent sample, in which number of turns is 6 and area size is the same as the permanent cross-section. As shown in the Fig.1, there are two samples between one air-gap. The area between the two samples is close enough so that it forms an uniform magnetic field strength area which is measured by the Hall-probe of Bell Gaussmeter 8030. In the full paper, the electro-magnetism finite element analysis illustrates the distribution of magnetic field strength and flux density and validates the rationality of our magnetic circuit structure. III Measurement Results and Discussion In the measurement system, the eddy current loss and its dynamic hysteresis loop of the permanent magnets can be directly measured. (A) Measurement of static magnetic properties The four permanent magnet samples and the magnetic yoke compose a closed circuit. Based on the static hysteresis loop of permanent magnet, the static working point can be calculated and measured. (B) Measurement of dynamic magnetic hysteresis loop Under the alternating current by the flexible excitation winding, the magnetic field inside the permanent magnet is alternatively changing at the static working point of static demagnetization curve. Fig.2 shows the dynamic hysteresis loop of the permanent magnet at 50 Hz. The area of hysteresis loop is the sum of the hysteresis loss and the eddy current loss according to the Poynting vector theorem $p = \int H\, dB$ As the B magnitude and frequency changing, a series of loss characteristics of permanent magnet will present in the full paper. (C) Eddy current loss of permanent magnet at different temperature In traditional finite element analysis, the eddy current loss calculation is based on the coefficient of conductivity of the permanent magnet. In the industry application, the conductivity and eddy current are strongly affected by the temperature. When the measurement apparatus is placed in the temperature variable box, the eddy current losses can be measured by the changing temperature. IV Conclusion In this paper, a novel dynamic hysteresis loop and eddy current loss measurement apparatus of permanent magnet material was designed. For the NdFeB material, neglecting the hysteresis loss, the area of hysteresis loop represents eddy current loss. The measurement results provide the basis for the eddy-current modeling of permanent magnetic materials at different frequency and temperature. GH-06. Reduction of Rotor Losses by Using Amorphous Rotor Core for Ultra-High-Speed Motors.

Y. Liu[1], *J. Ou*[1], M. Schiefer[1], P. Breining[1] and M. Doppelbauer[1]
1. Karlsruhe Institute of Technology, Karlsruhe, Germany

Abstract— This paper proposes to use the amorphous material in the rotor core for the ultra-high-speed motors to decrease the rotor losses. Due to the low core losses and the low saturation flux density of the amorphous material, the rotor core losses and the shaft eddy current losses can be reduced by using the amorphous material. To study the feasibility of the proposed rotor, the measured properties of the amorphous material are presented. The benefits and disadvantages of the amorphous rotor core are illustrated by comparing with a silicon steel rotor core in terms of torque, losses and the rotor thermal fields. Furthermore, the influence of the pulse-width modulation (PWM) on the rotor losses is studied. I. INTRODUCTION Due to the high power density and high efficiency, the ultra-high-speed PM synchronous motors have been used for varieties of applications, including electric engines for aircraft, flywheel energy storage systems, high-speed spindles, turbomolecular pumps, gas compressors, air blowers, and microturbines [1-6]. Currently, surface-mounted PM rotor configuration with a metal or fiber sleeve is widely used for the ultra-high-speed motors to protect the rotor from centrifugal forces. The metal sleeves can offer a high thermal conductivity but the rotor eddy current losses are also high, while the fiber sleeves can avoid the eddy current losses but the thermal conductivity is low. Hence, the rotor losses and heat dissipation are very important for the ultra-high-speed motor design. In this paper, the properties of the amorphous material are measured and the data is used to investigate the torque and the rotor losses of the motors. To consider the influence of the power electronics, FEA coupled with Simulink method is employed. Finally, the torque, losses and thermal fields of the rotors with different core materials are compared. II. PROPERTIES OF THE AMORPHOUS MATERIAL The properties of the amorphous core 2605SA1 are measured and compared with conventional silicon steel M330-35A. The measurement results are shown in Fig. 1. It can be found that the losses of 2605SA1 are about one tenth of M330-35A. Due to the small thickness of the amorphous material, the eddy current loss of 2605SA1 is much lower than M330-35A. However, compared with silicon steels, the amorphous material 2605SA1 has a relatively low saturation flux density which is about 1.5 T, and has a relatively low stack factor, which can decrease the torque ability of the motors. However, by using an amorphous rotor core, the motor can be benefited not only from the low core losses, but also from the relatively low saturation flux density, since saturated rotor core can help to reduce the armature reaction field on the shaft which leads to low eddy current losses in the shaft. III. INFLUENCE OF PWM ON ROTOR LOSSES Although the integral-slot configuration consisting of low amplitude spatial field harmonics is widely used in the ultra-high-speed motors, the rotor losses caused by the armature reaction are still super high due to time current harmonics caused by PWM. In this section, by using FEA coupled with Simulink method, the influence of the PWM on eddy current losses is investigated. The effects of the switching frequency and the air-gap length are discussed. IV. COMPARISON OF DIFFERENT ROTOR CORE MATERIALS The structure of the ultra-high-speed motor used in this paper is shown in Fig. 2 (a). The FEA coupled with Simulink model is shown in Fig. 2(b). In this section, the rotor losses and rotor thermal fields are calculated and compared. To make a fair comparison, the only difference of the two motors is the materials used in the rotor cores. To generate the same torque, the rotor losses of the motor with the amorphous rotor core are lower than that of the motor with silicon steel rotor core. However, the heat dissipation ability of the amorphous material is also poor compared with silicon steels. Hence, it is necessary to investigate the thermal fields of the two rotors. More detailed analysis will be presented in the final paper.

GH-07. Design and Optimize an external rotor Ironless BLDCM used in a Flywheel Energy Storage System.

K. Liu[1], M. Yin[1], X. Fu[1], M. Lin[1] and Y. Kong[1]
1. Institute of Electrical Engineering, Southeast University, Nanjing, China

Abstract —Based on the application and design requirements of energy storage system, the external rotor ironless brushless DC machine (BLDCM), which is suitable for use in FESS, is designed and further explored. The finite element method is adopted to do computational research on external rotor ironless BLDCM. Performance improvement and loss minimization of the machine are achieved through optimizing the magnetic pole and the winding. The research results show that the copper loss of the machine can be reduced by appropriate selection of magnetic steel thickness even under the condition that the main parameter of the flywheel machine is set. Proper choice of magnetic steel polar-arc coefficient is beneficial to reduce the flux leakage on the surface of the rotor. The width of air gap flux density can be increased by applicable selection of magnetic poles and magnetizing style. The flywheel energy storage machine prototype is fabricated based on the optimized design of the machine. The experiment results show that the test results almost coincided with the design values. I.INTRODUCTION The flywheel energy storage system (FESS) is a novel electromechanical energy conversion and storage device, whose advantages are long service life, high conversion efficiency, high adaptability and pollution-free[1], etc.. FESS has enormous application foreground at the Electromagnetic Launch, the aspects of aeronautics and astronautics, distributed generation, power system peak load regulation and electrical vehicles. The purpose of this paper is to design and Optimize the external rotor ironless brushless DC machine (BLDCM), which is suitable for use in FESS. The finite element method is adopted to do computational research on external rotor ironless BLDCM. Performance improvement and loss minimization of the machine are achieved through optimizing the magnetic pole and the winding. II. STRUCTURE AND PRINCIPLE The FESS presented in this paper is composed of two parts: the ironless BLDCM and its drive system. Fig.1 shows the structure of the iron-less BLDCM. The BLDCM includes an iron-less armature (fixed in a fiber frame), an iron core and the permanent magnets. III. OPTIMIZING THE MAGNETIC POLE Performance improvement and loss minimization of the machine are achieved through optimizing the magnetic pole. Fig. 2 shows that the width of air gap flux density can be increased by applicable selection of magnetic poles and magnetizing style. Fig. 3 shows that proper choice of magnetic steel polar-arc coefficient is beneficial to reduce the flux leakage on the surface of the rotor. The full paper will give the further discusses. IV. EXPERIMENT To validate the optimization method, an external rotor Ironless BLDCM prototype was built, as shown in Fig. 3. V. CONCLUSION The result shows that performance improvement and loss minimization of the machine can be achieved through optimizing the magnetic pole and the winding. The full paper will give the further discusses.

Introduction: In flywheel battery applications, the rotating flywheels are usually coupled to a shaft which leads to additional axial length, critical speed limitation, space waste, and low reliability [1-2]. Moreover, the mechanical bearings are a source of energy losses and require lubrication to relieve mechanical friction[3-4]. In order to avoid these problems, magnetic bearings(MB) [5] technology with several advantages, such as eliminating of a lubrication system, friction-free operation and low power consumption is applied for flywheel battery. The bearingless switched reluctance motor(BSRM) [6-7] can rotate and levitate by integrating the magnetic levitation winding of MB into that of the SRM. As high integration, low loss and high reliability are the main development trends of flywheel battery, this paper presents a four degrees of freedom(4-DOF) self-decupling bearingless motor(SDBM) specially for flywheel battery. The proposed motor exhibits the following advantages: 1) High integration. The proposed motor can realize energy conversion and 4-DOF suspension through the torque and suspension systems. Moreover the outer rotor can drive the flywheel directly. 2) Low loss. The biased flux is provided by the permanent magnet which leaves out the extra biased winding correspondingly. 3) Weak coupling. Self-decoupling is realized between the torque and the suspension systems according to the structural design. 4) Favorable controllability. The suspension force is only related to the current and has no relation to the rotor position, thereby increasing controllability. New Machine: The structure of the proposed novel bearingless motor is illustrated in Fig. 1. Fig. 1(a) presents the 4-DOF SDBM, which mainly consists of a PM ring (PMR) with axial magnetizing, a motor side structure, and a magnetic bearings(MB) side structure. The PMR between the motor and the MB side structures provides a biased flux for generating suspending forces. Fig. 1(b) and Fig. 1(c) depict the motor side structure and MB side structure. The motor side structure mainly consists of a torque system, a left suspension system, and four non-magnetic materials. The torque system has eight inner stator poles (two phases in total). For example, the *A* phase in the torque system contains A1, A2, A3, and A4 poles. The electric and power generations are realized with the principle of minimum reluctance. The left suspension system on the motor side has four inner stator poles (two phases in total). For example, the *C* phase in the suspension system of the motor side contains C1 and C2 poles which can produce the suspension force in y_1 direction. The torque and left suspension system share a outer rotor with 14 poles. The MB side structure mainly consists of a right suspension system with four stator poles (two phases in total) and a disc-type outer rotor. The *E* phase on the MB side contains E1 and E2 poles which can produce the suspension force in y_2 direction. The *A*, *B*, *C*, and *D* phases can provide 4-DOF radial suspensions in the x_1, y_1, x_2, and y_2 directions, respectively. Fig. 1(d) depicts the paths of biased flux Φ_m and control flux Φ_C and Φ_E. The biased flux Φ_m forms a close loop thought the stator poles in motor side, the outer rotor, and the stator poles in MB side. The control magnetic flux Φ_C and Φ_E do not pass through the PMR. Electromagnetic Characteristics: Fig. 2 depicts the main electromagnetic characteristics of 4-DOF SDBM. i_{FC} and i_{FE} are defined as the current of the left suspension system and right suspension system in the y_1 and y_2 direction, respectively. i_{TA} is defined as the *A* phase current of torque system. Fig. 2(a) and Fig. 2(b) present the values of air-gap flux density with different values of i_{FC}. It can been seen that the value of the air-gap flux density is approximately 0.7 with i_{FC}=0 A. When i_{FC} are conducted with 1 A, 2 A, and 3 A, the air-gap flux density increases with the increase in the current value in y_1 negative direction and decreases in the y_1 positive direction. Therefore, the air-gap magnetic flux density can be regulated by controlling the magnitude and direction of the suspension current, and the required suspension force can then be generated. Fig. 2(c) and Fig. 2(d) present the coupling relationship between suspension systems and torque system. The relationship among the left suspension current i_{FC}, right suspension current i_{FE}, and suspension force in y_1 direction is shown in figure 2(c). The suspension force value in the y_1 direction is approximately linear with the value of i_{FC}. This analysis denotes that the controllability of the magnitude of radial suspension forces in the 4-DOF direction can be achieved by adjusting the suspension force winding current magnitude. Moreover, the suspension force value in the y_1 direction is approximately zero with the value of i_{FE} within [0 A, 3A]. Thus, the self-decoupling is realized between the left and right suspension systems. Similarly the self-decoupling is realized between the suspension system and torque system as shown in figure 2(d).

GH-09. Comparison of Sleeve Types for Ultra-High-Speed Surface-Mounted PM Motors.

Y. Liu[1], *J. Ou*[1], M. Schiefer[1] and M. Doppelbauer[1]
1. Karlsruhe Institute of Technology, Karlsruhe, Germany

Index Terms—Metal sleeve, fiber sleeve, high-speed motors, rotor losses, surface-mounted PM, PWM. *Abstract*— This paper compares the rotor losses and the thermal fields of a surface-mounted PM synchronous ultra-high-speed motor with different sleeve types. Currently, fiber sleeves and metal sleeves are commonly used. Both types of sleeves have high yield strength. However, they have disadvantages either on rotor losses or on heat dissipation. It is well-known that the fiber sleeve can avoid high eddy current losses, but the thermal conductivity is low. Compared with the fiber sleeve, the metal sleeve has higher thermal conductivity. However, its electrical conductivity is also high which causes high eddy current losses. Hence, this paper compares the two sleeves to provide a reference for the machine designers. I. INTRODUCTION Although the metal sleeve used for ultra-high-speed motors will cause super high eddy current losses, the thermal dissipation ability of the metal sleeve is also high. Currently, the metal sleeve is more widely used according to the literature [1]-[11]. If the manufacture difficulty and the mechanical stress on the sleeves are not considered, which sleeve type is better in terms of the thermal field is the research emphasis in this paper. The properties of the carbon fiber and titanium are listed in Table I. By using the finite element analysis (FEA), dynamic mechanical analysis (DMA) and computational fluid dynamics (CFD) methods, the performance of the surface-mounted PM motors with different sleeve types in terms of electromagnetic, mechanical and thermal aspects are analyzed. II. DETERMINATION OF SLEEVE THICKNESS By applying the sleeve properties in Table I, the mechanical stress on the rotor can be analyzed. To make sure that the sleeve is safe, the maximum stress on the sleeve is limited to 600 MPa. Then, the thickness of the sleeve is determined. Since the Young's modulus, the Poisson's ratio and the permitted stress of the carbon fiber and titanium are comparable, the thicknesses of the two sleeves are equal in this paper. III. ROTOR LOSSES ANALYSIS In order to decrease the PM eddy current losses, the PM poles are divided into 8 segments per pole. Then, at the maximum speed, i.e. 125,000 rpm, when the torque of the two motors with different sleeves is equal, the rotor losses are evaluated through FEA. The influence of the pulse-width modulation (PWM) is considered in this paper. To evaluate the rotor losses caused by PWM, FEA coupled with Simulink method is used. IV. THERMAL FIELD COMPARISON To determine which sleeve has better performance in terms of the rotor thermal field, a CFD software STAR CCM+ is used. The thermal field of the motor with carbon fiber sleeve is shown in Fig. 1. By comparing the temperature rise of the two rotors with different sleeve materials, which sleeve is more suitable for the ultra-high-speed PM motors can be concluded.

GH-10. Simulation and Experimental Research on No-Load Losses of an IPM Motor under the Conditions of both Sinusoidal Supply and Converter Supply.

W. Tong[1], Y. Wang[1], R. Sun[1], S. Wu[1] and J. Jia[1]
1. School of Electrical Engineering, Shenyang University of Technology, Shenyang, China

Interior permanent magnet (IPM) motors driven by pulse width modulation (PWM) converters are widely applied to the industry due to many advantages, such as superior flux-weakening ability, high torque density by using the reluctance torque, etc. [1]. The electromagnetic field in IPM motors includes many harmonics, for instance, the slot harmonics, space MMF harmonics due to discrete current distribution and current harmonics generated by converter power supply. These harmonics may cause considerable harmonic losses in the stator and rotor cores and magnets. The thermal demagnetization of the magnet due to the eddy current loss is one of the biggest problems in the motor. Therefore, correct and quick estimation of the rotor losses is desired [2]. In this paper, an interior "V" type electric vehicle permanent-magnet motor is taken as an example as shown in Fig.1. The rated power is 20 kW, and the rated speed is 4500 rpm. The characteristics of the IPM motors, including the stator and rotor core loss, the permanent-magnet loss and the permanent-magnet temperature rise, are studied in no-load condition with both sinusoidal supply and converter supply. By using the time-step finite element method, each component of the no-load iron loss of the IPM motor with sinusoidal power supply and converter power supply are calculated. The calculation results of the no load losses of a 8-pole 48-slot motor and a 8-pole 9-slot motor are compared. The no-load loss in different parts of the motor with different converter parameters (switching frequency and modulation ratio) is calculated for the motor with distributed windings. The 3-D temperature distribution of the motor, especially the temperature of the permanent magnet is analyzed in the conditions of both sinusoidal supply and converter supply. The accuracy of the FEM results are validated by comparing the loss and temperature rise to corresponding experimental results. Fig. 2 (a) shows the losses at different switching frequency and modulation ratio. When the switching frequency increases from 2kHz to 8kHz, the no-load iron loss of the 8-pole 48-slot motor and 8-pole 9-slot motor reduces by 26.1% and 24.9%, respectively. When the switching frequency increases from 8kHz to 16kHz, the no-load iron loss of the 8-pole 48-slot motor and the 8-pole 9-slot motor reduces by 20.7% and 16.1%, respectively. When the modulation ratio increases from 0.6 to 0.8, the no-load iron loss of the 8-pole 48 slot motor and the 8-pole 9-slot motor decreases by 7.4% and 6.1%per growth of 0.1modulation ratio. This paper adopts a wireless temperature sensor in the motor rotor as shown in Fig. 1 to measure the temperature rise of the permanent magnets in both sinusoidal supply and converter supply conditions. The eddy current losses for both conditions are obtained according to the gradient of tested temperature-time curves at the initial time. The mechanical loss of the motor is obtained using another primary motor to drive this motor with a non-magnetic fake rotor, and the weight and volume of the fake rotor is identical to the real magnetic rotor. The stator and rotor core loss can be obtained subtracting the mechanical loss, no-load copper loss and permanent magnet loss from the total loss. Fig. 2 (b) shows the calculated value and experimental value of each component of the no-load losses for the 8-pole 48-slot IPM motor prototype in the conditions of both sinusoidal supply and converter supply. The no-load loss with sinusoidal power supply is less than that with the converter power supply by 35.2%. The loss of the stator and rotor core is reduced by 28.3%, and the loss of the permanent magnet is reduced by 78.8%.

GH-11. A Novel Topology of Magnetic Gear.

O. Molokanov[1], P. Dergachev[1], S. Osipkin[1], E. Kuznetsova[1] and P. Kurbatov[1]
1. Moscow Power Engineering Institute, Moscow, Russian Federation

Over the past few years, magnetic gears (MG) have attracted much attention. The main reason is the contactless nature of torque transmission in contrast with mechanical gears, that leads to some advantages such as high reliability and low maintenance requirements [1]. Unlike a traditional permanent magnet synchronous machine, electromagnetic torque in MG is produced by the interaction between two separate sets of permanent magnets, resulting in very high torque density up to 239 Nm/L [2] under natural air cooling. These peculiarities of modern MGs makes them promising solution, especially for low-speed applications. Recent studies on MGs have shown that the most viable topologies in terms of torque density are so-called coaxial planetary MG [1] and cycloidal MG [3]. Coaxial planetary MG [1] has only two concentric rotating parts which execute a simple rotating motion. However, the main problem with this topology is the inherent low mechanical strength of modulator [4] that at the same time is supposed to withstand high torque. In contrast, the structure of cycloidal MG can is very robust, but a rotor of cycloidal MG experiences rotating motion about two axis simultaneously which is very challenging to utilize. These disadvantages of modern MG limits their industrial application. This paper proposes a novel topology of MG, which eliminates drawbacks of existing MG. Proposed MG utilizes a simple rotating motion of input and output shafts and lacks the weak modulator in the construction. In the first section of the paper, the structure of proposed MG (fig. 1) is described and operational principle is discussed. Expressions for gear ratio and design considerations are presented. The second section of the paper presents a brief description of simulation method as well as results of modeling in static and quasi-static modes. Results of simulation show that proposed MG has high torque density (140 Nm/L) and is capable of transmitting constant torque with corresponding gear ratio. In the third section of the paper, the possible mechanical design of the novel topology of MG is presented, and its manufacturability is discussed. Finally, the work concludes that proposed MG topology has high torque density about 140 Nm/L and high level of utilization of permanent magnets about 860 Nm/L as well as more robust and reliable structure in comparison with existing topologies of MG.

GI-01. Channel modeling and multi-island recording scheme on bit patterned media with long-range island orientation fluctuations.

Y. Wang[1,2], V. Bhagavatula[2,3], Y. Wen[1] and P. Li[1]
1. School of Electronic Information and Electric Engineering, Shanghai Jiao Tong University, SHANGHAI, China; 2. Electrical and Computer Engineering Department, Carnegie Mellon University, Pittsburgh, PA, United States; 3. Carnegie Mellon University, Kigali, Rwanda

Usually for Bit patterned media recording (BPMR) [1], the media noise (island size and position fluctuations) exhibits short-range disordering [2]. However, recently some BPM fabricated with cost effective self-assembled technology exhibits long-range disordering, as shown in the TEM image (Fig. 1(a), courtesy of Jimmy Zhu and Vignesh at CMU). Specifically, the BPM consists of multiple small domains (rectangular frame in Fig.1(a)) with different island orientations (indicated by arrows). In each domain, the islands are relatively organized because islands in a domain have similar orientation, however, the islands' orientation varies much more from one domain to another. Hence such BPM introduces long-range island orientation fluctuations among domains besides the usual local island size and position fluctuations. Since such BPM appears to be more attractive due to its potentially lower fabrication cost, an interesting question is whether it is possible to record the information reliably on such BPM. To investigate the feasibility of reliably storing and retrieving data from such BPM, we first need to develop a channel model. For channel modeling, we assume that the track pitch and bit length are 12.7nm and 12.7nm, the island size is 7nm x 7nm, corresponding to the channel density of 4Tb/in^2. Based on the TEM image in Fig. 1(a), the island position and size fluctuations are modeled as strongly and weakly 2-D correlated Gaussian noise, respectively. To model orientation fluctuations, a mask (size L_M x W_M) with size larger than the domain (size L x W) is assumed, where the aligned islands within each mask are rotated with some angle. Then after the rotation, only the islands remaining within each domain are retained (Fig.1 (b)). The orientation fluctuation among each domain is assumed to uniformly distributed on the interval [-*a*, *a*] (i.e. *a* = the angle 0, 5° and 15° in Fig.2 (b), (c)). The modeled BPM is shown in Fig.1 (c). Then the write and read process is modeled as in [2]. A read head array with three elements (with free layer dimension of 15nm x 15nm x 4nm) and 13nm shield-to-shield spacing and 4nm magnetic fly height is used to readback three tracks. Then the multi-track signals are processed with 2D MMSE equalizer, detected with BCJR detector and the write/read errors are corrected with an LDPC code (Fig.1 (d)). For LDPC decoder, the number of internal and global iterations (N_{turbo}) are 10 and 3. Considering that the significant media noise and the write in errors for such BPM, we have proposed a recording scheme using multi-island (2 by 2 dots) representation for one bit information compared to the regular recording scheme by recording one bit on one dot (Fig.2 (a)). For the LDPC encoding, the code rate for 4 dots/bit (R=0.9) is about 4 times as high as 1 dot/bit (R=0.225) to obtain the same user areal density (i.e., 0.9 Tb/in^2), considering there are 4 Teradots/in^2. Then the raw BER performance is investigated (Fig.2 (b)). Here we assume 10% island position and size fluctuations (1.27nm, 0.7nm), 5% switching field distribution, 5% track mis-registration and 5% write clock phase shift. It is found that the raw BER performances for both recording schemes degrade with increasing orientation fluctuations. However, the 1 dot/bit case degrades much more severely than the 4 dots/bit case because the redundancy in the 4 dots/bit representation reduces the impact of write errors and decreases the effect of the media noise. More importantly, we have investigated the decoded BER performance of both recording schemes at the same user areal density (Fig.2 (c)). It is observed that when the angle fluctuation is small (<=5 degrees), the decoded BER performance for 1 dot/bit is better than 4 dots/bit due to the much lower code rate (0.225) and hence the much higher error correction capability of the LDPC code in the former case. However, when the angle fluctuationis large (for example, 15°), the decoded BER performance of the 1 dot/bit case becomes worse than the 4 dots/bit one because the write in error becomes increasingly dominant compared to the readback error caused by the inter-track interference (ITI) when the orientation fluctuation increases. However, for the 4 dots/bit case, the redundancy in the multi-island representation reduces the impact of the write in errors and media noise because the magnetic flux picked by the reader is the superposition of the magnetic fluxes from all the 4 dots when it scans over them. Even though when one dot in the 4 dots/bit pattern is written in mistake, the picked up magnetic flux is still quite likely to be correct. Here the greatly increased write in error and media noises (i.e., dominant at large orientation fluctuation) are more detrimental to the LDPC decoding performance compared to the read error caused by AWGN and ITI (i.e., dominant at small orientation fluctuation) for the 1 dot/bit case [3]. In conclusion, A channel modeling and multi-island representation scheme (4 dots/bit) was used to investigate the BPM with orientation fluctuation, which is compared to standard 1 dot/bit scheme. For the LDPC code encoded at the same user density, it is found that the decoded BER performance of the proposed 4 dots/bit scheme is better than 1 dot/bit scheme when the orientation fluctuation is large.

I. Introduction Inter-track interference (ITI) cancelation is one of the considerable challenges for high areal density (AD) magnetic recording such as in bit-patterned media recording (BPMR) systems. In literature, the two-dimensional (2D) modulation codes have been proposed to cancel the ITI effect [1,2] which can efficiently improve the overall system performance, e.g., a rate-5/6 2D modulation code [2]. Although the rate-5/6 modulation code ensures that the readback signal of the center track will not be corrupted by severe ITI; however, both the upper and lower tracks can still be interfered by their sidetracks. To improve this shortcoming; therefore, we propose the bit-flipping technique that performs together with the rate-5/6 2D modulation code. Here, the relationship between the data encoding condition and soft-information obtained from the soft output Viterbi algorithm (SOVA) detector is utilized to be a criterion for flipping the ambiguous data bits. Simulation results indicate that the proposed system is better than the conventional coded system under with/without media noise and track mis-registration. II. BPMR Channel Model We focus on a discrete BPMR channel model [2,3] as depicted in Fig.1. The user bit, a_k is encoded by 2D modulation code to obtain the recoded bit sequences. The readback signal of the k^{th} data bit of the l^{th} track can be expressed as $r_{l,k} = \sum_m\sum_n h_{-m,n} x_{l-m,k-n} + n_{l,k}$, where $x_{l,k}$'s are the recorded bits, $l \in \{0,\pm1\}$ represent the center, upper, and lower track, respectively, $h_{m,n}$'s are the 2D channel coefficients, $\{m, n\} \in (0,\pm1)$, m and n represent the time indices of bit island in the across- and the along-track directions, and $n_{l,k}$ is an additive white Gaussian noise (AWGN). The the readback signals are generated by three readers and are equalized by a 2D equalizers, followed by the 2D SOVA detectors to produce the soft-information, i.e., $[\lambda_{-1,k}\ \lambda_{0,k}\ \lambda_{1,k}]^T$. Then, these soft-information will be sent to the proposed bit-flipping and hard decision processes to generate the improved soft-information, i.e., $[\lambda'_{-1,k}\ \lambda'_{0,k}\ \lambda'_{1,k}]^T$ and estimate recorded bit, $[x'_{-1,k}\ x'_{0,k}\ x'_{1,k}]^T$, respectively. Finally, they will be sent to the decoder to decode the estimated user bits, a'_k. III. Bit-Flipping Technique A. 5/6 Modulation Code The rate-5/6 2D modulation code was designed to avoid the destructive ITI (DITI) data patterns i.e., $\pm[1\ -1\ 1]^T$. Due to these DITI data patterns are the worst patterns, which degrade the readback signal; therefore, these two patterns are not allowed to record onto the medium. In the rate-5/6 2D modulation coding, every 1×5 bits from user data sequence will be rearranged to become three data sequences in a matrix form of 3×2 bits [2]. This coding method provide the good performance for the center track; however, the upper and lower tracks still provide the poor bit-error rate (BER) performance because both of them were interfered from their sidetracks. In this work, we focus on how to cope with this situation. We consider the recoded pattern in each column vector in the form 3×1 of the constructive ITI (CITI) data patterns that are recorded onto medium, which consists of $[1\ 1\ 1]^T$, $[-1\ -1\ -1]^T$, $[1\ 1\ -1]^T$, $[-1\ -1\ 1]^T$, $[-1\ 1\ 1]^T$, and $[1\ -1\ -1]^T$, respectively. We observe that the upper or lower tracks of these CITI data patterns can be easily flipped to the opposite direction due to the ITI effect when their sidetrack bit has opposite direction with the data bit of upper or lower track. For example, $[1\ -1\ 1\ 1\ 1]^T$or $[-1\ 1\ -1\ -1\ 1]^T$ will be easily changed to $[1\ 1\ 1]^T$or $[-1\ -1\ -1]^T$, respectively. Therefore, we propose bit-flipping technique to improve BER performance for all three data tracks by considering the soft-information obtained from 2D SOVAs. B. Bit-Flipping Technique In the data bit-flipping process, we start with considering the soft-information values of the upper, center, and lower data sequences in the column vector form of 3×1 as shown in Fig.1. Firstly, the signs of all soft-information values will be checked, if their sign is according to $[1\ 1\ 1]^T$or$[-1\ -1\ -1]^T$, these three soft-information values will be normalized with their absolute maximum value. Then, if we found that one of the normalized soft-information values among three of them is less than 0.1, the lowest one will be flipped into another direction. Note that in our consistent study, the 0.1 value can provide the accuracy percentage of changing bit estimation more than 80%. IV. Results and Discussions We evaluate the BER performance between the conventional system (without coding), conventional coded system [2], and the proposed system (the rate-5/6 2D modulation code performs together with bit-flipping technique) at AD of 2.5 and 3.0 Tb/in². Here, the 2D Gaussian pulse response with the along-track PW_{50} of 19.4 nm and the across-track PW_{50} of 24.8 nm is considered. In simulation, a signal-to-noise ratio (SNR) is defined as $10\log_{10}(1/\sigma^2)$, where σ is a standard deviation of AWGN. As shown in Fig.2, it is clear that the proposed system provides the better performance for about 1.8 and 5.5 dB at the BER=10^{-4} over the conventional system at ADs of 2.5 and 3.0 Tb/in², respectively. Moreover, the proposed system is also superior to the conventional coded system at 3.0 Tb/in². I. Introduction Two-dimensional magnetic recording (TDMR) [1,2] is a promising high density storage technology, which is expected to increase an areal density (AD) up to 10 terabit per square inch (Tbpsi). This technology is required write narrow-read wide technique that opposite to write wide-read narrow of one-dimensional (1D) read channel. The narrow track writing operated by shingled writing can greatly improve track per inch (TPI) gain. However, the side reading effect of reader is an unwanted situation because the intertrack interference (ITI) from sidetracks, which degrades the overall system bit error rate (BER) performance. Therefore, we introduce the methods to overcome this severe ITI effect. For instance, the two-dimensional (2D) modulation code that designed based on cross-track data dependent readback. The data pattern such as $[1\ \text{-}1\ 1]^T$ and $[\text{-}1\ 1\ \text{-}1]^T$ are forbidden to record onto medium. The rate-5/6 2D modulation code will map the 5 user bits into a 6-bits codeword, which are not contained any forbidden patterns. Furthermore, since the recoded bit is protected from severe ITI effect using modulation code, the middle track can provide a very high reliability. Therefore, we present ITI subtraction to improve upper and lower track performance using data from middle track. Moreover, we also propose an unbalanced track pitch technique, which the middle track can be narrower than upper and lower tracks. The utilization from the high reliability of middle track can improve BER performances both of upper and lower tracks. The reason because the ITI effect that interfere from their sidetracks is reduced by using the properly wider track pitch. II. TDMR Channel Model A message sequence $u_k \in \{\pm 1\}$ is encoded by a low-density parity check (LDPC) encoder [3] to obtain a sequence a_k. Then, the sequence a_k is encoded again with a rate 5/6 modulation code [4] to obtain three recorded bit sequences, $a_{k,l}$. Two random sidetracks are then added to $a_{k,l}$ sequences. The $a_{k,l}$ is perfectly written on a granular medium generated by a discrete Voronoi model [5]. The perfectly writing is defined by the recording field of the writer covers only within a bit cell area, which magnetizes only grain that its centroid is placed inside the bit cell area. TDMR readback signal $r_{k,l}$ is obtained by convolving the magnetization of Voronoi grains, $M(x,y)$, with the reader sensitivity, $H(x,y)$, where x and y are the spatial indices of the bit period in the down- and cross-track, and then add an additive white Gaussian noise (AWGN) for time random noise. In this paper, the signal to time random noise ratio is 20-25 dB calculated by ensemble of waveform technique [6]. At the digital read channel, the readback data sequences $[r_{k,l}, r_{k,l+1}, r_{k,l+2}]$ are equalized by 2D finite impulse response (FIR) equalizers, which are designed based on a minimum mean-squared error approach with fixed 2D target. Then, the equalized samples $s_{k,l}$ is sent to a soft output Viterbi algorithm (SOVA), which exchanges the soft information among each track with $N_{\text{SOVA}} = 3$, before sending to 2D modulation and LDPC decoders to decode the recoded bit and estimated message sequence, respectively. III. An Areal Density Metric and Unbalanced Track Areal density capability (ADC) is a main key parameter for evaluating the performance of magnetic recording systems. The ADC test is performed by varying track density (track per inch, TPI) and linear density (bit per inch, BPI) until it reaches the maximum AD when the estimated user bits from the read channel are all converged. Here, the SOVA obtains BER = 10^{-3} is chosen to calculate the ADC. LDPC is employed to be as the error-correction code for this testing. The obtained data bits from LDPC are all converged within 40 local iterations when its input that obtains from SOVA has BER $\leq 10^{-3}$. Since the 2D modulation code can protect the middle recorded track from severe ITI, that means the middle track can provide a very high BER reliability, while the upper and lower recorded tracks have lower BER performance due to the sidetrack interferences. This work proposes unbalanced track pitch to optimize all three tracks reliabilities. The middle track can be written narrower than its sidetracks because of the help of coding protection. However, sidetracks should be wider than middle track to improve their BER reliability. Moreover, the ITI subtraction is also applied together with the proposed unbalanced track pitch, which can significantly improve the ADC. IV. Simulation Results We compare the ADC of four systems consists of: (1) conventional TDMR system, (2) TDMR system with the rate-5/6 2D modulation code, (3) TDMR with the rate-5/6 2D modulation code performs together with ITI subtraction technique, and (4) unbalanced track width TDMR with the rate-5/6 2D modulation code and ITI subtraction technique. Fig 1 shows that ADC of the all systems that obtained from nine media models. The small symbols indicate each media ADC and the large symbols represent the average value of all nine media model for each system. The result shows that ADC of systems: (1) = 4.51 Tb/in^2, (2) = 4.8 Tb/in^2, (3) = 5.18 Tb/in^2, and (4) = 5.28 Tb/in^2. The ADC gains of the system (2), (3), and (4) can be increased over the conventional TDMR system for about 6.52%, 14.88%, and 17.06%, respectively. GI-04. Spatially-Coupled Codes for Channels with SNR Variation.

H. Esfahanizadeh[1], A. Hareedy[1], R. Wu[1], R. Galbraith[2] and *L. Dolecek*[1]

Modern magnetic recording (MR) systems require error correcting codes (ECCs) with outstanding error floor performance. Low-density parity-check (LDPC) codes are a primary choice for MR systems because of their error correcting capabilities [1]-[3]. In a magnetic recording device, some sections can be more error-prone than other sections because of the read/write mechanism and physical properties of the device [4]. A realistic channel model for magnetic recording systems must consider the variation of signal to noise ratio (SNR) among consecutive sections of a hard disk drive. For channels with SNR variation, the conventional ECCs are designed to achieve the certain BER for the section with the lowest SNR. For the sections with higher SNRs, this approach results in an additional redundancy which is not necessary to achieve the target BER. Spatially-coupled (SC) codes are a family of graph-based codes that have attracted significant attention because of their capacity approaching performance [5]. SC codes are constructed by partitioning a parity-check matrix H of the underlying block code into component matrices $H_0,...,H_m$, $H=H_0+...+H_m$, and coupling L copies of the component matrices together to obtain the parity-check matrix H_{SC}, Fig. 1. The parameters m and L are known as the memory and coupling length, respectively. An SC code with coupling length L has L replicas, $\{R_1,...,R_L\}$, see Fig. 1. In this paper, we present an SC code design approach for channels with SNR variation. In our code design, the length of the underlying block codes is equal to the length of one section of the channel, and the number of sections spanned by one SC code is determined by L. Because of this structure, each check node (CN) receives messages from more than one section, so more reliable variable nodes (VNs) can help compensate for the sections that are highly affected by noise. In our model for a channel with SNR variation, each section is considered as an AWGN channel with SNR_i (i is the section index). For the i'th section, we state the SNR as $(SNR_i)_{dB}=(SNR_{abs})_{dB}+(\Delta SNR_i)_{dB}$, where $(SNR_{abs})_{dB}$ is the absolute SNR and $(\Delta SNR_i)_{dB}$ is the variation from the absolute SNR for the i'th section. We first describe our code construction approach: The length of the underlying block code is equal to the length of one section of the channel, so each replica of an SC code spans one section of the channel. The coupling length L determines how many sections are spanned by one SC code, so it must be chosen such that a variety of sections with different reliabilities are included. The minimum overlap (MO) approach is recently introduced for partitioning block codes and constructing SC codes [6]. In this approach, the matrix H of a block code is partitioned into several component matrices such that the number of detrimental objects in the graph of the derived SC code for AWGN channels is reduced. In this paper, we use MO approach for constructing SC codes with γ=3. Moreover, we extend this approach to construct SC codes with γ=4. The memory m of an SC code plays the critical role on its performance over channels with SNR variation. By increasing memory, sections are more cooperative, and the SNR variation among them can be alleviated better. The parameter m determines how many different sections are involved in the check equations in an iterative decoding. Because of our SC code construction, most CNs receive messages from VNs within m+1 consecutive sections. As a result, if there is one reliable section with a high SNR, it can in principle help the messages from other m sections be recovered more reliably. For interleaving, we divide the SC codeword into $L^2/(m+1)$ chunks. Then, we rearrange them by taking one chunk from each L consecutive chunks and putting them next to each other. This interleaved data is passed through the channel, and the de-interleaving is performed on the received data from the channel and before decoding. Due to interleaving, most CN receives an equal number of messages from all L different levels of reliabilities. Our simulation results show that our channel-based interleaving compensates for the performance gap that exists between the error rates of SC codes over non-uniform and uniform channels with similar average SNR. Our proposed scheme is the first channel-aware interleaving for SC codes, and the complexity of the proposed interleaving is inversely proportional to the number of component matrices. The regular interleaving has a fixed complexity with respect to the memory which is equal to the complexity of our interleaving scheme for the case m=0 (the uncoupled setup). Finally, we show some important simulation results. Block Code 1 is an array-based block code with γ=3, length 289 bits, and rate r=0.82. SC Code 1 and 2 are SC codes with Block Code 1 as the underlying block code. They both have L=30 and length 8670 bits. The memory and rate for SC Code 1 are m=1 and r=0.82, and for SC Code 2 are m=2 and r=0.81, respectively. Fig. 2 shows the BER curves for Block Code 1, SC Code 1, and SC Code 2 over the non-uniform channel. It can be seen that SC Code 1 shows 2 orders of magnitude performance improvement in the error floor area compared to the Block Code 1, with and without (regular) interleaving, respectively. We achieve further improvement when we apply our optimized interleaving to SC Code 1. Moreover, SC Code 2 secures even further improvement by providing more cooperation among different sections of the channel. The longer version includes results for our γ=4 SC codes.

GI-05. The Effective Fuzzy Logic Equalizer Based Adaptive Nonlinear Equalization for the Nonlinear Perpendicular Magnetic Recording Channels.

R. Wongsathan[1] and P. Supnithi[1]
1. Electrical Engineering, King Mongkut\'s Institute of Technology Ladkrabang (KMITL), Bangkok, Thailand

Abstract. It was demonstrated that the channel equalization based adaptive nonlinear equalizer outperforms the conventional detector and equalizer in nonlinear perpendicular magnetic recording (PMR) channels. To improve the detection performance, in consequence, this paper alternatively proposes the efficient adaptive equalization based on fuzzy logic equalizer (FLE). To fulfill the effectively handling design and reducing complexity, genetic algorithm (GA) and multi-objective hierarchical GA (MOHGA) are used to optimized the FLE in order to fine-tune the fuzzy parameters and simultaneously generate the significant fuzzy rules. The BER performance of the proposed FLE-GA and FLE-MOHGA has been compared with that of the partial response maximum likelihood (PRML) detector, Volterra equalizer (VE), multilayer perceptron neural network (MLPNN) based equalizer and the hybrid MLPNN-VE (hMLPNN-VE). From the the simulation results, the proposed FLE-MOHGA clearly outperforms the rest for a nonlinear Volterra channel at high normalized recording density. Subsequently, the performance comparison in terms of the tradeoff between accuracy, computational complexity and reliability between the proposed FLE and the adaptive neurofuzzy inference system (ANFIS) based equalizer supported the effective of the proposed FLE. Outline: Nonlinear distortions and noises cause the errors for detection in high-density magnetic recording (MR) systems. To tackle this issue, various approaches have been proposed [1]-[4]. On the transmit side, pre-compensation method helps reduce the nonlinearity by varying the write current [2]. However, on the receive side, previous works studied the use of PRML detector [3], VE [1] among others. A PRML (Viterbi) detector [1] based on partial-response (PR) linear equalization is ineffective for nonlinear channels, but it can be improved by including the nonlinear channel coefficients on the trellis branches when these coefficients are known. Therefore, without the priori information of the nonlinearity, alternative approaches based on nonlinear equalization are of interest. The nonlinear VE has been proposed to combat the nonlinearities in MR channels [1] and satellite channels [5]. However, its performance is only slightly better than that of the linear equalizer while the complexity is prohibitively complex as the number of channel coefficients increases. To further improve the BER performance, MLPNNE is introduced to the nonlinear PMR channels [4] as well as the optical communication [6]. This approach outperforms PRML and VE at the expense of complexity. Recently, the hMLPNN-VE has been proposed and implemented in the nonlinear PMR channels modeled by Volterra series (VS) model [7]. It outperforms the MLPNE, VE and the conventional PRML detector, respectively. However, a number of system parameters, the complexity, BER performance compared to the optimal detector are disadvantages. To solve this problem, this work alternatively introduces the adaptive nonlinear equalization based FLE. Since it was evident for the successful in order to apply into various communication channels [8]-[13]. From the test, it was shown that the FLE performs better than the transversal filter equalizer in the presence of channel nonlinearity and its BER is closely reached to that of the optimal equalizer. However, in the data storage channels, FLE seems to be limited. In this work, it is an attempt to develop effectively the adaptive FLE for the nonlinear PMR channels. Unfortunately, the construction of proper fuzzy rules for equalizer is difficult. Using human experts through the trial and error to design the fuzzy rules is often incomplete and incorrect description of the system. One of the effective techniques found in ANFIS or neurofuzzy based equalizer (NFCE) is the use of NN learning the input output data pattern to formualte the fuzzy rules [12]-[13]. However, this technique increases more complexity from a large number of parameters of NN and the system parameters may likely fall to local minima during training using NN [12]. By using evolutional learning through GA, it does not require derivative calculation like the back-propagation (BP) in NN, then it is less likely to be trapped in local minima. Therefore, GA has been suggested to optimize the fuzzy parameters [14]. The nonlinear PMR channel model and the FLE design is shown in Fig.1. However, it was found that the number of self-generated fuzzy rules do not improve the accuracy or performance more but increase the complexity. To improve the performance further, the MOHGA was used to optimize the fuzzy rules by the modified criterion function. The BER of FLE-MOHGA provides about 1 dB, 1 dB, 3 dB, 6 dB and 12 dB SNR gain over the FLE-GA, *h*MLPNN-VE, MLPNNE, VE, and PRML detector at the BER of 10^{-4}, respectively, Fig. 2(a). To verify the effective of the proposed FLE by comparing with NFCE, it can be seen from Fig. 2(b) that the NFCE provides the BER performance slightly better than that of the FLE-MOHGA. However, the AIC [15] is supported that the proposed FLE-MOHGA gives the better performance in terms of the tradeoff between accuracy, computational complexity and reliability than that of the NFCE and also the others.

GI-06. Flexible Inter-track Interference Cancellation for Generalized Interlaced Magnetic Recording.

S. Yoon[1] and *E. Hwang*[1]
1. School of Mechatronics, Gwangju Institute of Science and Technology, Gwangju, The Republic of Korea

Interlaced magnetic recording (IMR) shows potential to achieve higher areal density capability (ADC) than conventional magnetic recording by recording tracks in an interlaced manner [1]. Top and bottom tracks can be recorded in different frequencies such that the bit error rate (BER) performance can be balanced, providing extra track or linear density pushes. For example, heat assisted IMR (HIMR) enables higher ADC than conventional heat assisted magnetic recording (HAMR) and shingled recorded HAMR by allowing broader bottom tracks with sharper bit transitions and narrow top tracks by control the heat spot [2]. On the other hand, bottom tracks in IMR can suffer from sever inter-track interference (ITI) by subsequent top track writes on both sides, especially as the track density increases [3]. In order to mitigate the ITI effect for such double-sided squeezed tracks, customized ITI cancellation scheme has been introduced, where the asynchronously written tracks are processed in the oversampled domain and overall ADC can be improved [4]. In this study, ITI cancellation scheme is extended for generalized IMR framework, where the ITI can be distributed for top and bottom tracks by applying dual write configurations. One of the major contributions of the tangible ADC gain by HIMR is the additional laser spot control to form narrow but sharp bit transitions in top tracks [2]. In this manner, the wide and sharp bottom tracks are only partially erased by the subsequent top track writes, and, thus, the ITI can be effectively managed. Likewise, the write track widths can be modulated for conventional perpendicular recording and may provide the ADC gain once the ITI is efficiently handled. Note that ITI cancellation can also be needed for top tracks as well, and the relative linear density differences of ITI can be both positive and negative. Therefore, flexible ITI cancellation scheme is proposed in this study to handle the widely varying synchronization issues. The waveforms need to be over-sampled first to effectively synchronize the neighboring tracks, and double of baud rate of lower density track can be used. For example, under 2500 and 2000 kBPI dual writer configurations, the oversampled data can be denoted as $x_{(t)2x}$, $x_{(b)1.6x}$ respectively, relative to its baud rate. Then, the error signal is first estimated, $e_{(t)2x}$, $e_{(b)1.6x}$, resampled to the side track data rate, $e'_{(t)1.25x}$, $e'_{(b)0.8x}$, and then the ITI response is estimated for tracks m_t and m_b as, $\{h'_{(t)mt-1}, h'_{(t)mt+1}\}=\arg\min_{h(t)mt-1,h(t)mt+1} \| e'_{(t)1.25x} - h_{(t)mt-1}*n_{mt-1}- h_{(t)mt+1}*n_{mt+1} \|^2$ $\{h'_{(b)mb-1}, h'_{(b)mb+1}\}=\arg\min_{h(b)mb-1,h(b)mb+1} \| e'_{(b)0.8x} - h_{(b)mb-1}*n_{mb-1}- h_{(b)mb+1}*n_{mb+1} \|^2$ where n_m is the recorded binary data of the track m, and estimated side track data will be used for actual implementation. The ITI signal is estimated from {h'}'s, resampled to baud-rate if needed, and subtracted from the baud-rate readback signal. The feasibility of such generalized IMR with flexible ITI cancellation is investigated with the numerical channel simulations. For numerical evaluations of IMR, microcell channel model [1] is employed, where the media is modeled by the square micro-cell of 1.5nm sides, and the granular effect is accounted by shifting the bit and track boundaries randomly for the locally clustered cells. If the writer configuration is maintained except the write frequency for IMR, bottom tracks should be recorded at the relaxed density due to the ITI. If dual write configurations can be used for narrow top tracks, bottom tracks can be recorded with aggressive linear density by forming relatively sharp bit transitions in the remained portion. Figure 1 illustrates the averaged media polarization of repeated [1 1 -1 -1] patterns with single write configuration in (a) bottom and (b) top tracks at 2000 and 2500 kBPI with 529 kTPI. The writer width is assumed to be 60 nm, and the transition curvature is modeled by the ellipse with depth of 20 nm. As illustrated, the bottom tracks are erased by the top track writes and expected to suffer from ITI. On the other hand, same track density 2T patterns with dual write configurations is illustrated in (c) bottom and (d) top tracks at 2500 and 2000 kBPI. The writer width is changed 20% and -20%, while the depth is factored $1/2^{½}$ and $2^{½}$, respectively. As shown, the ITI is distributed for both tracks, and ITI cancellation is needed for both tracks. Readback waveforms are evaluated with the Gaussian read sensitivity function and BER performance is investigated. Other experimental setups are set to as [1], and head electronic signal to noise ratio (HESNR) is scanned from 12 to 30 dB under the track and linear densities illustrated in Fig. 1. Figure 2. shows BER with flexible ITI cancellations in (a) single and (b) dual write configuration IMRs. For the single mode, bottom track BER performance improved significantly by ITI cancellation, while the top track experiences negligible ITI. On the dual mode, both tracks are experiencing the ITI and are improved by the ITIC. In overall, -1.5 order target BER can be achieved at 30 dB HESNR by the dual mode IMR with the flexible ITIC.

GI-07. 1/f thermally excited noise in asymmetric oscillators.

T. Pipathanapoompron[1,5], A. Stankiewicz[2], A. Grier[4], K. Subramanian[3] and A. Kaewrawang[1]
1. Electrical Engineering, Khon Kaen University, Khon Kaen, Thailand; 2. Seagate Technology, Bloomington, MN, United States; 3. Seagate Technology, Shakopee, MN, United States; 4. Seagate Technology, Spring Town, United Kingdom; 5. Seagate Technology, Korat, Thailand

Many physical systems and devices operate in a (quasi)static regime in contact with a thermal bath, which leads to fluctuating oscillations around the energy minimum. For linear systems, the spectrum of these oscillations replicates the resonance curve of a damped oscillator [1]. In particular, power spectral density grows monotonically with frequency in the low frequency range, until reaching a maximum at the resonant frequency. Small sizes of contemporary magneto-resistive readers and other MEMS/NEMS devices pushes oscillations to non-linear regimes, which may lead to resonance line broadening, bifurcations, etc. [2]. However, non-linearity does not change the monotonicity of thermal fluctuations in the low frequency range, until the energy profile is symmetric around the minimum. Asymmetry of the energy profile around the stable point leads to low frequency thermal noise, with 1/f-like spectral profile. This phenomenon results in M-shape low frequency noise dependence vs magnetic field in magnetic tunneling readers [3]. This provides the motivation for the detailed study about the relationship between low frequency noise and asymmetric oscillations presented below. In magneto-resistive readers, it has been shown that the magnetic precession can be described in term of a 1D damped oscillator [4]. This serves as the primary basis for this investigation. 5 GHz asymmetric oscillators (which is the typical resonant frequency for the reader free layer) in contact with a thermal bath is analyzed using the Langevin equation. Potential energy profiles were generated using bi-harmonic and skew normal approximations [5], providing the ability to generate symmetric and asymmetric potentials using a single adjustable parameter. Asymmetric oscillations will introduce a DC shift, but the presence of random fluctuations in this asymmetric potential produces a broadening of the DC frequency spike leading to a pronounced 1/f-like low-frequency shape to the spectral density. Fig.1 depicts the simulated oscillation spectra for the bi-harmonic oscillator potential and shows the increasing power spectral density at low frequencies as asymmetry is introduced. In order to further characterize the nature of this 1/f-like low frequency noise profile, the time domain signal for the asymmetric oscillator was decomposed into low and high frequency components as shown in Fig. 2a. Fig. 2b shows the two dimensional histogram of the low frequency noise and the high frequency instantaneous amplitude. The strong correlation seen confirms that the 1/f-like low frequency noise originates from the fluctuations of the asymmetric oscillations. This model demonstrates a new mechanism of 1/f noise generation, which in many practical cases have been classified as being of unknown origin [6]. Experimental evidence for this behavior in the context of magnetic tunnel junction readers used in magnetic recording has been reported as well [7].

GI-08. Molecularly Structural Change of PFPE Lubricant Accumulated on Pin Surface at Laser Heating.

H. Tani[1], Y. Shibahara[2], R. Lu[1], S. Koganezawa[1] and N. Tagawa[1]
1. Mechanical Engineering Dept., Kansai University, Suita-shi, Japan;
2. Graduate School of Kansai University, Suita-shi, Japan

With increase in the storage capacity of hard disk drives, the flying height of the magnetic head is now typically less than a few nanometers. Picked up lubricant on the slider surface causes the head flying instability. On the head disk interface (HDI) of heat assisted magnetic recording (HAMR), the disk surface is heated to a high temperature of 400 - 500 K. If the lubricant is evaporated by laser heating and that should accumulate as smear on the slider surface. Kiely et al. concluded that the head smear played a key role not only for the stability of the HDI, but also for the transmission efficiency of the thermal energy from the near field transducer to the recording media in the HAMR system [1]. In this study, we have studied the molecularly structural change of perfluoropolyether (PFPE) lubricant accumulated on the pin surface at laser heating using TOF-SIMS in order to obtain the design guideline of lubricant film with the high heat resistance for the HAMR. TOF-SIMS spectrum of lubricant accumulated on a pin surface was compared to that of disk lubricant inside and outside laser heated track as shown in Fig. 1. The molecular weight could be obtained from these TOF-SIMS spectra. In addition, the progress of end-groups dissociation by laser heating could be estimated by the intensity of end-group fragments. As the results, the molecular weight of accumulated lubricant was smaller than that of disk lubricant and that of disk lubricant was larger than that of normal lubricant. The dissociation of end-groups increased with the temperature of laser heating as shown in Fig. 2.

GI-09. HAMR Air Bearing, Water Monolayer Vaporization and Diffusion.

O.J. Ruiz[1]
1. Advance Tribology, Western Digital, San Jose, CA, United States

In HAMR drives the intense heat under the NFT produces an increase in the air bearing pressure by following mechanisms: thermal gradient driven molecular creep flow, vaporization of the water monolayer adsorbed on the disk surface, clearance reduction driven by the thermal protrusion of the NFT and disk hot spot, and elastic deformation of the head and disk surface induced by the gas pressure. The pressure effect of the thermal gradient is considered by including a known molecular thermal creep flow term in the Reynolds equation. The problem of water evaporation and condensation in the gas bearing is addressed by solving the associated gas diffusion problem. Under equilibrium conditions the concentration of water vapor within the gas is uniform. Depending on the local pressure and temperature, some water is lost to condensation and some is added by evaporation of the water monolayer on the disk. Such addition or removal creates an imbalance in the local vapor concentration thus permitting vapor diffusion. The diffusion of water vapor in a gas is described by the Fick diffusion equation. In addition to solving the lubrication equation for the pressure the time domain vapor diffusion is solved concurrently. Quantities such as the mean free path, viscosity and diffusivity become pressure, spacing, temperature and concentration dependent and are location dependent. The replenishing of the water monolayer on the disk is addressed by considering a simple Langmuir isotherm. The water vapor molecules impinging on the disk get adsorbed and induce a concentration gradient that drives vapor diffusion toward the disk and limits the duration needed for the replenishing of the monolayer. The mechanical deformation of the disk and slider due to the gas pressure is also considered. Results for a time domain simulation considering transient effects caused by laser power changes as the head traverses the servo wedges is presented. Some comments on the corrosive effect of the superheated steam are offered.

GI-10. Modified MGL Equation Considering Both Effects of Surface Roughness and Accommodation Coefficient for Ultra-thin Gas Film Lubrication.

B. Shi[1,2], K. Guo[1], Y. Sun[1] and Y. Feng[1]
1. School of Mechanical and Electrical Engineering, Shandong Jianzhu University, Jinan, China; 2. School of Mechanical Engineering, Hebei University of Technology, Tianjin, China

1. Introduction The clearance between the read/write head and the disk surface, which is normally referred to the flying height (FH), should be small and stable as the FH is one of the important components of the head-media spacing [1-2]. To achieve a higher areal density, the FH of the slider continuously decreases and has been reduced to about 1-2 nm in modern disk drives [3-4]. Under such low spacing, the considerations of gaseous rarefaction effects and roughness effects of the magnetic recording system become more important. By solving modified Reynolds equation, effects of gaseous rarefaction and surface roughness were investigated [5-6]. The influence of surface accommodation coefficient (AC), which determines the behavior of the reflected molecules at the boundary walls, is an important factor to govern the flying characteristics of the air bearing slider [7-8]. By solving modified molecular gas film lubrication (MGL) equation, which governs ultra-thin gas film lubrication problems, effects of surface accommodation were investigated [9-10]. However, most of the published work considered gaseous rarefaction effects with either surface roughness effects or surface accommodation effects. 2. Modified MGL equation In the present study, a modified MGL equation is proposed considering both effects of surface roughness and AC for ultra-thin film lubrication, in addition to the gaseous rarefaction effect. Solving the modified model, the effects of surface roughness and AC are combined to study the static characteristics of the air bearing film. Numerical results are presented for both symmetric molecular interaction and asymmetric molecular interaction. 3. Numerical results and discussions *A. Effects on the pressure distribution in symmetric molecular interaction* Figures 1 and 2 show the pressure distributions for various surface roughness combinations in two cases of symmetric molecular interaction. There are five curves in each figure. The solid one without any mark represents the "smooth" case, in which both of the slider and the disk have no roughness. The two solid curves with marks of plus and circle signs represent two roughness cases, in which both the slider and the disk have the same roughness of 0.2 nm and 0.3 nm, respectively. The two solid curves with marks of product and point signs represent another two roughness cases, in which either the disk or the slider only has roughness of 0.3 nm, respectively. From Figs. 1 and 2, we have following observations: 1) When both the slider and the disk are rough, the pressure distribution will increase with the increase of ACs and/or the increase of surface roughness. 2) When the slider only is rough, the pressure distribution is much higher than that of both the slider and the disk in smooth case. While when the disk only is rough, it has opposite effect on the pressure distribution. 3) With the increase of ACs for various roughness cases, the location of maximum pressure moves towards the trailing edge of the slider. 4) In general, in the case of symmetric molecular interaction, the pressure distribution of the film increase with the increase of ACs with various surface roughness combinations. For a given surface roughness, the pressure distribution increases if the slider only is rough, while it will decrease if the disk only is rough. These phenomena will be futher explained in the full paper. *B. Effects on the pressure distribution in asymmetric molecular interaction* We also investigated the effects on the pressure distribution for various surface roughness combinations in the case of asymmetric molecular interaction and compared with the phenonmena observed in the case of symmetric molecular interaction. In general, the AC's variations of the slider and the disk will result in opposite effects on the pressure distribution in the case of asymmetric molecular interaction. These phenomena will be presented and discussed in detail in the full paper. 4. Summary and conclusion 1) Starting from a simplified molecular gas film lubrication (MGL) equation, a modified MGL equation is proposed for ultra-thin gas film lubrication to consider the combined effects of surface roughness and accommodation coefficient (AC) simultaneously, in addition to the gaseous rarefaction effect. 2) For the case of symmetric molecular interaction, pressure distribution of the air bearing film increases with the increase of ACs with various surface roughness combinations. For a given surface roughness values, pressure distribution of the air bearing film will increase if the slider only is rough, while there will be opposite effect if the disk only is rough. For the case of asymmetric molecular interaction, the AC's variations of the slider and the disk lead to opposite effects on the pressure distribution. The phenomena observed will be further explained in the full paper. 3) More detailed numerical results of the effects on the pressure center and the load-capacity in both symmetrical and unsymmetrical molecular interactions will be reported and discussed in the full paper. *Acknowledgments* This work was supported by the National Nature Science Foundation of China (Grant No. 51275279) and the Tribology Science Fund of State Key Laboratory of Tribology (Grand No. SKLTKF16A01), China.

Abstract: With the continually increase of HDD areal density, the required clearance between magnetic head and disk is lower than 1 nanometer (nm). The HDDs reliability becomes a significant concern due to the inevitable contact of intermittent/ continuous head-disk contact. To reveal the related factors to slider wear, a serious experiments under near-contact/ contact region based on a drive-based tester were carried out in this paper. Based on the theoretical explanation and the slider wear identification results using Scanning electron microscope (SEM), it is concluded that slider with high temperature is prone to producing more wear to slider, which agrees well with the atom-atom wear model proposed by I.Introduction To increase the areal density to 1 TB/in^2, the required clearance between magnetic head and disk is lower than 1 nanometer (nm) [1]. At such small clearance, the intermittent/continuous head-disk contact is inevitable. As a result, the slider wear becomes a significant concern for the HDD researchers and engineers. Although the slider wear under sliding-contact condition has been explored extensively [2], the design and environmental factors influencing on slider wear under near-contact or intermittent-contact condition are still not clear. In this paper, we investigated such factors under a near-contact/contact region, e.g., slider just touching down. Both room temperature and high temperature were considered. II.Experiment A drive-based tester was used to perform the experiment. And the tester was placed in a temperature champer, which can control the enviormental temperature during test. The pemto-size thermal flying-height control (TFC) sliders were used. An AE sensor was used to detect the slider touch down. During the test, the sliders continuously flied over five hours after setting a touch down power to the TFC heater. Scanning electron microscope (SEM) was used to inspect the slider wear after the test. III. Result and Discussion To investigate the temperature impact on slider wear, we also tested the 32 samples under room temperature (25 Celsius) and high temperature (55 Celsius), respectively. From SEM inspection results, as demonstrated in Fig. 1 (a) and (b), under high temperature slider has much larger wear area. AFM results (Fig.1 (c)) show that the slier wear under high temperature is much more serious. This means high temperature is prone to producing more wear to slider. At nanoscale wear, wear can be described as atom-atom removal. Based on prevous wear model, we have a modified wear model for slider wear which assumes slider tip is a part of sphere, as shown in Fig. 2. From this model, we can find the wear amounts is highly related to temperature, which means the test results agree well with the wear model.

GI-12. Effect of Pressure and Temperature on Lubricant Transfer from Disk to Slider in Helium-filled Hard Disk Drives.

Z. Tang[1], D. Zhou[1], T. Jia[1], C. Zhang[2] and B. Shi[3]
1. School of Mechanical Engineering, Guizhou University, Guiyang, China; 2. School of Mechatronics Engineering, Harbin Institute of Technology, Harbin, China; 3. School of Mechanical and Electrical Engineering, Shandong Jianzhu University, Jinan, China

1. Introduction Helium, proved to be a good medium to reduce windage loss and disk flutter [1-3], has been filled in hard disk drives in recent years to improve storage [4]. Meantime, lubricant transfer between slider and disk has been widely studied due to the decreasing space between the slider and the disk [5-6]. We know that helium can greatly reduce the flying height of a hard disk drive. But question arises as to how the lubricant transfers in helium-filled hard disk drives. In this paper, a model of slider with a cylindrical asperity flying over a disk in helium-filled hard disk drive was developed. The pressure and temperature distribution at helium-filled head/disk interface was obtained by calculating Reynolds equation and energy equation. Thereafter, the effect of pressure and temperature on lubricant transfer from disk to slider in helium-filled hard disk drives was numerical simulated using molecular dynamics. 2. Air bearing model Fig.1 shows the schematic drawing of a slider with a cylindrical asperity flying over a disk in helium-filled hard disk drive. The minimum flying height is 2 nm. The initial temperatures at the slider surface and the disk surface are set to be and, respectively. A finite element method was used to calculate the Reynolds equation and the energy equation. Thereafter, the pressure distribution and the temperature distribution of the air bearing in helium-filled hard disk drive are obtained. The effect of helium (physical properties such as density, mean free path, viscosity, and thermal conductivity) on the pressure distribution as well as temperature distribution is studied. Finally, the results are simulated as an input in the model of molecular dynamics. 3. Model of molecular dynamics Fig. 2 shows the molecular dynamics model and the process of lubricant transfer from disk to slider. The dimensions of the model are exactly the same as the model of air bearing interface, which is shown in Fig. 1. Fig. 2 a) shows the molecular dynamics model before the pressure and the temperature are applied. We observe that a clear gap between the slider and the disk, which means there is no lubricant transfer. However, the lubricant starts to transfer from the disk to the slider surface after the pressure and the temperature were applied, as shown in Fig. 2 b). The pressure over the cylindrical asperity first increases and then decreases according to the air bearing results. The highest pressure happens at the first half cylinder while the lowest happens at the second half cylinder. We observe the lubricant transfer occurs at the area of the slider surface in front of the cylindrical asperity. This is caused by the great difference of pressure induced by the cylindrical asperity. In addition, the lubricant stays at the slider surface if the flying height increases. In the full paper, the effect of helium on the pressure and temperature distribution of air bearing will be shown and discussed. And how the obtained pressure and temperature will affect the lubricant transfer at the head/disk interface will be presented as well. 4. GP-02. Comparison of Unbalanced Forces in a BLDC Motor Considering Difference in Resistance According to the Number of Parallel Circuits and Winding Concept.

H. Lee[1], K. Shin[1], S. Cho[1], T. Bang[1] and J. Choi[1]
1. Dept. of Electric, Electronic and Comm. Eng. Edu., Chungnam National University, 99 Daehak-ro, Yuseong-gu, Daejeon 34134, Korea, Daejeon, The Republic of Korea

Brushless direct current (BLDC) motors have favorable characteristics, such as high output power, high torque density, wide operating range, high efficiency, precision controllability, simple driving method and low price. They are widely used in technological applications, such as electric vehicles, robotics and home appliances, and are gradually replacing DC motors because BLDC motors do not have a mechanical commutator and brush [1]. The outer rotor BLDC motor, which is the analysis model of this paper, has a structure in which the rotor rotates on the outside, and has a large inertia. This is advantageous for constant rotation and also means that the magnet can be attached to the inside of the yoke. The merit of this structure is that a large torque can be obtained even with a magnet that has a weak magnetic force [2]. The causes of noise and vibration in these motors are divided into electromagnetic and mechanical factors. In the case of electromagnetic factors, the electromagnetic forces generated by permanent magnets and armature windings contain harmonic components that cause noise and vibration due to the stator teeth and slot structures [3]. Among the electromagnetic forces involved, radial force density is the external excitation force, which is the primary source of vibration of the motor acting on the teeth surface of the stator. In particular, when its frequency is equal to the natural frequency of the motor, resonance causes wear of the motor parts and generates excessive noise. Therefore, it is essential to analyze the radial force density during high performance operation of the motor [4]. The radial force density distribution on the stator surface, which results from the air-gap magnetic field under no-load (open-circuit) and on-load conditions, is the main cause of electromagnetically induced noise and vibration. In this paper, the differences resistance caused by changing the number of parallel circuits and the resulting unbalanced forces was analyzed using a 2D finite element method. When the number of parallel circuit is increased during motor design, the air-gap become non-uniform due to bearing wear. Thus, as the reluctance of the magnetic poles is not uniform, the magnitude of the electromotive force induced in each parallel circuit may become unbalanced. If the voltages of the parallel circuits are not balanced, a circulating current and an unbalanced force is generated [5]. In our analysis model, an 8 pole-12 slot BLDC motor was analyzed under on-load conditions according to the number of parallel circuits, winding concept and the electromagnetic unbalanced force that occurs due to resistance differences arising from an increase the number of parallel circuits. Our analysis model is shown in Fig 1 (a). The Y-connection of the BLDC motor's stator is shown in Fig 1 (b). The Δ-connection is shown in Fig 1 (c). The simulation was based on these two winding methods and on the use of either two or four parallel circuits per phase, as shown in Fig 1 (d). In analysis methods that use radial force density, the noise and vibration characteristics of the motor are difficult to predict due to differences in resistance arising from the manufacturing process. Figs 2 (a) and (d) show the spatial radial force density distribution on the air-gap contours with and without resistance differences. The level of unbalanced magnetic force is almost same. The global force applied to the rotor was computed. Figs 2 (b), (c), (e), and (f) show the unbalanced forces on the rotor axis. Force_x and Force_y are the x-axis and the y-axis components of the unbalanced forces in the rotor, respectively. From our results, in can be seen that when there are resistance differences, the global force applied to the rotor becomes unbalanced, as shown Figs 2 (c) and, (f). When noise and vibration are produced in a machine with a BLDC motor, the result obtained in this study can provide a hint at what resistance condition is present. A more detailed results analysis for two, four parallel circuits, and discussion will presented in the full paper. GP-03. Improvement of torque ripple characteristics of double winding PMSM with using twin inverter.

S. Noguchi[1]
1. Motor Drive Laboratory, Tokyo City University, Setagaya-ku, Japan

In recent years, double winding machines are more interested because it has wide range of application by motor control better than general three phase machines [1], [2]. It is known that these machines have fault tolerant feature, so it is got much attention especially for application which needs failure tolerance like aircraft, electric vehicle, electric rolling stock, and marine ship. These machines need two or more inverters, which leads higher costs than one inverter drive. But controlling each winding by independent inverters lets improvement drive characteristics like extending speed range, and reducing torque ripples. But controlling each winding by independent inverters expects letting improvement drive characteristics like extending speed range, and reducing torque ripples, so it is widely considered[3]. For examination object of double winding machines, PMSM and induction machine is mostly used. Especially 10poles-12slots PMSM is superior as AC servo motor, so the PMSM is widely used as examination object. Test machine using in this paper has 10poles-12slots configuration shown in Fig.1(a). And each complementary pair of three phase winding is connected in serial, then the connected winding pair is connected in parallel as 2S2P connection, shown in Fig.1(b). In generally, when the motor drives using all windings, gives same phase AC current to each of three phase winding group. Each of three phase winding group is able to excite by two inverter independently controlled by one microcontroller, shown in circuit diagram Fig.1(c). It is able to suppose many motor drive pattern by exciting three phase winding group separated group1 and group2 independently. In this paper, comparing driving characteristics of following driving patterns by using 2 inverter to verify phase difference drive and fault tolerant characteristics. i. Normal Driving (using all windings, excited by same phase AC current) ii. Driving in case of one inverter is fault. (One inverter is stopped, only use the other inverter.) iii. Driving in case of having current phase difference between inverters. Fig.2(a) shows U-phase current and torque characteristics when normal driving using all windings. Fig.2(b) shows the characteristics when group1 inverter is stopped and disconnected and only use group2 inverter. Fig.2(c) shows the characteristics when group2 output current is 60 degrees delayed from group1 output current. The motor is driving by field oriented control at 150rpm speed and 0.2Nm rated torque load in this experiment. From fig.2(a), in normal driving, inverter output current phases are same and peak currents are same in 0.6A. The torque ripple rate is 28.1% in normal driving. Here, group1 inverter is stopped and released from the circuit, then no current of group1 because of unconstructed circuit, as shown in fig.2(b). Group2 current is covered the torque which group1 supposed to assume, and increase to peak current 1.7A. And, group2 current phase is delayed from group2 current phase of normal driving. The torque ripple rate is increased to 36.3% from normal driving torque ripple rate. However, because the motor does not step out in operating and keeps these drive characteristics constantly, it is confirmed that double winding motor with driving by 2 inverter gets fault tolerant characteristics. As shown in fig.2(c), when group2 current is excited 60degree delayed from group1 current, group1 peak current is increased to 1.2A, and group2 peak current is increased to 1.4A, which means these currents are twice current of normal driving. It is thought that excessive amount of group2 current led by phase difference is corrected by increasing group1 current. The torque ripple rate is worse increased to 50.2% from normal driving torque ripple rate. However, in this case too, because the motor does not step out in operating and keeps these drive characteristics constantly, it is confirmed that double winding motor with driving by 2 inverter when unexpected current phase difference is occurred gets fault tolerant characteristics. Therefore, because drive characteristics like peak current and torque ripple is worse than normal driving in case of one inverter fault or occurring current phase difference, but events disturbing motor operation like step-out did not occurred, so it is confirmed that double winding PMSM used in this paper with driving by 2 inverter can keep redundancy and get fault tolerant characteristics. Also, as a state of inverter failure, it can be considered that the group1 is normal and group2 fails or the faulty inverter is connected to the circuit in the regenerative mode. In these case too, it was confirmed that the motor has fault tolerance characteristics by same experiments. Moreover, in case of inverter differential operation, we examined when phase difference between group1 and group2 was changed from 60 degree lead to 60 degree delay at 15 degree intervals. In this case too, because the motor does not step out in operating, it is confirmed by same experiment that double winding motor with driving by 2 inverter gets fault tolerant characteristics, and found that it is possible to reduce torque ripple by inverter phase differential operating.

GP-04. Compensation of Imbalanced Current for Dual-Three PM Machine with Asymmetrical Windings by Three-Phase Decomposition.

J. Zhang[1] and Z. Zong[1]
1. NanJing University of Aeronautics And Astronautics Graduate School, Nanjing, China

I. Introduction Compared with three-phase permanent magnet synchronous motor (PMSM), the dual three-phase PMSM has fault-tolerant capability and low torque ripple, which obtains wide application, such as aerospace, electrical automobile, and wind power generation systems etc. [1][2]. The two-individual current and the vector space decomposition (VSD) controls are commonly employed for dual three-phase PMSM. The two-individual current control adopts two dq-synchronous frames to drive each set of single three-phase windings individually, which can suppress the imbalanced current resulting from asymmetries between the two sets of three-phase windings [3]. However, this neglects complex coupling between the two dq-synchronous frames. Therefore, the output torque can track performance dynamic performance. For VSD control, it treats the motor as a six-phase machine [4]. The six-phase system is decomposed into three orthogonal sub-spaces, alpha-beta, z1-z2, and o1-o2. There is no coupling between the three sub-spaces. The VSD control can provide excellent dynamic torque performance without the influence of coupling voltages between two sets. Four-vector SVPWM is often used for VSD control, where the currents of z1z2 sub-space cannot be feedback controlled [5][6]. This will result in imbalanced currents for the dual three-phase windings with asymmetrical phase resistances. This paper aims to suppress the imbalanced currents in two winding sets resulting from asymmetrical phase resistances. The three-phase decomposition algorithm in this paper is proposed for balancing the phase current in the two winding sets. II.Three-phase Decomposition PWM Algorithm According to various variables of dual three-phase PMSM in the natural coordinate transformed into the stationary coordinate by the two-individual current control and the VSD control, the relationship between two schemes can be obtained. On this basis, voltage vectors in the six-phase VSI can be decomposed as Fig. 1 (a), it follows that the diagram of three-phase decomposition, as shown in Fig. 1 (b). It can be seen as the combination of the two-individual current control and the VSD control. The experiment is carried out on the dual three-phase machine with asymmetrical phase resistance among two winding sets, as shown in Fig. 2 (a). The phase resistance and inductance are given in TABLE I. Note the asymmetry is severe and Fig. 2 (b) shows the currents of phases A and X under rated load by four-vector SVPWM at 300 rpm. It can be observed that the imbalanced current exists for the two sets of windings, being 3.4A and 6.4A, respectively. This is because the four-vector SVPWM is an open-loop control for z1-z2 sub-space harmonic currents. It can be seen from Fig. 2 (c) that the imbalance is compensated to around 4.9A for two winding sets by the proposed method (Fig. 1). The results clearly demonstrated that balanced current sharing can be achieved between asymmetrical windings. The proposed method in this paper combines the advantages of the two-individual current control and the VSD control, and it not only has excellent dynamic torque performance, but also obtains real-time and the direct feedback control of z1-z2 harmonic currents. Though three-phase decomposition adopts two traditional SVPWM for voltage modulation, it treats the machine as a six-phase machine and reflects the advantages of multi-degree of freedom. The detailed analysis will be given in the full paper.

GP-05. Comparison of Electromagnetic Vibration of PM Motor Considering time and space Harmonics.

I. Jang[1]
1. Hyundai Mobis, Yongin-si, The Republic of Korea

1. Introduction The vibration occurring in an electric motor can be largely divided into the mechanical vibration due to nonaligned bearings and shafts, and the electromagnetic vibration caused by the electromagnetic force. Since the motor is prominent in human life in electronic and hybrid vehicles, and motors of high torque density have been used recently, the importance of electromagnetic vibration and noise has gradually increased. The electromagnetic vibration can be predicted by analyzing the radial force density—the vibration source—in the electromagnetic design of the motor. Thus, if the space and time harmonic of radial force density is analyzed, the harmonic that affects vibration the most can be found. This study compared and analyzed the characteristics of the vibration according to the combination of the number of poles and slots in the 8-pole SPMSM model. The harmonic of the air gap flux density was compared and analyzed according to the number of poles and slots, and the radial force density was separated into time harmonics and space harmonics, which were then compared. Finally, the vibration velocity was calculated using the components of radial force, and its validity was verified through an electromagnetic-vibro coupled analysis. 2. Analysis of the Harmonics of the Exciting Vibration Forces The electromagnetic vibration takes the radial force density as its existing vibration force, and is composed of the square of the gap flux density, as shown in Equation (1). The analysis of airgap flux density should be preceded in order to analyze the harmonic of the radial force density. This study used the teeth-concentrated winding, 8-poles, 9-slots and 8-poles, 12-slots, and the distribution winding, 8-poles, 48-slots, as the comparison models. The comparison was made with all other conditions the same except for the number of slots. The common elements are shown in Table I. Fig. 1 shows the comparison of 8-pole models. A. Airgap Flux Density In Fig. 2, the FFT analysis results of the spatial distribution of airgap flux density when was presented. B. Radial Force Density The electromagnetic excitation force of the motor, the radial force density, is expressed as in Equation (2) and is a waveform that rotates about time. Thus, when the time harmonics and space harmonics of the radial force density are separated and analyzed, the vibration frequency affected by each space harmonic can be calculated. Fig. 3 shows the radial force density of the 8-pole comparison models when they were separated into time and space harmonics. The order of the space harmonics about time harmonics is presented in Table II, using the analysis of the vibration velocity of electromagnetic force. [1] 3. Comparison of Characteristics of Vibration In this study, the vibration velocity is calculated using an electromagnetic-vibration coupled analysis. The RMS vibration velocity about the comparison model has been compared in order to examine the characteristics of the vibration. The RMS vibration velocity can be calculated from the vibration velocity according to the vibration frequency, as follows : Equation (3) The RMS vibration velocity of the comparison model is shown in Fig. 4, using Equation (3). To compare the vibration velocity, in the case of the 8-pole, 9-slot model, the value is highest because in the 8-pole-9-slot, the 1st vibration mode occurs in the 2nd vibration frequency (as shown in Table II), which is the cause of the high vibration velocity. 4. Conclusion In this study, the electromagnetic vibration characteristics that depend on the combination of the number of poles and slots were compared in 8-pole models. The harmonic component of the air gap flux density was analyzed through electromagnetic FEM analysis. Time and space harmonics components of the radial force density, the excitation vibration force, were compared. Also, regarding vibration velocities, the characteristics of the comparison models were analyzed. The vibration characteristics (which depend on the number of poles and slots) depend mostly on the harmonics components of the stator magnetic flux density, by way of the combination of the number of poles and slots. Thus, further study is being done regarding the generalized equation about the harmonics components of the stator magnetic flux density, so that it is possible to analyze the excitation vibration force according to the combination of the number of poles and slots.

GP-06. Decoupling Control for Bearingless Synchronous Reluctance Motor Based on Exact Feedback Linearization.

X. Diao[1] and H. Zhu[1]
1. Jiangsu University, Zhenjiang, China

I. Introduction Bearingless motors (BMs) with built-in magnetic bearing are receiving increasing attention. Among all types of BMs, the bearingless synchronous reluctance motor (BSRM) has been extensively investigated due to its advantages of high speed, high efficiency, low cost, simple and robust structure [1]. BSRM is a typical nonlinear, multivariable and strongly coupled system, and then the dynamic decoupling control is of particular importance [2]. In this paper, a new decoupling control strategy based on exact feedback linearization theory of nonlinear systems is proposed for BSRMs. The necessary and sufficient conditions for exact feedback linearization of the system are proved, and then the coordinate transformation and state feedback control law can be derived. The original nonlinear system is converted into a Brunovsky canonical form and decoupled into three linear subsystems. For this linearized system, the closed-loop controller can be designed by using the single-input-single-output linear system theory. II. Mathematical Model The BSRM combines torque windings and radial force windings in one stator. We can control the size and direction of the radial suspension force by changing currents of two sets of windings respectively, by which the rotor can achieve a stable suspension. The mathematical models of torque subsystem and radial force subsystem can be deduced using Maxwell stress tensor method. III. Decoupling Control Based on Exact Feedback Linearization Firstly, the state equation of the BSRM is established, and the original nonlinear system is converted to an equivalent affine nonlinear system. Secondly, the necessary and sufficient conditions for exact feedback linearization of the system are proved. By using exact linearization theory and coordinate transformation, the state feedback control law is derived. By combining the state feedback control law with the composite plant of BSRM, the original system can be linearized and decoupled into three independent linear subsystems. Then, the linear control theory can be used for the closed-loop control of the system. The BSRM is a complicated nonlinear multivariate system. In case of parameter drift or external disturbance, the decoupling control based on exact linearization cannot achieve the ideal performance and thus additional PID controllers will be designed for the linearized system. The PID controllers and the decoupling control law form the composite decoupling controller of the BSRM. The block diagram of the control system is shown in Fig. 1. IV. Simulation and Experiment Research In order to verify the effectiveness of the proposed decoupling control method in this paper, the simulation model is constructed. Fig. 2 shows the simulation results with varying load and external disturbance. As shown in Fig. 2, when the speed and the radial displacements in the *x*- and *y*- directions are disturbed respectively, the three variables come back to the given value quickly. Moreover, they are almost not affected each other. It is shown that the electromagnetic torque and the radial suspension forces are decoupled, and this decoupling control method has good performance of disturbance rejection. To validate the effectiveness of the proposed decoupling control method, the experimental platform of BSRM is developed. The motor achieves stable suspension at the speed of 1500 r/min. When the load changes, the speed is almost constant and the radial displacement fluctuation of the rotor is very small. When the external disturbance force in *x*-direction is added on the rotor, the vibration amplitude of the *y*-axis radial displacement is extremely small. The experimental results further verify the effectiveness of the decoupling control strategy. V. Conclusion A new decoupling control strategy based on exact feedback linearization theory has been proposed for BSRMs. By using exact feedback linearization and coordinate transformation, the nonlinear model of BSRMs can realize dynamic decoupling control among the torque and the radial suspension forces in *x*- and *y*- directions. When the load changes or external disturbance appears, the control system has strong capability of attenuating external disturbance. Both simulation and experiment results confirm the validity of the proposed decoupling control strategy for BSRMs.

1. Electrical Engineering, Hanyang university, Seoul, The Republic of Korea; 2. Korea Testing Certification, Gunpo, The Republic of Korea

1. Introduction Recently, permanent magnet synchronous motors with high efficiency are attracting attention due to the environment friendly policy. If a permanent magnet motor is used, the output density of the induction machine is higher than that of the conventional induction machine. A control method that reduces the friction between the railway vehicle and the rail through the lateral displacement force by the force due to the inclination in the lateral axis ramp has been studied in a vehicle composed of a permanent magnet synchronous motor having these advantages. When a railway vehicle passes through a steep curve or a place where the ground is not flat, it receives a force on the tilted side, and there is a risk of flange contact, squeal noise and derailment of the vehicle in worst case. In order to prevent this phenomenon, a resistance to external force is required internally in the vehicle. This paper suggests an algorithm that can assist gentle driving by using repulsive force when tilting by using lateral displacement force. The validity and usefulness of the proposed control algorithm is verified by experimental results using a small-scale bogie system However, in order to achieve advanced control, it is necessary to consider the mechanical characteristics of the vehicle. For this purpose, the characteristics of the vehicle when driving the front wheel only and the characteristics of the vehicle when driving only the rear wheel are respectively investigated. 2. The Actual model of Independently Rotating Wheelsets Observe these results to improve the algorithm considering all vehicle control In actual systems, the electrical and mechanical characteristics of the system are cross-coupled to each other, so the results of the electrical characterization obtained by simulation are different from the actual results. Therefore, the verification of the algorithm was performed through actual experiments. Also, the actual size of the bogie requires costly production time and space. Therefore, the vehicle model was scaled down in size as shown in Fig. 1. and the ratio was 1/125 in 1/5 of the length. It also increases the torque of the miniature vehicle model by installing a 6: 1 ratio reducer between the wheel and the motor. In addition, by in-stalling a laser sensor on the wheel, lateral displacement is detected and the lateral displacement resilience is controlled ac-cording to the displacement. In addition, as shown in Fig. 1. the test environment was configured to allow bogies to run through roller equipment instead of rails. The wheels of the reduced car and the rail wheels of the roller equipment come in contact with each other for operation. In addition, the small-scale roller levers are designed for slope and left and right curves. 3. The Control Strategy of the Lateral Displacement Restoring Force The motor of the small-scale vehicle to be used in the experiment is used as the PMSM. The block diagram of the combination of the lateral displacement restoration control algorithm and the PMSM control algorithm. The topology of the entire system IRWs is completed when a block corresponding to the right front wheel and be a total of four of the same topology. The torque required to start is referred to as Te, and the displacement is detected by the laser sensor whenever the lateral displacement is changed. The torque command inputted to the DSP by the command is added to each motor. Since this is PMSM, set d axis current value to 0 and control it by q- axis current command. The current command passes through the PID regulator to generate the command voltage. The command voltage determines the switching state of the three-phase inverter by three-phase conversion of the two phases using the position information received through the encoder, which is a position sensor, and the generated voltage is applied to the PMSM. the straight line driving of an independently rotating wheel sets and the restoring force against disturbance. A lateral force must be generated to recover the angle to avoid flange contact when disturbance is applied via the laser displacement sensor. Therefore, the steering torque of each motor is required. Independently controlled four wheels can be independently controlled to generate different lateral displacement restoring torques depending on the position of the bogie. when the disturbance occurs to the left, the torque of the motor corresponding to the However, in order to perform such control well, it is necessary control the vehicle in consideration of the mechanical characteristics due to the difference of the physical positions of the right side must be increased to return to the original state. to front wheel and the rear wheel, and to perform more advanced control in the case of the entire vehicle. Therefore, after confirming the characteristics through experiments, the whole vehicle is controlled considering the characteristic. The algorithm to obtain the advanced control is constructed. and the maximum lateral displacement restoration force is calculated after estimating the required lateral displacement force by taking the lateral displacement value as input. After that, the force is converted into torque, and then the front and rear wheels are instructed how to generate the restoring torque, respectively.

Abstract : In this paper, a novel rotor position estimation method for permanent magnet synchronous motor (PMSM) using cost-effective hall-effect sensors is presented. Unlike traditional control system, the proposed method uses newton interpolation method and least square method to estimate continuous rotor position and speed information by obtaining discrete rotor locations from the hall-effect sensors. This method promises to eliminate the position-step of the rotor position estimation and provides stable and reliable rotor position, so that the stability of the closed - loop system is improved. Keyword: permanent magnet synchronous motor; Hall-effect sensors; rotor position estimation I. INTRODUCTION With the development of rare earth permanent magnet materials in the 1970s, the PMSM has been rapidly developed. The PMSM is widely used in the modern AC motion control system because of its advantages such as high efficiency, high power density and good dynamic behavior[1]. Accurate and reliable rotor position directly affects the control effect of PMSM. Traditional position sensors have high resolution and provide accurate position in real time, but increase the size and cost of the system and are limited by environmental constraints. Sensorless detection method reduces the system cost but has a large amount of calculation, requires high parameters and cannot guarantee the low speed performance. Hall sensors have the advantages of low cost, small size and high reliability, so it becomes a cost-performance option in low-resolution position sensors[2-4]. To obtain the rotor position with a simpler and more accurate way, an interpolation based on newton interpolation method and least squares method has been proposed in this paper. II. POSITION AND SPEED ESTIMATION METHOD USING THREE HALL-EFFECT SENSORS Three Hall sensors is placed 120 electrical degrees apart in stator winding. Therefore, six Hall signals are obtained for each electrical cycle, corresponding to 0°,60°,120°,180°,240°,and 300°, for 60 electrical degree between adjacent signals. A. Traditional Position Estimation Method In the traditional position estimation method, the average speed is calculated for each interval and then the acceleration is calculated to predict the speed at the next moment. Each Hall signal arrives, the difference between the estimated value and the actual rotor position will be forcibly corrected from the estimated value to the actual value, which will result in a step in the output of the position. B. Improved Rotor Position Estimation Method In order to solve the step phenomenon of the estimation results in the traditional estimation methods, an improved rotor position estimation method based on the newton interpolation method and least square method is developed in this paper which can be realized simply and eliminate the position-step. In Fig. 1(a) taking the position (angle) as the abscissa and the time as the ordinate, the coordinates of the discrete Hall signals are established. Let C point be the current Hall signal, A and B points be the two Hall signal closest to the current moment. Using A, B, C three discrete points, curve fitting by least square method. Fitting curve can be expressed as: $t=f(\theta)=a+b_1*\theta+b_2*\theta^2$ (1) Where a is a constant term in the above equations, b_1 and b_2 are the curve first-order terms and quadratic terms coefficient, respectively. The fitting curve is shown as a curve l_2 in Fig. 1(a) which used to predict the next Hall signal point, and $\theta_{k+1}=\theta_k+60°$ is substituted into equation (1) to obtain the next discrete point D'. Similarly, points A', B', C' and D' in Fig. 1(b) are estimated using Newton interpolation. B', C' and the latest D' three points are used to fitting curve of position by newton interpolation method. Fitting curve can be expressed as: $\theta=f(t)=a'+b'_1*t+b'_2*t^2$ (2) Where a' is a constant term in the above equations, b'_1 and b'_2 are the curve first-order terms and quadratic terms coefficient, respectively. The fitting equation is shown in the curve B'-C'-D' in Fig. 1(b), and is interpolated along the C'-D' segment of the curve. Assuming that the current moment is $t'_{k,x}$, the current rotor position (X point) can be expressed as: $\theta=\theta'_{k,x}=f(t'_{k,x})$ (3) The rotor position interpolated by newton interpolation method will be used for PMSM in real time. This method improves the accuracy of position and effectively solves the step phenomenon of traditional method to estimate rotor position. III. SIMULATIONS Simulations with Plecs have been carried out to study the proposed position estimation algorithm. Fig. 2 shows the estimated position and error of the two estimation methods when the motor decelerates. The error of the position calculated by the traditional estimation method reaches ± 2.5%, while the improved rotor position estimation method drops to ± 0.6 % or less. IV. CONCLUSIONS Results of the simulations verify the feasibility of the proposed improved rotor position estimation method over the traditional one.

GP-09. Dynamic DC link Voltage Control Strategy of Electric Vehicles Considering the Cross Saturation Effect.

H. Li[1], J. Gao[1], S. Huang[1] and P. Fan[1]
1. Hunan University, CHANGSHA, China

I. INTRODUCTION The interior permanent magnet synchronous machine (IPMSM), which could generates reluctance torque in flux weakening region to enhance the motor performance and efficiency, is widely applied in electric vehicles (EV) [1, 2]. In order to dig out the maximum potential of the traction system of EV further, dynamic DC link voltage control strategies has been explored by several researchers [3, 4]. Generally speaking, keeping a low DC link voltage at low operating speed could reduce the switching losses of the inverter while boosting its value at high speed could benefit the flux weakening operation [5] However, the IPMSM parameters will become different with operating conditions, for example, the inductance and the magnetic characteristic will change with current due to the cross coupling and magnetic saturation effect (omitted to cross saturation effect) [6]. Therefore, the conventional control strategy of IPMSM ignoring the cross saturation effect needs to be revised. II. DC LINK VOLTAGE CONTROL STRATEGY The overview of the proposed control strategy is shown in Fig.1. The current vector adjustment strategy is discussed in [6]. The FEM simulation is conducted to obtain the value of inductance depending on stator current. Two dynamic models are set up to evaluate the performance of the control strategy influenced by the cross saturation effect, as shown in Figure 2. MODEL I represents the control strategy taking the cross saturation effect into consideration. MODEL II stands for the fixed parameter model. It demonstrates that the cross saturation will degrade dq-axis voltage value in high speed range, however the output torque still meet its requirement. The proposed control strategy can help the current trajectory tract the Maximum Torque per Ampere (MTPA) curve perfectly in low speed region and fit the constant torque line at high speed without breakthrough the current limit circle. As shown in Fig. 2 (b), the reference value of the DC link voltage grows up as the speed increase. Once the speed of motor beyond the nominal value, which is 1500 rpm, the DC link voltage reference is kept at 700V, therefore, the flux weakening operation can be delayed meanwhile the maximum potential of inverter can be fully used. In Fig.2 (b), (e) and (f), it can be seen that the bus voltage in MODEL I is lower than it in MODEL II below the nominal speed, thus, it indicates that the proposed dynamic DC link voltage control strategy considering the cross saturation effect can reduce the switching loss and related junction temperature of electronic devices, which is proportional to the bus voltage. The performance of IPMSM using the proposed control strategy under different models will be fully described in the final paper and the control strategy translates the voltage and torque required incremental value into current adjustment amount to modify current control signals will be investigated in full paper.

1. Introduction: The recent fluctuating prices of rare earth magnet used in PMSM has encouraged the researchers towards the other candidates, such as, PM-assisted synchronous reluctance machine (PMa-SyRM) and wound rotor synchronous machine (WRSM). Whereas, in WRSM, the assembly of brushes and slip rings connect the machine to its excitation system on the rotor side. To get rid of brushes and slip rings, because of wear and tears in the long run, several brushless topologies have been proposed in the literature [1-3]. In [1], two inverters are used to supply different amplitude currents to two-different portion of the stator windings to generate the sub-harmonic airgap magnetomotive force (MMF). This sub-harmonic component then couples with the corresponding sub-harmonic winding (HW) on the rotor. The use of two inverters in this topology makes it less suitable for practical applications. In [2], a controllable third harmonic (TH) zero-sequence current is generated using single inverter topology, which induces the current into a dedicated rotor HW. The rotor winding current is then rectified and supplied to the main field winding. Although, this topology used single inverter, but six extra thyristor switches are needed to generate TH currents, which switches during the positive and negative half cycles to generate zero sequence currents. The switching losses and high torque ripple are the other drawbacks. In [3], a spatial TH zero sequence MMF is generated with open winding by means of two inverters. one inverter is used to supply the fundamental current and a second inverter is utilized to inject the TH current into the three-phase open stator winding terminals. A HW as well as a conventional field winding are installed on the rotor, whereas, the HW is used to induce and then rectify the magnetic field generated by the airgap TH-MMF. The field winding is used to produce the rotor main magnetic field, which then interact with stator fundamental MMF for torque production. The disadvantage of this scheme is the utilization of two inverters, which increases the cost and size of the overall system. This paper presents a new scheme to produce time generated airgap MMF having two components, i.e. fundamental and a TH, using single inverter. The time generated TH-MMF is then induced in the rotor HW. After rectification, the rotor field winding is excited to realize the brushless operation. 2. Topology and working principle: The machine topology is shown in Fig. 1, in which stator winding current is supplied by single inverter. The stator winding has a semi-open configuration with the help of two back to back diodes to avoid suppression of third order current component generated by special gating pulses in the inverter. There are two separate windings on the rotor i.e. HW and the field winding. Both windings are connected through a bridge rectifier mounted in the rotor periphery. The TH-MMF component is induced in the consistent pole HW. After induction in the HW, the current is fed to the main field winding through rotating bridge rectifier. The machine (18s4p) winding configuration is shown in Fig. 2. The TH current component is generated by injection of TH control signal in the inverter gating switching pulses. The block diagram for generation of the inverter gate switching pulses is shown in the Fig. 3. The reference voltage V_{ref} is added with signal having frequency three times of fundamental frequency (zero sequence). The resultant is then passed through comparator which compares the modified signal with carrier signal and desired output pulses are generated as shown in Fig. 4. The back to back diodes are used to avoid the suppression of triplen current harmonic at the star point of the stator winding as shown in Fig. 1. The 3-phase currents applied to the stator windings are given in (1) $i_a = I_m (\sin \omega t + n \sin 3\omega t)$ $i_b = I_m (\sin (\omega t - 2\pi/3) + n \sin 3(\omega t - 2\pi/3))$ (1) $i_c = I_m (\sin (\omega t + 2\pi/3) + n \sin 3(\omega t + 2\pi/3))$ The corresponding machine airgap MMF is shown in (2) $F_a = i_a N_{\psi 1} (\sin \theta_e + \sin 3\theta_e)$ $F_b = i_b N_{\psi 1} (\sin (\theta_e - 2\pi/3) + \sin 3(\theta_e - 2\pi/3))$ (2) $F_c = i_c N_{\psi 1} (\sin (\theta_e + 2\pi/3) + \sin 3(\theta_e + 2\pi/3))$ The induced emf in the rotor HW is given in (3), $emf_h = 6\, d\Psi_h /dt = 18 N_h N_{\psi 1} I_3\, \omega \sin 3(2\omega t + \theta_o) / R_g$ (3) The induced EMF is rectified through rotating bridge rectifier mounted on the rotor periphery, and rectified direct current (DC) is supplied to the rotor main field winding. 3. Analysis and performance comparison: 2-D FEA analysis is performed for 60 cycles to get steady state rotor currents and output torque; the stator winding of the machine is provided with the current shape containing two components. According to the principle already discussed, the TH-MMF is induced in the rotor HW. The induced harmonic current and field current is shown for single cycle in steady state region in Fig. 5. The output torque for single cycle in steady state region of the machine is shown in Fig. 6. Consequently, the proposed brushless topoplogy is used to fed the field winding for stable torque generation in steady state and hence, the brushes and slip rings are avoided. The detail electromagnetic analysis will be provided in full paper.

GP-11. Investigations on the Sensorless Position Estimation of an IPMSM with Short-Circuited Rotor Windings.

C. Hittinger[1], D. Thyroff[1] and I. Hahn[1]
1. Institute of Electrical Drives and Machines, University of Erlangen-Nuremberg, Erlangen, Germany

1.) Introduction The mechanical encoder of an electrical machine can be omitted in certain cases. Applications, where the requirements are fulfilled, can be realized by using sensorless control. At very low speeds the commonly used methods based on the back-EMF are not suitable [1]. Therefore, a saliency, based on the position-dependent electromagnetic properties of the machine configuration, is required to correctly estimate the rotor position with signal injection methods. The main drawback is the occurrence of cross-coupling effects between the HF-inductances, if some machine parts are saturated [2], which can result in a reduced magnetic anisotropy [3–5] and a worsened capability of estimating the rotor estimation. A special machine topology which provides this property was derived in [6, 7] and was investigated further in [8–10]. In this concept, the high frequency magnetic flux gained by the signal injection method in the field-oriented d-axis is suppressed by attaching a short-circuited electrical winding (SC-winding) on the rotor of the machine. It can be applied on machine topologies without an inherent (e.g. geometric) electromagnetic saliency. After performing analytical simulations including the frequency behavior [9], additional investigations using the frozen permeability method (FPM) within the finite element (FE) method, simulations were carried out to evaluate the performance of this new concept [8]. These results will be verified by measurements on an experimental setup. In contrast to [8], permanent magnets (PMs) will be included on the rotor as well, which result in an inherent magnetic saliency due to their low magnetic permeability. For this case, the performance of SC-windings on the rotor for sensorless position estimation will be investigated as well. 2.) Fundamentals of Test Signal Injection and the FPM In general, the stationary as well as the dynamic behavior of an electrical machine can be described by its voltage equations including the resistive and inductive quantities of the machine. This approach can also be used for the test signal methods. In [8, 9] these equations are derived including differential quantities, which means, that they are only depending on the injected test signal. Based on this, an evaluation of the machine can be achieved. The main property for the self-sensing performance are a high difference of the self-inductances and a low mutual inductance. The frozen permeability method is used as a compromise between stationary DC (no simulation of frequency behavior) and transient AC-simulations (time-consuming simulations). Using the FPM, nonlinear magnetostatic DC-solutions are generated for taking local saturation effects into account. For this solution, the permeability tensor in the middle of each element of the FE mesh is saved and, hence, can be taken as a previous solution for the following linear AC simulation. This means, that the influence of the AC test signal can be evaluated depending on the actual saturation level of the machine. Another advantage of the FE simulations is that there are no iterative steps necessary to calculate the currents in the SC-windings, which is an important parameter to estimate additional I^2R-losses of this concept. 3.) Results The results of the simulations will be compared to those of the measurements. The measurements are performed with three linear power amplifiers. The DC operating points are provided in rotor-fixed coordinates, whereas the current test signal is injected in only one of the three phases. The AC currents in the neighboring phases are controlled to zero and the voltage response is evaluated. First, the estimation error will be discussed. By comparing the results for measurements and simulations in Fig.1, it can clearly be seen, that the error only reaches very small values, which means a good performance for sensorless position estimation. Additional, the values of the measurements are slightly smaller, especially at operating points with higher currents. This behavior can be described by the modeling of the frequency behavior based on virtual eddy current coils as presented in [9]. The discussion will be included in the final paper. Furthermore, a comparison of the measured and the simulated currents in the SC-windings for evaluating the I^2R-losses will be given. Next, the improvement of the sensorless position estimation by using additional short-circuited windings on a rotor including PMs will be discussed. The width and the position of the SC-windings are identical to the setup without PMs. As can be seen in Fig. 2 the estimation error for the setup with SC-windings is significantly reduced to the initial case over almost the whole operating area. The reasons for this behavior will be discussed in detail within the final paper by evaluating differential self and mutual inductances. Summing up, the concept of SC-windings on the rotor can be adapted on a machine with three phases and buried PMs. 4.) Conclusion The FEA using FPM was verified by measurement results. The advantages and the limitations of this method will be discussed within the full paper. It is shown that the concept with SC-windings on the rotor is still suitable when using buried PMs on the rotor. The sensorless performance is increased by the additional windings over the whole operating area.

I. Introduction Today, interior permanent magnet synchronous motors (IPMSMs) are widely used because of their advantages such as high output and torque density. In order to implement a high-performance system by vector-controlling the IPMSM, it is essential to use a position sensor to detect the rotor position. However, the importance of sensorless control, which is controlled without a position sensor, is emphasized because of the increase of price and volume of system, increase of complexity and decrease of reliability. In addition, the importance of sensorless controlled machines is also mentioned for the purpose of system failure control. In IPMSMs, the reluctance of the *d*-axis and the *q*-axis is different because the position of the permanent magnet (PM) and the configurations of the rotor core is not spatially uniform. This is due to the saturation phenomenon of the magnetic flux path in *d*-axis caused by the PM flux, and at the same time, the reluctance of the PM existing on the *d*-axis is significantly higher than that of the rotor core. Therefore, by using the high-frequency signal injection method, the inductance waveforms affected by the PM on the *d*-axis can be obtained, and the position of the rotor can be estimated [1]. If the *d*-axis of the PM is the position where the voltage injection angle is 0 degree, the inductance becomes the smallest value due to the reluctance at this time [2]. However, in the conventional IPMSM, it is difficult to obtain the inductance waveform having the smallest value in the *d*-axis along the voltage injection angle when the rotor position and the load conditions are changed. This is because the distributions of the magnetic saturation and reluctance are changed. Therefore, in conventional IPMSM, the *d*, *q*-axis inductance waveform is varied with them, and it is hard to estimate the rotor position precisely [3], [4]. Therefore, appropriate decision of pole-slot number combination for the sensorless controlled IPMSM is important. II. Analysis of IPMSMs According to Pole-Slot Combinations In this study, the appropriate combination of pole-slot number for sensorless controlled IPMSM is determined by examining sensorless controllability as well as noise and vibration characteristics of the several models. The proposed models have four different pole-slot combinations including not only pole-slot ratio of 2:3 such as 12-pole 18-slot, but fractional slot combination such as 8-pole 9-slot, 10-pole 12-slot, and 16-pole 15-slot. The characteristics of the four models are analyzed, and the appropriate pole-slot combination for the sensorless-oriented IPMSM is proposed. *A*) Analysis of Noise and Vibration Characteristics The radial force distribution is shown in Fig. 1 to visually confirm the noise and vibration characteristics. If the radial force distribution in the air gap is symmetrical, the radial forces in the opposite direction cancel each other out, which is advantageous for noise and vibration characteristics. It infers that noise and vibration characteristics of 10-pole 12-slot and 16-pole 15-slot models is poor compared to those of the other two models due to the asymmetrical radial force distribution [5]. *B*) Analysis of Sensorless Controllability The *d*, *q*-axis inductance waveforms as the response of injected high frequency voltage signal according to the change of the rotor positions and load conditions are analyzed to evaluate the sensorless controllability. The inductance waveforms of the two models 12-pole 18-slot and 16-pole 18-slot are analyzed except for the other two models 10-pole 12-slot and 16-pole 15-slot with poor noise and vibration characteristics among the four proposed models. As shown in Fig. 2, the magnitude and the minimum position of the *d*-axis inductance of the 16-pole 18-slot model are changed much more greatly according to the current phase angle rather than those of the 12-pole 18-slot models. Conclusively, considering the various input currents and current phase angles, the 2:3 pole-slot combination machine such as 8-pole 12slot, 12-pole 18-slot, and 16-pole 24-slot is generally easier for saliency-based sensorless drive rather than the fractional pole-slot combination machines. III. Future Work In the full paper, equations to analyze the noise and vibration characteristics including force order will be described. Also, the analysis method of the inductance waveforms to evaluate the sensorless controllability will be explained in detail. In addition, considering the analysis results of the proposed models, the sensorless-oriented IPMSM is designed. Lastly, the validity of the proposed analysis methods and simulation results are verified through the experiments.

GP-13. Position Sensorless Control of Switched Reluctance Motors Eliminating Mutual Inductance Effect.

H. Wang[1], H. Cai[1], *M. Li*[1] and S. Shen[1]
1. Hunan University, Chang Sha, China

Abstract — Mutual inductance effect between the adjacent phases is prominent for Switched Reluctance Motor in status of the adjacent phase energized simultaneously. Consequently, the mutual coupling will distort the response current profile of the injection voltage phase, thereby affecting the position estimation precision. This paper presents a unique rotor position estimation approach to eliminate the mutual inductance effect by employing the phase current slope difference method. By setting a low threshold and a high threshold, a series of voltage pulses are injected in idle phase alternately synchronized with the chopping current control. Without a prior knowledge of mutual inductance and any additional position sensor, a precisely estimated rotor position is achieved. A dynamic model of a 12/8 SRM model is established to evaluate its validity and both of simulation results and experimental evaluation indicate that the proposed sensorless control can be accomplished with an adequate precision. *Index Terms*—Switched reluctance motor, position sensorless, mutual inductance, rotor position. I. INTRODUCTION Switched reluctance motor(SRM)makes its entrance into a variety of applications since its reliability,robustness and low cost characteristic. Accurate rotor position is essential to the control of an SRM in the four quadrants. Both of turn-on angle and turn-off angle are the key parameters which are associated with the load and speed. The appropriate choice and optimal tuning is a requirement of accommodating a good performance of the SRM. High-resolution encoder such as incremental encoder,hall sensors and rotary transformer are typical provided to obtain the rotor position information. However,the sensor devices are subject to be affected when located in a hostile environment such as electrical noisy and a hot state. With the purpose of eliminating the additional sensors and making the cost reduction, a great amount of sensorless approaches have been demonstrated. By employing only one current sensor and decoupling the excitation current, the rotor position of the SRM is estimated precisely and the performance is investigated fully in [1]. Most of the pulse injection method is focused on the low speeds, the rotor position is determined by injecting a single pulse in the non-conduction phase at high speed in [2], the proposed pulse injection strategy is suited both of the low-and high speed condition. Magnetic characteristic is fully utilized to estimate the rotor positon in [3], the voltage pulse is injected the idle phase and the negative torque produced by the residual current is also eliminated. Traditionally, the idle phase of the SRM is injected pulse voltage with a quite short duration, the response current is adopting to estimate the rotor positon, nevertheless, the amplitude of which is greatly affected by the mutual inductance produced by the chopping current of the conducting phase, furthermore, the condition will be deteriorated as the chopping current increasing. To solve the problem, this paper proposes a sensorless control technology to eliminate the effect of mutual inductance. The idle phase windings are energized by a series of voltage pulse in sequence and the rotor position can be identified by employing the self-inductance characteristics in real time. Meanwhile, the estimation position error caused by mutual inductance is fully analyzed. II.THE PRINCIPLE of SRM POSITON ESTIMATION CONSIDERING MUTUAL INDUCTANCE The flux density distribution map of single-phase excitation and two-phase excitation for a 12/8 SRM are described in Fig.1 (a), (b), respectively. Compared with the single-phase excitation mode, the two-phase excitation mode is defined as the short magnetic excitation and magnetic circuit are mutual influence. In figure 1 (c), when individual phase is conducted, one can note that the self-inductance curves will appear the saturation phenomenology. As described in figure 1 (d), when the adjacent phase are energized simultaneously, the mutual inductance appears. It indicates that the absolute value of mutual inductance increases as the energized current increasing and the value approaches 8.61% compared with the self-inductance. Following, the Influence of mutual inductance on self-inductance estimation and position estimation is analyzed. Furthermore, making the voltage pulses pulse injection synchronized with the the sequence of chopping control is the resolution to eliminate the mutual inductance effect in this paper. III. SIMULATION AND NEXPERIMENTAL RESULTS The comparative experiment is implemented by adopting the proposed approach,the motor is under overload state (given current 45A), the simulation waveforms are shown in Fig.2. The maximum position error of the proposed control scheme is about 1.55 degrees. The experimental waveforms shown in figure 2 indicate that the estimation positon error is about 2.6 degrees, more precisely than that employing the conventional approach.

GP-14. Maximum torque per ampere control for hybrid excited switching flux permanent magnet machines.

X. Liu[1], D. Xing[1], Q. Wang[1] and S. Li[1]
1. State Key Laboratory of Reliability and Intelligence of Electrical Equipment, Hebei University of Technology, Tianjin, China

Permanent magnet synchronous machines (PMSMs) have been widely used for electric vehicles (EVs) and hybrid electric vehicles (HEVs) due to their high efficiency and high power density. However, due to the constant PM flux linkage, a negative d-axis current will be used in the flux weakening region, which increases the copper loss and the risk of irreversible demagnetization. The hybrid excited PM machines, which also employ dc field winding to adjust the air-gap flux density, have been developed. In Fig. 1, the 12/10 hybrid excited switching flux permanent magnet (HESFPM) machine, which has a double salient structure, is presented [1]. The PMs, armature windings and dc field windings are located in the stator, while in the rotor there is no PM or coil. In the high-speed region, both d-axis and dc field currents can be used to weaken the flux-linkage in d-axis. Therefore, in this paper the effectiveness of d-axis and dc field current on adjusting the d-axis flux-linkage will be investigated. A novel control method with the optimal ratio of d-axis current to dc field current is presented to realize the maximum torque per ampere control. In the d-q frame, the flux-linkage and voltage of HESFPM machie can be written as: $\psi_d=L_d i_d+\psi_f$ $\psi_q=L_q i_q$ $\psi_f=\psi_{pm}+\psi(i_f)$ $U_d=R_s i_d+d\psi_d/dt-\omega_e\psi_q$ $U_q=R_s i_q+d\psi_q/dt+\omega_e\psi_d$ $U_f=R_f i_f+d\psi_f/dt$ The electromagnetic torque can be expressed as: $T_e=1.5pi_q(\psi_f+i_d(L_d-L_q))$ where ψ_d, ψ_q are the flux-linkage in d- and q-axis respectively, $\psi(i_f)$, ψ_{pm} are the flux-linkage generated by filed excitation and permanent magnets respectively; U_d, U_q are the voltage in d- and q-axis respectively, U_f is the voltage of field winding; R_s, R_f are the armature winding and field winding resistance respectively; ω_e, p, T_e stand for electrical rotor speed, the pole pairs and the electromagnetic torque respectively. Fig.2. shows the d-axis flux-linkage against field excitation. It shows that almost linear relationship between d-axis flux-linkage and field excitation can be observed. At low speed, the copper loss can be expressed by: $P_{cu}=1.5R_s(i_d^2+i_q^2)+R_f i_f^2$ By using the extended Lagrange multipliers method, the torque constraints will be: $L(i_d,i_q,i_f,\lambda)=1.5R_s(i_d^2+i_q^2)+R_f i_f^2+\lambda(1.5pi_q(\psi_f+i_d(L_d-L_q))-T_e)$ where λ denotes the Lagrange multipliers. By setting the partial differentiation of (5) with respect to and to zero, the d-axis and field excitation reference current can be obtained by: The d-axis and field excitation reference current can be obtained by: $i_{dref}=2R_f(L_d-L_q)i_{fref}/(3R_s\, d\psi_f/di_f)$ $i_{fref}=3R_s d\psi_f/di_f(-\psi_f+\mathrm{sqrt}(\psi_f^2+4(L_d-L_q)^2 i_{qref}^2)/(4R_f(L_d-L_q)^2$ Thus, the copper loss minimization control strategy for HESFPM machine is developed in Fig.3. As shown in Fig. 4, the simulation results indicate the benefit of the proposed method. Compared with the conventional method ($i_d=0$), the proposed method can reduce the 26.43% copper loss at 400rpm speed and 1.5 Nm. In the full paper, the experimental results will be presented to verify the minimum copper loss control.

GP-15. A Flexible Position Sensorless Control of Switched Reluctance Motors Considering Both Embrace Design and Magnetic Saturation.

H. Cai[1], H. Wang[1], *M. Li*[1] and S. Shen[1]
1. Hunan University, Chang Sha, China

Abstract —Precise estimation of position is essential in the control of switched reluctance motor (SRM). Traditionally, the intersection of the adjacent inductance can be utilized to estimate the rotor position, however, magnetic saturation brings about the variations of the intersection positon when the motor is operated at heavy load. To solve the problem, this paper develops a sensorless position estimation strategies considering the magnetic saturation and the embrace design. Firstly, the relationship between the embrace and the intersection position is fully investigated. At low inductance region, the intersection position is not sensitive to the saturation current when the embrace is small, thus, the typical specific position can be used as an update point for position estimation. Disparately, the intersection position is influenced by a great extent when the embrace is a bit larger, the relationship between the saturation current and the intersection position is necessary to be explored. At high inductance region, the intersection position is a function of the saturation current which is irrelevant to the embrace. Consequently, the sensorless control approaches can be chosen flexible according the characteristic of intersection. The rotor position estimation is achieved by employing six typical inductance positon without a requirement of additional positon sensor. The feasibility and validity of the proposed position estimation method is verified under the inertial operation, light load, heavy load, load mutation and high speed condition. Index Terms—Switched reluctance motors, position sensorless control, embrace deign, magnetic saturation. I.INTRODUCTION Switched reluctance motor (SRM) has been widely used since its inherent feature such asrobust structure and fault-tolerant. The motor is a potential candidate for high temperature and high speed appliances. The rotor position plays an extraordinary role in the control of the motor. However, some problem such as low reliability and susceptibility to interference are accompanied. Variety of sensorless strategies have been proposed to eliminate the machine sensors. A plus-injection method is present in[1], voltage pulse injection is usually employed and the method is suited for low and high speed range condition. When the motor is operated at suitable value, the observed hall signal is sensed by the injected narrow voltage pulse in [2], then the estimated speed and angle is obtain. An accurate position is estimated by applying the phase inductance vector coordinate transformation and the phase current slope difference method in [3]. II. PROPOSED POSITION ESTIMATION PRINCIPLE Rotor position can be predicted by extracting the information from the corresponding phase inductance, however,the magnetic circuit will be gradually saturated as the load current increases, and the "concave" phenomenon will appear at the inductance curve. As a result, the estimation encounters implementation issues at magnetic saturation operations, even inaccuracy of the estimated rotor position is achieved when the motor is operated at saturation condition. In order to improve this situation,this paper proposes a sensorless position estimation strategies considering the magnetic saturation effect and the embrace. There is a total of six inductance intersections within a 360 °electrical cycle, all of which are chosen as the update points for position estimation in this paper. The FEM analysis indicates that the embrace is of significant to the intersection position. Assuming the embrace is small, the intersection positon during the low inductance region is almost coincident and insensitive to the magnetic saturation. This typical position can be applied in the estimation directly. Supposing the embrace value is selected comparatively large, the intersection position will be diverse as the saturation current changes. for the sake of obtain the accurate intersection position, the relationship between the saturation current and the intersection position is required to be investigated. As is shown in Fig.1(c), the intersection position at low inductance is less sensitive to the saturation current when the embrace is set 0.4, therefore the fixed intersection position is able to be utilized. As the embrace value is selected as 0.5, the inductance profile is as shown in Fig.1(c), the intersection position changes from 7.5° to 10.5°,the angle is inevitable to be different when the saturation current changes. III.SIMULATION AND EXPERIMENTAL EVALUATION The simulation results are shown in Fig.2 (a), the given current is set as 40A, which is a magnetic saturation value. One can note that the estimated speed can track the actual speed exactly, the maximum estimation error is equivalent to 3 °. Considerating the electrical interval, the speed between the two updated points is basically taken as constant. Position estimation is affected obviously in case of variable and low speed, position estimation error slightly increases under these conditions due to that the calculated speed is applied. The experimental waveform of current and estimated position profile are shown in Fig.2 (b), the tracking error amouts to 4.2°, matching the simulation results well.

GP-16. Fault-Tolerant Design and Control of Hybrid Excitation Axial Field Flux-Switching Permanent Magnet Machines.

W. Zhang[1] and X. Liang[2]
1. School of Electrical Engineering, Nantong University, Nantong, China; 2. School of Computer Science and Technology, Nantong University, Nantong, China

I.Introduction Fault tolerance of drive motor is a critical facet for many applications, such as aerospace, traffic, and military. Because continuous operation under fault conditions can improve the reliability and safety of the whole system, many researchers are attracted to investigate the fault tolerant machines. [1] proposed a three-phase axial flux-switching permanent magnet machine (AFFSPMM). Because of the simple and robust rotor, short axial size, and high torque density, it is suitable to directly drive electric vehicle (EV). However, it is noticed that the fault tolerance of AFFSPMM should be considered in order to keep the drive system of EV operate safely under the fault conditions. It was found in [2]-[3] that E-core topology could reduce magnet volumes and mutual coupling between phases in contrast with U-core one. However, the air-gap field was not able to be regulated due to only excitation of permanent magnets for the two AFFSPM machines, and therefore [4] proposed a hybrid excitation topology on the basis of E-core AFFSPMM, viz. a hybrid excitation axial flux-switching permanent magnet machine (HEAFFSPMM), in which the air-gap flux could be regulated by the DC excitation current. In this paper, the HEAFFSPMM is optimized for achieving better fault-tolerance with reference of the original U-core AFFSPMM, and the performances are compared and analyzed between the two machines. A novel fault-tolerant control method is proposed to improve the fault-tolerant capability by virtue of the special structure of the HEAFFSPMM. II.Topology of HEAFFSPMM Fig.1 shows the 3-D topology of the HEAFFSPMM, which exhibits one rotor is in the middle of two stators, and the magnets with opposite polarity are alternatively placed between the stator cells. The two adjacent side teeth are wounded around concentrated winding, for example A1 and A2. Compared with the conventional AFFSPMM, the stator is designed as E-shaped laminated segments instead of U-shaped ones. This reduces volumes of magnets and magnetic loading, and increase slot area to accommodate more armature windings and the added field windings. The field windings are wound around the middle teeth, which can be excited to improve the performances of the machine, and act as fault-tolerant windings at the same time. III.Fault-Tolerant Optimization Design The parameters of the HEAFFSPMM are optimized step by step to enhance the fault tolerance by 3-D finite element method (FEM) on the basis of a 600W prototype of 12/10-pole U-core AFFSPMM, including the number of rotor poles, the split ratio, the width of permanent magnet, the width of stator middle teeth, the width of rotor pole and rotor length. After optimizing the machine, the coupling component between phases, viz. the ratio of mutual- and self-inductance, is reduced by 63% in comparison with U-core AFFSPM. IV.Comparative Study of The Two Machines The simulating platform of the drive system is established in order to compare the performances of the two machines. The SVPWM fault-tolerant control method based on minimum copper loss is proposed in the paper and applied in the drive system of HEAFFSPMM. Fig.2 compares the torque-speed curves of the two machines at normal operation. It is found that 12/10 pole AFFSPMM has wider constant torque area than that of HEAFFSPMM, however, the speed operation range is apparently narrower than that of the HEAFFSPMM when increasing the field. Meanwhile, the output torque of HEAFFSPMM with DC excitation is almost 1.4 times of 12/10-pole AFFSPMM at rated speed. Therefore, the HEAFFSPMM is better suitable to drive the EV than the conventional AFFSPMM. Moreover, it is found from the simulating results that the speed and torque under the fault-tolerant control system can keep the same with those at normal operation when A-phase windings happen different faults. V.Experiment Validation The experimental setup is built in order to further validate the fault-tolerant control method of the HEAFFSPMM. The experiment results are similar to the simulating results. VI.Conclusion The dimensions of a HEAFFSPMM are optimized in order to attain large self-inductance and low coupling component with reference of a 600W conventional AFFSPMM. By comparing the performances of the two machines, it is found that the improved HEAFFSPMM has better operation performance and fault-tolerant capability. Moreover, the experiments are done to validate the control method under the different fault cases.

GQ-01. Tribological and viscoelastic behaviors of core-shell structured carbonyl iron/polystyrene particle based Magnetorheological Fluid.

Y. Dong[1], P. Zhang[2], H. Choi[1] and C. Lee[3]

1. Polymer Science and Engineering, Inha University, Inchon, The Republic of Korea; 2. Nanjing Research Institute for Agricultural Mechanization Ministry of Agriculture, Nanjing, China; 3. Mechanical Engineering, Inha University, Incheon, The Republic of Korea

I. INTRODUCTION Magnetorheological (MR) fluid [1] is a kind of actively controllable intelligent and smart materials that responds to an applied magnetic field with a dramatic change in rheological and viscoelastic behaviors such as shear viscosity, shear stress, dynamic modulus and so on. In the absence of magnetic field, MR particles dispersed freely in the carrier medium show fluid-like behaviors, while under an external magnetic field, MR particles aggregate to form chain-like structures, being transformed to a solid-like state within a few milliseconds and recovered to a fluid-like state when the magnetic field is removed. Being of benefit to these excellent properties, MR fluids have been applied in many engineering fields [2], [3], such as dampers, brakes, polishing and so on. Soft magnetic carbonyl iron (CI) particles have been considered as one of the most excellent candidates for MR materials because of their spherical shape, proper particle size, and high saturation magnetization. However, sedimentation problem of the CI particles in MR fluids due to their high particle density often limits the application of CI based MR fluids in industry. In addition, regarding on durability and mechanical properties of the MR fluids in many applications, the effects of friction and wear are important factors that must be considered. In this work, in order to improve the dispersion stability of CI based MR fluids based on the reduction of particle density, polystyrene (PS) was coated on the surface of CI particles via a conventional dispersion polymerization method to produce core-shell structured CI/PS particles. In addition, PS coating can not only prevent the oxidation of CI particles, but also change the particle topology and surface roughness, which may give the CI/PS particle-based MR fluid superior wear and friction performance in its tribological study compared to the pristine CI particle-based MR fluid. II. EXPERIMENT CI particles (100 g) were initially treated with methacrylic acid (MAA) by dispersing the CI particles in a mixture of MAA (100 g)/methanol (1000 mL) and ultrasonicated for 30 min, then the MAA-modified CI particles were selected by a magnet. In order to prevent the aggregation of particles, the modified CI particles were dispersed in a homogeneous solution of polyvinylpyrrolidone (66 g) in methanol (1400 mL). Then, the mixture was transferred to a reactor (2000 mL) and heated to 65 °C with intense stirring. A styrene monomer (50 g) containing the initiator, 2,2-azobisisobutyronitrile (0.5 g) was slowly added to the reactor, while the system was maintained at 65 °C for 24 h. The final product was washed with methanol and distilled water, and finally dried at 60 °C for 12 h. The MR fluid was prepared by dispersing 50 wt% of the CI/PS particles in silicone oil, and the rheological properties of the MR fluid were measured by rotational rheometer (Physica MCR 301 Rheometer Anton Paar, Austria). The tribological behaviors were further tested by a reciprocating friction and wear tester (RB 108-RF, R&B, Korea). III. RESULT AND DISCUSSION Figure 1 shows shear stress for the CI/PS based MR fluid versus shear rate under various magnetic field strengths on a log-log scale. In the absence of the magnetic field, the relationship between shear stress and shear rate is almost linear, showing a general fluid-like state. However, when the magnetic field is applied, the fluid behaves like a Bingham fluid [4] with a stable shear stress value independent of shear rate and distinctive yield stress due to the chain-like structure caused by the magnetic field. Furthermore, the yield stress increased with increased magnetic field strength, indicating that a stronger chain-like structure formed under higher magnetic field strength. Figure 2 shows the change in the coefficient of friction for CI/PS based MR fluid in the absence of a magnetic field and when a magnetic field with strength of 10 mT is applied. The coefficient of friction can be calculated by the equation as: $\mu=F/N$ (1) Where μ represent the coefficient of friction, F and N are the friction force and normal load, respectively. The results show that the friction coefficient shows instability and a slightly decreased value without an input magnetic field. However, when the magnetic field is applied, the friction coefficient becomes very stable due to the fact that when the magnetic field is applied, particles in the MR fluid are magnetized and form chain-like structures in the same direction as the magnetic field and participated in friction. In addition, owing to the involvement of the CI/PS particles in the friction after forming chain-like structures by the magnetic field, the coefficient of friction shows an upward trend. According to our analysis, the change in the coefficient of friction is caused by variation of the resistance of the MR fluid [5], [6]. In other words, as the strength of the magnetic field increases, the interaction between the magnetized particles increases and the strength of the chain-like structure stronger so that the viscosity and resistance of the MR fluid also increase, resulting in an increase of the friction force (F). As shown in Eq. (1), at a fixed normal load (N) value, as the friction increases, eventually it leads to the increases in the coefficient of friction which is good for its application.

1. Mechanical and Automotive Engineering, Kongju National University, Cheonan, The Republic of Korea

1. Introduction A variety of structures and methods for magnetic millirobots has been extensively investigated as a promising means to replace conventional medical treatment for occlusive vascular diseases [1-4]. Multi-modular magnetic millirobots able to accommodate multiple modules especially attracted attention [2-4]. Since this structure allows a relatively large space along the longitudinal axis to utilize various functional structures, a multi-modular magnetic millirobot can be used to perform complex tasks such as stent deploy and drug delivery in tubular environments [3, 4]. However, due to the complex and lengthy structure, the millirobot cannot be easily applied to tubes with a relatively high curvature such as the one shown in Fig. 1. *2. A Multi-Modular Helical Magnetic Millirobot Composed of Soft Modules* In this research, we propose a multi-modular helical magnetic millirobot (MHMM) composed of soft modules that can be effectively applied to curved tubular environments, as shown in Fig. 1 [4]. Each module of the MHMM is serially connected by a universal joint, and the rotational motion of the first (head) module can be effectively transferred to the other modules. Therefore, every module of the MHMM can rotate in sync with an external rotating magnetic field (ERMF) even if they are not aligned. The MHMM can also employ more modules if necessary by simply serially connecting additional modules with universal joints. From the geometric constraints of two orthogonal revolute joints of a universal joint, the angular displacement of the kth module, Θ_k, of the MHMM can be expressed in terms of the first module's angular displacement, Θ_1, as follows [4]: $\Theta_k=\tan^{-1}(\tan(\Theta_1)/\prod_{j=1}^{k-1}\cos\Phi_{j,j+1})$ (1) where $\Phi_{k,k+1}$ is the angle between the *k*th and the (*k*+1)th modules. Eq. (1) can be used to control each module's angular displacement, speed, and acceleration by means of an ERMF which can be used to generate a certain type of the MHMM's mechanical motions, such as navigating, unclogging, and stent deploying motions. Also, due to the flexibility of the soft modules, the MHMM can be easily deformed with respect to the tube which can make it more steerable in tubes with a relatively high curvature, as shown in Fig. 1. This flexibility can also make the MHMM be more anchorable in curved tubes because of the relatively large contact area between the MHMM and the tube derived from the deformation. This ability is especially useful when the MHMM performs complex tasks such as stent delivery and drug delivery within human blood vessels while overcoming pulsatile blood flows [3, 4]. In this research, we verified the proposed MHMM by constructing a magnetic navigation system (MNS) and a prototype MHMM, as shown in Fig. 2. The MNS shown in Fig. 2a can generate and control various ERMFs required to manipulate the MHMM. An in-vitro pulsatile flow environment was also constructed to mimic the condition of human blood vessels. Figs. 2c, 2d show the prototype MHMM constructed with a stereolithography-based 3d printing technology using flexible resin, and the MHMM showed a sufficient flexibility as shown in Fig. 2b. We then examined the navigating, steering, and unclogging abilities of the prototype MHMM compared to that of an MHMM constructed with a harder material (acrylic plastic), as shown in Fig. 2e. And the results showed that the MHMM constructed with flexible resin (soft module) not only can effectively navigate in a highly bent tube but also can effectively anchor to the tube against a pulsatile flow. We also measured the maximum angular speeds of the MHMMs in the tube that they can rotate in sync with an applied ERMF, and the MHMM constructed with flexible resin could rotate in sync with a much faster ERMF. Whereas the MHMM constructed with acrylic plastic only could rotate in sync with a relatively slow ERMF due to the irregular contact between the robot body and the tube during rotation. *3. Concluding Remarks* This research proposed a novel type of MHMM that can navigate in curved tubular environments effectively. It also examined the navigating and anchoring ability of the MHMM by observing and examining various mechanical motions of the MHMM in an in-vitro pulsatile flow condition. This research can contribute to the development of multi-modular magnetic millirobots able to conduct complex tasks required for many biological and biomedical applications.

SUMMARY Magnetic robots and their magnetic manipulation systems are innovative approaches for the diagnosis and therapy of minimally invasive medicine. Medical magnetic robots have been applied to targeted drug delivery, drilling in blood vessels, and a robotic capsule-endoscope for diagnosis and therapy [1-3]. Typically, the magnetic robots are controlled by various types of magnetic field: gradient, alternating, rotating, and uniform magnetic fields. The combination of Maxwell coil and Helmholtz coil are general configuration of magnetic manipulation system. However, the configuration is complicated and many power sources are required. To overcome these issues, we proposes a new method of hybrid control of magnetic fields for magnetic micro-robot manipulation based on three-axis Helmholtz coil. The hybrid control utilizes both gradient and uniform fields through switch control of the three-axis Helmholtz coil. For hybrid control, we utilizes 9 relay switches. Three switches separate the x, y and z coils. Six switches separate configuration of Helmholtz coil. In other words, three Helmholtz coils becomes six coils. When generating a rotating magnetic field, the six switches are turned on. When controlling the gradient field, the six switches are selectively turned off according to the moving direction. The hybrid control can provide precision control of micro/nano robot. In addition, the control method with system can be applied to micro/nano robot control without limitation to the robot mechanisms. To verify these advantages, we conducted various experimental tests. *ANALYSIS* Figure 1 (a) shows the three-axis coil structure and the switching method of a pair of Helmholtz coil. A pair of Helmholtz coils are connected by a switch and can not act as Helmholtz coils when the switch is off. Figure 1(b) shows the results of magnetic field distribution for steering of magnetic microrobot through the gradient magnetic field. For steering of the robot based on the gradient field, the switches constituting the x- and y-axis Helmholtz coils are each turned off to form a single coil. We applied to current signals at Y_1 and X_1 coils. The steering angle is determined by the strength of the two magnetic fields of Y_1 and X_1 coils. When a current of 6A is applied to the Y_1 coil, the difference of the magnetic field at a distance of 3.5 cm from the center point is 1 kA/m. When a current of 6 A is applied, a magnetic field of 4 kA/m is generated at a point of 3.5 cm. Figure 2 shows the results of active locomotion by hybrid control. First, we verified active locomotion based on the gradient magnetic field, as shown in Fig. 2 (a). In this test, we used a cylindrical permanent magnet. The magnet was controlled by translational force within gradient magnetic field. The movement path is shown in Fig. 2 (a). Figure 2 (b) shows the hybrid control using the rotating magnetic field and gradient magnetic field. In this experiment, we utilized the spiral-type microrobot. To control the robot, it was driven with a magnetic field of 5.7 kA / m and 3 Hz in the rotating magnetic field mode. The robot was moved to the rotating magnetic field mode from the starting point to the 21-second point, and the robot was moved in translational motion to the gradient magnetic field mode for 41 seconds: The points 1 to 5 are controlled by a gradient magnetic field. From point 1 to point 5, it is controlled by the gradient magnetic field, and then it moves forward at point 5 by using the rotating magnetic field, as shown in Fig.2 (b). In general, a rotating magnetic field is used to control the spiral-type robot. However, it can be limited in direction control in a narrow space. The proposed hybrid control can control the movement of the robot more quickly and accurately in a narrow space. Also, it is experimentally proved that it can be used irrespective of the mechanism of the robot.

GQ-04. Experimental Verification of Transcranial Magnetic Stimulation Using Anatomically Accurate Brain Phantom.

H. Magsood[1], F. Syeda[1] and R.L. Hadimani[1]
1. Virginia Commonwealth University, Henrico, VA, United States

Transcranial Magnetic Stimulation (TMS) is a promising and non-invasive technique for diagnostics and treatments of various neurological diseases [1]–[3]. However, the lack of anatomically realistic brain phantoms has made the experimental verification of induced electric fields in the brain tissues an impediment to the development of new treatment protocols. We have developed a 3-D anatomically accurate brain phantom that can mimic the electrical conductivity of different brain regions [4]. The phantom will enable the professionals in the field of the brain modulation and treatment to test and perform brain stimulations on the phantom that are accurate and match the clinical setting of the of TMS treatment. To produce the phantom for the work at hand, we 3-D printed shells for each tissue layer of the brain. Brain tissues are divided mainly into cerebrospinal fluid (CSF), white matter (WM), grey matter (GM), ventricles, and cerebellum. These layers are made into shells and after 3D printing them, they are filled with a conductive material (silicon polymer polydimethylsiloxane PDM with electrically conductive filler multi walled carbon nanotubes MWCNT) to impart electrical conduction to the brain phantom. Then, the shells are broken or dissolved to finally produce the brain phantom. The electrical conductivity of the brain phantom tissue that we are matching in this phantom is in the range between 0.4-1.0 Sm^{-1}. The phantom is then examined under different TMS parameters and compared with FEM modelling of induced electric and magnetic fields in the brain. For the experimental part, we positioned the TMS coils on the brain phantom and an oscilloscope probe is placed just underneath the surface of the phantom in order to measure the voltage (phantom probe). Also, we placed another probe at the same distance (from the coils) of the first probe but it is placed outside the phantom to measure the voltage induced on the probe just from the TMS coils (reference probe). Then, we applied the magnetic field from the coils at four distances 1, 2, 3, and 4cm and at four different power intensities 25, 50, 75, and 100% at each distance. The brain phantom and experimental set up is shown in fig.1. Also, we replicated the same setting of the experimental work with FEM simulation where the coils in the software are places at four distances 1, 2, 3, and 4 cm form the surface of the brain model and with four intensities 25, 50, 75, and 100% at each distance. The voltage readings for both experimental and simulation cases are shown in fig.2. Voltage readings of the experimental work shown in the upper graph of Fig.2 representing the difference between the voltages induced on phantom probe and the reference probe. This indicates that there is a noticeable induced electric field in the phantom due to the applied magnetic field from the TMS coils. Comparing both graphs, experimental and simulation, it can be seen that there is an overall similar behavior. The voltage and e-field readings are linearly dependent with intensity in both graphs. Also, the induced voltage decreases almost exponentially with the distance. However, the gap between the 1cm and 2cm is larger in the experimental results than it is in the simulation. This behavior can be due to the complexity of the experimental set up. For example, there could be some discontinuities within the phantom due to the tear in the polymer caused by the repeated probe insertion. Also, the magnetic field is sensitive to the distance from the source; therefore, there might be a slight difference between the intended and the actual distances from the probes to the coils. Finally, even though the phantom is fabricated to be globally homogenous but, there could be some local inhomogeneity within the phantom that result in slight deviated voltage readings. We have planned to overcome these experimental inaccuracies in our future work by adopting a Cartesian servo motor stage. GQ-05. Magnetically axial-coupled propeller-based portable electro-mangetic energy-harvesting device using air and water stream.

J. Lee[1], G. Jeon[1] and *S. Kim*[1]
1. Department of Electronics Convergence Engineering, Wonkwang University, Iksan, The Republic of Korea

Introduction Energy-harvesting devices have been widely developed and reported [1-3]. In general, energy-harvesting devices utilize piezoelectric, electrostatic, and electromagnetic methods. Piezoelectric generators convert vibration into a voltage output but generate relatively high voltage (to a maximum of hundreds of V) and low electrical current. Electrostatic generators provide a relatively high output voltage and often high output impedance (up to tens of MΩ). In the case of EM generators, they generate comparatively high output current levels at low output voltages. The output voltage and current depend on the magnet properties and the number of turns in the coil. Energy-harvesting devices can be used for charging portable electronic devices, such as smart phones, notebook computers, and lanterns. In addition, the devices can be applied as a permanent power source for wireless water meter reading based on wireless sensor networks. For these functions, energy-harvesting devices must generate minimum of scores of mW. In this study, we developed an electromagnetic energy-harvesting device, which is potable rotary-type generator, using fluid and air streams. The harvesting device utilizes a permanent axial flux magnet structure. The device consists of 8 permanent magnets, 16 pick-up coils, and a single axial-coupling magnet for easy installation of the turbine. Because the axial-coupling magnet allows for a detachable turbine according to changes in the environment, the proposed device can use tap water and gas flows as an energy source. Thus, the proposed structure can be used in a number of applications. The device generated 18.6 Vrms and 35.34 mW at a rotating speed of 800 rpm and a load of 10 kΩ. Through simulation and various experimental analyses, we conducted a performance evaluation of the proposed device. Fabrication and analysis Figure 1 (a) shows the configuration of the proposed energy-harvesting device. The device is composed of 8 permanent axial-flux magnets with 16 pick-up coils for power generation. The diameter and height of a single disc-type magnet is 20 mm and 3 mm, respectively. A single pick-up coil is 12000 turns with a wire thickness of 0.05 mm. The air gap at the top and bottom between the axial-flux magnets and the pick-up coils is 3 mm, respectively. Figure 1 (b) shows the coupled axial flux of two magnets in a generator according to changes in distance (d is 20 mm) and height (h is 10 mm). The magnetic fields are induced at the pick-up coils. The observed magnetic field intensity is approximately 45 kA/m at a height of 6.5 mm (center of the pick-up coil). Figure 1 (c) shows the detachable turbine on the devices. We utilized synchronous magnetic axial coupling using magnetic torque and force for combination between the turbines and the power generator. The interactive force becomes a virtual shaft. Because of the magnetic axial coupling between the turbine and the generator, the device allows for a contact or non-contact combination. In the case of the non-contact combination, rotational torque depends on the axial coupling force. Therefore, we controlled the coupling distance using a screw mechanism between two magnets. A high coupling force causes a wider rotating speed, and increases the torque. We installed the coupling magnets, comprised of an NdFeB and an NdFeB-bonded magnet, in wind turbines and water turbines. In addition, the generator includes an NdFeB-bonded magnet for an axial-coupling magnet. The magnetic axial coupling between an NdFeB-bonded magnets resulted in a lower coupling force, up to a coupling distance of 6 mm. Under the condition, the coupling force was 0.467 N, whereas the coupling between the NdFeB magnet and the bonded magnet produced a coupling force of 0.54 N. This configuration is suitable for water turbines. Figure 1 (d) shows the fabricated generator and total configuration. The two turbines were fabricated by 3D printer. Using the generator, we observed the converted voltages and electrical power according to changes in rotating speed up to 800 rpm, as shown in Fig. 2. Figure 2 (a) shows energy harvested from wind and water streams. Figure 2 (b) shows load tests at 1 kΩ, 10 kΩ, and 100 kΩ, up to 800 rpm. The device generated a maximum of 2.45, 18.6, and 53.6 Vrms at 800 rpm. Under the condition, the converted electrical powers were 6.2, 35.34, and 29 mW at 1 kΩ, 10 kΩ, and 100 kΩ, respectively. In addition, using a diode rectifier, we conducted a charge test using a 1 F super-capacitor. It took about 45 minutes for full charge.

GQ-06. Improved Performances of Micro-electromagnetic Energy Harvesting Devices by Minimizing the Demagnetization Field.

D. Mallick[1] and S. Roy[1]
1. Micro-nano-systems Center, Tyndall National Institute, Cork, Ireland

The potential of wirelessly connected smart world of 'Internet of Things' technological platform is restricted by the lack of ambient energy sources capable of powering the sensors perpetually [1, 2]. This issue has surged the research to investigate the prospect of harvesting the energy out of ambient mechanical vibrations [3-5]. Among the different vibrational energy harvesting (VEH) transduction mechanisms, electromagnetic (EM) transducers are the most promising one. However, the difficulty in miniaturisation and integration of the high performance permanent magnets in MEMS scale devices hinders the continuous demand of increasing power density (= power/device volume). In general, CMOS compatible development of high energy product (BH_{max}) permanent magnets with thickness of the order of microns to hundreds of microns is a key challenge for a number of magnetic MEMS applications including VEH [6-7]. But the problem extends beyond just high energy product magnetic material deposition and relates to the lack of intelligent design strategies. When a relatively thin film/block of permanent magnet is used in a MEMS device as source of magnetic field, the stray magnetic field appears only from the edge of the magnet and a large part of the material is wasted. This is due to the presence of the demagnetization field which acts to demagnetize the magnet in a direction which is opposite to the direction of the magnetization [8]. Hence, the magnetic flux intensity is greatly reduced which affect the performance of integrated magnetic transducers. Here, we propose to replace a block of permanent magnet by micro-patterned array of magnets, diminishing the demagnetization effect and enhancing the magnetic stray field. In that case, the magnetic flux density can be intensified over a small space due to increase of the edges of magnetic elements, which is shown quantitatively in Fig. 1(a) using FEM simulation in COMSOL. Thus electromagnetic coupling co-efficient can be substantially improved resulting in higher output power. Different patterned structures are simulated to derive the optimized configuration to be used in MEMS based EM VEH devices. To demonstrate the potential of the proposed approach, micro-patterns of the Co-rich CoPtP permanent magnets are developed at room temperature using a combination of standard lithography and an optimized pulse reverse electrodeposition techniques. Among different deposition methods [9, 10], electrochemical route is an attractive choice due to its low cost and relatively high deposition rate at CMOS compatible temperature. Compared to the conventional DC plating, significant improvements in the microstructure of the developed thick CoPtP micro-magnets are obtained using the pulse reverse electroplating technique which improves the hard magnetic properties as well. Up to ~30 μm thick patterned structures are developed with intrinsic coercivity > 3 kOe and maximum energy product of 45.9 kJ/m^3. In order to demonstrate the substantial advantage of optimized, micro-patterned magnetic structures compared to a block of integrated magnet, a novel device topology of micro EM VEH is adopted as shown in Fig. 2(a). The device consists of assembled components such as micro-fabricated silicon spring structure (natural frequency = 500 Hz), double layer electroplated copper coil with 144 turns and 190 ohm internal resistance and different micro-patterns of CoPtP magnets. The magnetic arrays are placed only above one side of the coil so that the later can move from a region of high magnetic flux density to zero flux density, generating large flux gradient vis-à-vis induced voltage. By changing the magnetic structure from block to square patterned magnet the electromagnetic coupling co-efficient increases from 0.2 mWb/m to 1.6 mWb/m, as obtained from FEM simulation. Experimental results show (Fig. 2(b)) that under optimized load condition, the device with square micro-patterned magnets produce 4 times higher output power compared to the same produced by a device with an entire block of magnet of similar footprint. In conclusion, this work reports a novel integration strategy to incorporate rare-earth free, CMOS compatible micro-magnets in fully integrated MEMS based EM VEH device in order to improve the device performance significantly, thereby, making it a suitable candidate for powering the sensors within Internet of Things technology. Further improvements can be obtained by developing higher aspect ratio, highly anisotropic magnetic structures which can be attributed to future works.

GQ-07. Characteristic Analysis of Periodic Electromagnetic Force in Wireless Power Transfer System.

X. Ni[1], X. Zhang[1], Q. Yang[1] and Y. Li[1]
1. School of Electrical Engineering and Automation, Tianjin Polytechnic University, Tianjin, China

The coupling mechanism in wireless power transfer(WPT) system, due to the existence of inductive current and time-varying electromagnetic fields, inevitably be affected by electromagnetic force, which would cause vibration and deformation [1]. Periodic electromagnetic force(PEMF)is an action mode of the electromagnetic force, and its amplitude and phase will vary with time periodically. The PEMF is the main inducement for continuous periodic vibration of the coupling mechanism. Under the long-term action of the PEMF, there is an adverse influence on service life, security and reliability of WPT system. And it also produces noise pollution to the surrounding environment. In this paper, the characteristics of the PEMF on coupling mechanism with magnetic shielding in WPT are revealed. The PEMF of WPT system can be divided to Lorentz force and Kelvin force. Coupling coils will be subjected by Lorentz force, which is the force of the magnetic field on the motion charge, and Kelvin force is defined as force caused by the magnetization in magnetic shielding materials. Korteweg-Helmholtz force density method [2] is used to investigate the value of PEMF in coupling coils and magnetic shielding materials. It can be recognized that the frequency of PEMF is twice that of current density and magnetic flux density, and there is phase difference between Lorentz force and Kelvin force. To evaluate the characteristics of the PEMF on the coupling mechanism with magnetic shielding, a two-dimensional finite element model is set up, based on WPT coupling mechanism boundary condition of physical model. The coupling mechanism is a symmetric square with side length 484mm. Both the transmitting coil and the receiving coil are square coils made of Litz wire, which are winded by a double-wire winding manner with 6 turns, embedded in grooved ferrite. The coils are coupled in a 200mm air gap, and the fundamental frequency amplitude of exciting current is 120A. Fig. 1(a) shows the 2-D simulation model which is on central axial section of the coupler. Measuring points of PEMF are located at the coupling coils and the magnetic shielding on the transmitting and receiving side, respectively, as shown in Fig. 1(b). And the EMF of the coupling coils is shown as Fig. 1(c). In Fig. 1(c), the current of the receiving coil is smaller than that of the transmitting coil, and there is a phase difference between them. The frequency of PEMF in coupling coils is twice of the system resonant frequency, owing to make a cross product between current density and magnetic flux field. And the direction of PEMF is opposite to the resonant current. In the measuring point a, there is a PEMF up to 3000N, which is dramatically higher than the PEMF of the same position on the receiving coil. In addition, it can be known that the force between the transmitting and receiving coil is repulsive force. As shown in Fig. 1(d), the frequency of PEMF acting on magnetic shielding is also twice that of the current density. And it is noteworthy that, camparing with coupling coils and magnetic shielding, the direction of PEMF is on the contrary. According to the simulation model, an isometric experimental prototype is built to verify the characteristics of PEMF in the former sections, as shown in Fig. 2(a). The inverter supply is powered by 380V voltage, and the frequency of the supply is 10kHz. Limited to the structure of the coils and measurement implements, only the property and character of PEMF are studied. Using a vibration sensor to gather voltage signal, the PEMF of coupling mechanism are shown in Fig. 2(b)-(e). It can be seen that the frequency of PEMF is 20kHz, which is twice of the system resonant frequency. Since the accurate measurement of PEMF is also quite hard, it can be considered that both magnitude and tendency are in good agreement. So, the PEMF of transmitting side is still larger than that of receiving side, demonstrate the consistency of simulation and experiment. In this paper, aimed at the vibration of the coupling mechanism, the characteristics of the periodic electromagnetic force are studied by theoretical analysis and simulation. The frequency of the coupling mechanism is twice of the system. There is repulsive force between the transmitting and receiving side, and the direction of coils and magnetic shielding materials are opposite. Then set up a experimental model to verify the characteristics. The characteristics of the PEMF could help to solve the problem of electromagnetic vibration, and improve the stability and security of WPT.

1. Division of Physics and Applied Physics, Nanyang Technological University, Singapore, Singapore; 2. Department of Electrical and Computer Engineering, Shinshu University, Nagano, Japan

Recently, the study of the Villari effect on ferromagnetic/magnetostrictive microwires has been the focus of studies due to their potential in energy harvesting projects [1] [2]. The need for self-power generation in internet-of-things (IOT) applications has increased the interest in such investigations. Many studies have focused on stress induced domain wall movements in magnetostrictive wires. The dynamics of domain wall motion depends on the size and shape of the magnetostrictive wires. However, there has been a lack of study in different shapes of microwires that affect domain wall motion under applied stress. Moreover, these studies emphasize on the multiferroic structures, where the stress on ferromagnetic layer is applied by applying the electric field to the ferroelectric layer [3]. Using the electric field for the energy harvesting application undermines the main objective of this research. Here, we report a study on novel zig-zag shaped microwires of FeCo with different dimensions to study the effect of the shape and dimensions on domain wall motions under a purely applied mechanical stress. The samples used in this study are the stack of CoNi/FeCo/CoNi, where the bottom and top CoNi layer was used as underlayer for introducing the anisotropy in FeCo layer and as capping layer to protect FeCo from oxidation, respectively. The zig-zag shaped microwires of different dimensions were patterned using photolithography. A facing targets sputtering system was used to deposit the stack on a flexible polyamide film. Under various sputtering parameters, the thickness of the stack was varied as 30, 40, 50, and 60 nm to investigate the effect of thickness on the stress induced domain wall motion. Kerr microscope was used to observe the deposited microwires. Moreover, to study the domain wall motion of the deposited microwires with different dimensions, we used the Bitter Pattern technique with the Kerr microscope. Stress application to the wires were carried out by pasting the films onto a metallic curvature of different radii, which induced stress to the samples. Comparisons between bitter patterns of different microwires were carried out to study the effect of different dimensions and thickness on the domain wall motion under applied various stresses values. Figure 1 shows the Kerr image of the 30 nm thick zig-zag FeCo microwires on the flexible substrate. It can be noticed from the figure that the dimensions of the deposited microwires are different. However, not a single domain wall was observed by using Kerr Microscope only. FeCo, being a soft magnetic material, is expected to show domains. Therefore, to observe domains and to study the effect of the applied stress on these deposited microwires, we used the bitter pattern technique along with a Kerr microscope. Figure 2(a) shows the bitter patterns of the as deposited sample and figure 2 (b) shows the bitter patterns of the sample pasted to the 24 mm curvature radii for stress application. The domain walls can be easily seen from the bitter patterns, which are in the longitudinal direction of the zig-zag microwires. The inset in figure 2 shows the magnified image of the microwire. From the insets, it can be easily noticed that the domain wall has been moved. In addition to this, domain wall movement in zig-zag microwires of varying sizes and different thicknesses has been investigated. This motion of domain wall under the applied mechanical stress can help in energy harvesting, when used with a pick-up coil. The presentation will discuss the domain wall motion results in detail.

INTRODUCTION : Equilibrium configuration design and tokamak coil design are two of the most fundamental studies in tokamak fusion science [1]. A fixed boundary equilibrium code has been applied on Experimental Advanced Superconducting Tokamak (EAST) to deal with the reference configuration design [2]. In the EAST experiments, the quasi-snowflake (QSF) configuration was obtained with I_p= 250kA. Based on the reconstructed plasma shape of shot 56573 at 5 s by EFIT code, the QSF configuration with I_p= 300kA is designed as well as the calculation of the poloidal field (PF) coil current, but the results show that the currents of PF6 and PF14 will exceed the limit [3]. This paper is to investigate the impact of the plasma shape parameters on PF coil current distribution, and the orthogonal method is used to optimize the plasma shape of QSF discharge. PLASMA CONFIGURATION DESIGN AND SHAPE OPTIMIZATION: The cross-section of the EAST and plasma are shown in Fig. 1. The preliminary design of the QSF configuration with = 300kA has the approximately same equilibrium profiles of the reference from shoot 56573. To avoid the excessive coil current, the orthogonal method is employed to tweak the shape parameters. The currents of PF6 and PF14 are set to be the target of the optimization. Plasma shape parameters triangularity, elongation and squareness are determined by the order. The analysis result is shown in Fig. 2. It shows that the elongation and inner bottom squareness are the most important fact that influence the PF6 and PF14 current, respectively. Furthermore, a comparatively better plasma shape and PF current distribution could be achieved. Fig 3 compares the 2D poloidal flux distribution and PF current distribution calculated by fixed boundary equilibrium solver before and after optimization. It can be seen that after the optimization, the currents of PF6 and PF14 are less than the maximum allowable value 12kA. More results and discussions will be given in the full paper.

GQ-10. Characteristics of Impulsive Force on coupler of Wireless Power Transfer.

Z. Yuan[1], X. Zhang[1], Q. Yang[1] and Y. Li[1]
1. Tianjin Key Laboratory of Advanced Electrical Engineering and Energy Technology, Tianjin Polytechnic University, Tianjin, China

The nature of Wireless Power Transfer (WPT) technology is that the electromagnetic field produced by the high frequency current in the transmitter is coupling with the receiver. It should be noted that the coupler will inevitably be affected by electromagnetic force over the power transmission, due to the coupling of high frequency electromagnetic field. The electromagnetic force will seriously affect the security and reliability of WPT system. In addition, the short circuit and load mutation will cause the abrupt change of current resulting in impulsive force. There will be a great impact on the load, threatening the system security and stability. With the improvement of high power WPT, the magnetic material is used to improve the coupling degree, which will inevitably increase the coupling effect, and consequently increase the electromagnetic force. In [1], the semi-analytical solution of electromagnetic force of coaxial elliptical coils is derived by using Elliptic integral and Lambda function. In [2] and [3], the electromagnetic force on receiving coil is observed and used to drive and steer the micro-robot. Further, the authors use the high-speed camera to analyze the moving speed of receiving coil which is floats on the water, then the electromagnetic force is calculated [4]. However, the effects of impulsive force to high power dynamic WPT system have not been analyzed and studied at home and abroad. The characteristics of impulsive force on coupler should are studied in this paper. In WPT system, considering the material of coupler as magnetically linear material and incompressible, the mechanical model of EMF can be established with analysis of force of coupling coils, based on Lorentz force density theory. For coupling coils, the force can be calculated by $J\times B$ caused by eddy current effect. For magnetic shielding material, the force can be obtained by $-1/2H\bullet H\nabla\mu$ caused by magnetization. μ is the permeability of material. J and B can be expressed as the superposition of several sinusoidal signals of different frequencies. When pulse current produces impulsive force, $J=\{\Sigma[-J_{1n}\sin(nwt+a_0)+J_{2n}\sin(nwt+a_1)\ l(t_0)]\}\theta_1$, and $B=\{\Sigma[B_{1n}\sin(nwt+\beta_0)+J_{2n}\sin(nwt+\beta_1)\ l(t_0)]\}\theta_2$. Then the characteristics of impulsive force can be obtained. Fig. 1 shows the 2D simulation model and the results of impulsive force on coupler. The pulse current is produced by *if* condition. The results illustrate that the pulse current have a major effect on current density in magnetic shielding. The frequency of force is twice the resonant frequency of system. When there is pulse current, the amplitude of force will be increased. A prototype is built to experiment on impulsive force on coupler of WPT, as shown in Fig. 2(a). The pulse current is obtained by time relay. Part of the results are shown in Fig. 2(b) to (e). The amplitude of force on coupler is increased. And the force on transmitter is more increment than receiver. It indicates that this simulation results are correct. The research in this paper can be referred in further research of high frequency electromagnetic force in WPT system.

GQ-11. Nanoscaled magnetic Cu-Co alloys with tuneable properties processed by high-pressure torsion deformation.

A. Bachmaier[1], H. Krenn[2], P. Knoll[2] and R. Pippan[1]
1. Erich Schmid Institute of Materials Science, Austrian Academy of Sciences, Leoben, Austria; 2. Institute of Physics, University of Graz, Graz, Austria

In this study, severe plastic deformation by high-pressure torsion (HPT) deformation is used as alternative fabrication method for nanocrystalline bulk magnetic Cu-Co alloys. Full supersaturation with a single-phase structure can be achieved by HPT deformation at room temperature (RT) of two-phase Cu–Co materials or powders (Fig.1). Subsequent isothermal annealing above the decomposition temperature results in the formation of a nanoscale composite structures investigated in detail by transmission electron microscopy and atom probe tomography (APT). Both, the size as well as the composition of the Cu and Co regions can be influenced by the annealing time. The magnetic properties of the as-deformed and annealed structures are investigated by SQUID-magnetometry and correlated to the evolving nanostructures. As-deformed nanostructures can be further tailored by HPT conditions (i.e. by additional HPT deformation at liquid nitrogen (LN) temperature) and the structural evolution strongly affects magnetic properties. The magnetic properties of the alloy can thus be also used as a valuable fingerprint for the microstructural changes (Fig.2). This project has received funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme (grant agreement No 757333).

GQ-12. Preparation and thermoelectric properties of $Mn_2V(Al_{1-x}Si_x)$ full-Heusler compounds.

H. Li[1], K. Hayashi[1] and Y. Miyazaki[1]
1. Tohoku University, Sendai, Japan

1. Introduction: Recently, thermoelectric materials that can convert thermal energy into electricity have attracted much attention as clean energy harvesting materials. The efficiency of a thermoelectric material is evaluated by the dimensionless figure of merit, $zT = S^2\sigma T/\kappa$, where S, σ, T, and κ are the Seebeck coefficient, electrical conductivity, absolute temperature, and thermal conductivity, respectively. In order to achieve a high zT, a high power factor (PF = $S^2\sigma$) is desired. It is reported that a half-metallic Co_2MnSi full-Heusler alloy shows a relatively high PF of 2.9×10^{-3} $Wm^{-1}K^{-2}$ at 550 K [1]. Since Co_2MnSi is n-type, it is necessary to develop a p-type full-Heusler alloy to be paired with it. In this work, we calculated and measured thermoelectric properties of one of the Mn-based full-Heusler compounds, Mn_2VAl. Furthermore, we performed partial substitution of Si for the Al site to improve PF of Mn_2VAl. 2. Methods: We calculated an electronic band structure of Mn_2VAl in a ferromagnetic phase using the first-principles density function theory. The Seebeck coefficient of Mn_2VAl was calculated using the semi-classical Boltzmann's equation. $Mn_2V(Al_{1-x}Si_x)$ polycrystalline samples (x = 0, 0.005, 0.01, 0.03, 0.05, 0.07, 0.1, and 0.15) were prepared by the arc-melting method followed by the spark plasma sintering (SPS) method. A crystal structure of the SPSed samples was characterized by powder X-ray diffraction (XRD). The Seebeck coefficient and electrical conductivity were simultaneously measured in vacuum from 300 K to 1050 K. 3. Results and discussions: From the XRD patterns, the x = 0, 0.005, 0.01, 0.03, and 0.05 samples were found to be in a single phase of the full-Heusler compound. On the other hand, the samples with $x \geq 0.07$ contained a secondary phase of $(Mn_{0.17}V_{0.83})_3Si$. Thus, the solubility limit of Si in Mn_2VAl was below x = 0.07. Temperature dependence of measured and calculated Seebeck coefficients was shown in Fig. 1. The x = 0 sample (Mn_2VAl) showed a positive Seebeck coefficient in the entire measurement temperature range, indicating a p-type conduction. The temperature dependence agreed with the calculated Seebeck coefficient of Mn_2VAl in a qualitative manner. The measurement and calculation both exhibited a maximum Seebeck coefficient around 700 K. However, it is noted that the calculation was for the ferromagnetic Mn_2VAl case. In fact, it is reported that a ferromagnetic-paramagnetic phase transition occurs at T_C = 760 K for Mn_2VAl [2]. Thus, to discuss the temperature dependence of Seebeck coefficient above 700 K, the Seebeck coefficient of Mn_2VAl in a paramagnetic phase is required. Turning to the sample dependence, the x = 0.005, 0.01, 0.03, and 0.05 samples showed a higher Seebeck coefficient than the x = 0 sample. The highest value reached 32 μVK^{-1} at 664 K for the x = 0.005 sample. The increase in Seebeck coefficient was partly due to an decrease in hole carrier density. Above x = 0.03, the Seebeck coefficient became equal to or lower than that of the x = 0 sample, probably due to the increase in the metallic secondary phase of $(Mn_{0.17}V_{0.83})_3Si$. Although not shown here, the electrical conductivity of Mn_2VAl was as high as 4.20×10^3 S/cm at 355 K. With increasing temperature, the electrical conductivity slightly decreased to 3.89×10^3 S/cm at 715K, and then increased above 715 K, which might be related to the ferromagnetic-paramagnetic phase transition. The partial substitution of Si for the Al site decreased the electrical conductivity up to x = 0.03. Above x = 0.03, the increase in the metallic secondary phase of $(Mn_{0.17}V_{0.83})_3Si$ led to the upturn of the electrical conductivity. Mainly reflecting the increase in Seebeck coefficient by the partial substitution, the power factor was successfully enhanced (Fig. 2). The highest PF of 3.95×10^{-4} $Wm^{-1}K^{-2}$ at 664 K was obtained for the x = 0.005 sample, which was about 1.3 times higher than that of the x = 0 sample.

GQ-13. A MLC STT-MRAM based Computing in-Memory Architecture for Binary Neural Network.

Y. Pan[1], P. Ouyang[1], Y. Zhao[1], W. Kang[1], S. Yin[2], Y. Zhang[1], W. Zhao[1] and S. Wei[2]
1. Beihang University, Beijing, China; 2. Tsinghua University, Beijing, China

Due to add operations dominated computation and simplified network in Binary Neural Network(BNN), it is promising for IOT scenarios, which demand ultra-low power consumption and hardware area overhead[1]. By means of exploiting the in-memory computing methods and high density of MLC STT-MRAM [2][3], this work designs a MLC-STT-CIM(Compute-in-Memory) based computing in-memory architecture to achieve add operations for BNN, to further reduce power consumption and area overhead. With MLC STT-MRAM cell, we can store two bits in one cell and achieve add operation in one cell between the two bits. Compared to the design in [2] of which two addends are stored in two different bit-cells of the same column and both WLs are enabled to connected with NMOSs, this design reduces the capacity and energy consumption (see Fig.1: I_{SL} will be lower as it represents the current through one cell while in STT-CIM I_{SL} represents the sum of the current through two cells). Meanwhile, this design achieves lower read failure possibility because one read operation is enabled by only one WL. In this design (See Fig.1), there is a larger MTJ and a small MTJ in a cell to store two bits in one cell. The relative magnetic orientation of the free and reference layers determines the resistance offered by the MTJ. The resistance for the parallel configuration R_P, is lower than the anti-parallel resistance R_{AP}. R_P of small MTJ is lower than that of large MTJ, and so does R_{AP}. We assume R_{AP} represents logic "0" and R_P represents logic "1", then the resultant current I_{SL} flowing through the bit-cell is determined by the stored data in MTJs. If the first bit is stored in large MTJ and the second bit is stored in small MTJ, I_{SL} satisfy $I_{00}<I_{01}<I_{10}<I_{11}$ for $R_{AP\text{-}AP}> R_{AP\text{-}P}> R_{AP\text{-}P}> R_{P\text{-}P.}$ We can choose proper reference resistances to generate reference currents that satisfy $I_{00}<I_{ref3}<I_{01}<I_{ref2}<I_{10}<I_{ref1}<I_{11.}$ Basing on the modified sensing circuit combined by sense amplifiers(SAs), MOSs and logic gates, we can realize both memory and computing mode. Memory mode: When WLs are enabled, we can write the bits to the cell with a two-step writing scheme: a large current is used to change the magnetic orientation of the large MTJ to write the first bit bit1.Because switching current of the small MTJ is smaller than the large one, the magnetic orientation of the small MTJ is changed as we write bit1.Basing on the second bit bit2, a small current is used to switch the small MTJ if necessary. To read the bits, we connect I_{SL} to the positive input of the sense amplifier SA1, SA2, and SA3 respectively. Connecting I_{ref2} to the negative input of SA1 to read the first bit, and the second bit signal will be sensed from the positive output of SA2 or SA3 by accordingly feeding I_{ref1} and I_{ref3} to their negative input. If the first bit is "1"("0"), we will get the correct second bit from SA2(SA3). Respectively, connecting the positive output of SA2 and SA3 to D ports of NMOS and PMOS which are controlled by the first bit, and connecting the S ports to output bit2, the second bit is got. Computing mode: Except sensing the second bit in memory mode,SA2 can realize logic AND and NAND. As mentioned above, only I_{11} is larger than $I_{ref1.}$ In other words, only both MTJS are in the P configuration (both store logic "1"), leads to an output of logic "1" ("0") at the positive (negative) output of SA2, while all other cases lead to logic "0" ("1"). Thus, the positive and negative outputs of SA2 evaluate the logic AND and NAND of the values stored in the enabled bit-cells. Obviously, A OR (NOR)operation can be realized at the positive (negative) terminal of SA3. And an XOR operation can be realized when feeding the AND output of SA2 and the NOR output of SA3 to a CMOS NOR gate. Suppose An and Bn(the n-th bits of two words, A and B) are stored in large MTJ and small MTJ in a cell within a MLC-STT-CIM array. Suppose that we wish to compute the full-adder logic function (the n-th stage of an adder that adds words A and B). According to Sn= An XOR Bn XOR $C_{n,}$ Cn =((An XOR Bn) AND C_{n-1}) OR (An AND Bn), the sum Sn and the carry out Cn Can be computed using An XOR Bn and An AND Bn, in addition to C_{n-1} (carry input from the previous stage). We can see that ADD operation in terms of the outputs of bitwise operations, AND and XOR. Three additional logic gates are required to enable this computation. In this mode, the amounts of energy consumption for add operation is reduced within one cell, which can compute BNN efficiently. Meanwhile, since I_{SL} is smaller, the full-add operation is more reliable which benefits from lower sensing disturbing probability.

I. INTRODUCTION Nanocrystalline $SmCo_5$ magnet has been investigated for many years due to its extraordinary high anisotropy filed as well as coercivity. Therefore, producing an anisotropic structure $SmCo_5$ magnet through hot deformation has attracted considerable interest in order to acquire higher magnetic performance. Nevertheless, most of precursors magnets are crystal matrix before hot deformation, while amorphous matrix can maximize the retention of fine grains and control grains growth, which will definitely benefit the magnetic performance[1]. In this study, we report a novel approach to synthesize bulk anisotropic $SmCo_5$ nanocrystalline magnets from $SmCo_5$ amorphous precursor. II. EXPERIMENTS The alloy ingot with nominal composition of $SmCo_5$ was prepared by induction melting with 10 wt.% excess of Sm to compensate for the evaporation losses. The ingot was then melt-spun into as-spun ribbons, and manually crushed into powders. 20 g of the crushed powders were ball milled for 5 hours in a tungsten carbide vial using high energy ball milling machine with the ball-to-powder weight ratio of 10:1. The as-milled powders which contain an amorphous SmCo matrix were put in a Φ15 tungsten carbide mold, which then consolidated into bulk amorphous precursors at 200°C under 500 MPa by using spark plasma sintering (SPS) method[2], followed by hot deformation at 800°C under 50 MPa with a height reduction of 85%. The microstructures of the samples were examined by scanning electron microscopy (SEM) and high-resolution transmission electron microscopy (HRTEM), which showed a large number of nanoscale twins formed. The crystal structure and texture was determined by X-ray diffraction (XRD). The room-temperature magnetic properties parallel and perpendicular to the pressure direction were examined by using a physical property measurement system (PPMS) with a magnetic field up to 7T. The density of the hot-deformed magnets was measured by Archimedes method. III. RUSULTS AND DISSUSION Figure 1 shows five different XRD patterns that separately are as-spun ribbons, milled powers, hot pressed magnet and the two surfaces of hot deformed magnet which are perpendicular and parallel to the pressure direction, respectively. A pure hexagonal phase of $SmCo_5$ is observed in the as-spun ribbons. Then, the as-milled powers show a broad hump in the XRD pattern, suggesting that an amorphous matrix is obtained. Subsequently, the $SmCo_5$ amorphous powers were consolidated into bulk amorphous precursor by hot pressed at 200°C, and the corresponding XRD result shows that there is no obvious crystallization. Followed by hot deformation, the intensity of (00*l*) diffraction peaks is obviously enhanced in the surface perpendicular to the pressure direction, as shown in fig. 1, revealing that strong c-axis textures were obtained for the hot deformed $SmCo_5$ magnet. The relative intensity ratio, I(002)/I(111), can be characterized as crystallographic alignment. The ratio I(002)/I(111) of the surface perpendicular to the pressure direction is 0.91, while the ratio is 0.25 for the standard $SmCo_5$ XRD pattern and 0.17 for parallel, indicating strong anisotropic nanostructure $SmCo_5$ magnet is obtained. Shown in Figure 2 are the hysteresis loops tested along the easy and hard axis of the hot deformed $SmCo_5$ magnet. The large difference of remanence along the easy and hard axis of the hot deformed $SmCo_5$ magnet demonstrates the strong c-axis texture, which has a good agreement with the XRD results. In addition, A high remanence ratio ($M_r/M_s = 0.88$) is exhibited along the easy axis which also shows the strong texture for the hot deformed magnets. It is worth mentioning that the high coercivity of 32.1 and 36.4 kOe is obtained for the hot deformed $SmCo_5$ magnet along the easy and hard axis, respectively. IV. CONCLUSION In summary, bulk nanostructure $SmCo_5$ magnet with strong c-axis texture can be prepared by hot deformation from the amorphous precursor. The high remanence ratio of 0.88 and coercivity of 32.1 kOe are obtained in the hot deformed magnet. We believe that this novel approach could be applied to nanocomposite magnets by further optimizing the process.

Co-ferrite with spinel structure is one of the attractive materials for spintronics and artificial multiferroics. Due to the high resistivity and high-Curie temperature properties, Co-ferrite thins films have potential applications in such so-called spin filters, where a combination of insulating ferrite with a non-magnetic electrode is believed capable of creating pure spin polarized currents. Co-ferrite also shows large magnetostrictive effect, that can be used for enhancing magnetoelectric coupling between ferroelectric phase and ferromagnetic phase of multiferroic nanostructures. Films with (00l) orientation and perpendicular magnetic anisotropy are essential to realize the interesting properties of Co-ferrite thin films. So far, Single crystal substrate such as $SrTiO_3$, MgO have been reported for the heteroepitaxial growth of (00l) orientated Co ferrite films. However, from the practical application point of view, it is strongly recommended to prepare orientated Co ferrite films onto thermally oxidized silicon wafers (SiO_2/Si) Here, a unique process has been developed to deposit Co-ferrite thin films onto thermally oxidized silicon wafer with perpendicular magnetic anisotropy by facing target sputtering. Metallic FeCo was used as underlayers. Co-ferrite films with preferential (00*l*) orientation have been successfully prepared. In this experiment, all the films are deposited without substrate heating. The as-deposited films show nanocrystalline structure with the X-ray diffractometry (XRD) characterization. We have also checked the depth profile of X-ray photoelectron spectroscopy. It is confirmed that the metallic FeCo underlayer got fully oxidized after annealing. Fig. 1 shows hysteresis loops of as-deposited Co-Fe-O films with thickness of 60 nm. The films are deposited without FeCo underlayer (a) and with 3 nm thick of FeCo underlayer. Films deposited without FeCo underlayer show saturation magnetization of around 110 emu/cc. The value is almost one fourth of bulk Co-ferrite. Which indicates that non-magnetic amorphous phase in the nanocrystalline films. However, saturation magnetization dramatically increases with FeCo underlayer of only 3 nm. X-ray diffractometry results clearly exhibit the formation of crystallized spinel structure even without substrate heating with FeCo underlayer. These results suggested that FeCo underlayers can dramatically decrease the crystallization temperature for spinel structures. For all the films, a dramatically increases of coercivity have been achieved by annealing the samples at 800 ^{o}C for 2 hours. Fig. 1 shows hysteresis loops of (c) annealed films without FeCo underlayer and (d) annealed films with FeCo underlayer. Both films show preferential perpendicular magnetic anisotropy. However, films deposited onto FeCo underlayer show smaller in-plane coercivity. Which indicate that such a film have better perpendicular magnetic anisotropy as compared with films without FeCo underlayer. Fig. 2 shows XRD results of (a) annealed films without FeCo underlayer and (b) annealed films with FeCo underlayer. It is clearly that films deposited without FeCo underlayer show (311) plane as the strongest diffraction but films deposited onto FeCo underlayer show (004) plane as the strongest diffraction. Further investigation shows three-dimensional lattice parameters determined by in-plane X-ray diffractometry to be a=b=8.43 Å, c = 8. 35Å. This indicating a compressive c-axis of for the cubic spinel structure. Such a compressive crystal structure leading to the very large coercivity in Co-ferrite films. In summary, we have developed a novel process to prepare Co-ferrite films with perpendicular magnetic anisotropy onto amorphous thermally oxidized silicon wafer. The large perpendicular coercivity of the films is attributed to the compressive x-axis of the cubic spinel structure.

I. Introduction Fused Deposition Modeling (FDM) is a widespread method in 3D printing for its advantages of being less expensive, rapid, and easy to use. Therefore, the extrusion molding is adopted to manufacture the synthesis magnet powder and Acrylonitrile-Butadiene-Styrene (ABS) particles for the FDM. Compared to the properties of bonded-type magnetic devices, the magnetic properties, the quantity contained, and three-dimensional structure of hard magnetic composite materials are improved; thus, the applications of bonded-type magnets have expanded. II. Model Description and Simulation It is difficult to form certain shapes when utilizing Nd-Fe-B composites made by melting or casting. The rapid prototyping method is a promising approach to manufacturing complex shapes of hard magnetic composite components. Magnetic properties of hard magnetic materials are affected by many factors, such as composition, microstructure, particle shape, particle size, and packing density. Instead of heat-pressing process, FDM [1] provides a solution to improve the high porosity issue, enhance the three-dimensional structure magnetic properties of hard magnetic composite materials, and replace the traditional bonded-type magnet. ABS polymer composite is a mixture of different methods to improve the uniformity operation of composite. The components in the volume of the system keep the same in the basic volume with the refinement and homogenization distribution, and that is a physical mixing process including distributive mixing and dispersive mixing effects. Dispersive mixing effect refers to the particle size of components that have been downsized to the degree of molecular patterns during the process. In the actual mixing process, distributive and dispersive effects mostly exist synchronically. Via various hybrid mechanical energies, such as mechanical energy, thermal energy, and other factor effects, the mixed magnetic material particles continue to increase and disperse during the redistribution. In this study, the basic material, Nd-Fe-B powder, is blended with ABS to granulate the magnetic powders to be 1.75mm in diameter during drawing, and utilize in 3D printing by FDM. The wire cross-section of Nd-Fe-B powder in the ABS is analyzed with the scanning electron microscope, and the result is shown as Figure 1. An obvious uniformity distribution can be observed. The hysteresis loop of different weight percentages of magnetic properties of polymer composite material is shown in the Figure 2. It is observed that, in the proportion of 65 wt% and 70 wt% of kneading conditions, the hysteresis loop of hard magnetic material is relatively weaker. However, when the proportion is increased up to 75 wt%, the hysteresis loop achieves the optimal condition. III. Conclusion In this work, when the content of magnetic material is raised comprehensively, the magnetic properties of the element are also increased. However, when the content of ABS is decreased, the liquidity of the composite material also significantly declines, which brings difficulties to the FDM of 3D printing. According to the analysis, it is observed that when the magnetic kneading ratio of ABS is up to 75%, the uniformity of distribution and magnetic properties also progresses.

Micro-magnets have much potential for use in the fields of bio-technology, energy transformation and management, information technology... Hard magnetic films based on RE-TM (NdFeB, SmCo) or 3d-5d (FePt, CoPt) materials can be produced by sputtering and PLD, and in the case of the latter, by electro-deposition. Micro patterning of such films is needed to produce μ-magnets. In the case of high performance RE-TM films, we developed both *topographic patterning*, in which μ-magnets are produced through the use of clean-room procedures (e.g. etching) [1], and *Thermo-magnetic patterning (TMP),* in which the direction of magnetization of the film is locally modified through localized heating with a ns-pulsed laser [2]. Characterization of the stray fields produced by such structures showed that magnetization reversal during TMP was limited to a depth of 1-2 μm. RE-TM μ-magnets produce field gradients of up to 10^6T/m [3], and have been used in a range of bio-applications [4-7]. Multi-polar patterns similar to those produced by TMP have been prepared by *Micro flux concentration (μFC)*, in which patterned soft magnetic micro-structures serve to concentrate the flux of an externally applied field in the vicinity of a hard magnetic layer [8-10]. In this study we explore the use of μFC for the patterning of high performance NdFeB films. Firstly we carry out a comparison of the stray fields produced by identical films patterned using both μFC and TMP, results are compared with simulations, and the μFC technique is modelled. Secondly, we propose the use of a recently developed compact table-top pulsed magnetic field generator for the facile application of μFC to the patterning of hard magnetic films. The 5.6 μm thick NdFeB films used were prepared by triode sputtering [11] onto silicon (100) substrates, either maintained at RT (isotropic), or heated at 450 °C (out-of-plane textured), and then annealed (750 °C/10 min.). 50 nm Ta layers were deposited as buffer and capping layers. Two routes were used to fabricate the μ-flux concentrators: 1) stacking of 50 μm copper and iron foils followed by fixation in epoxy; 2) extrusion of a Cu matrix containing a hexagonal array of Co wires (final diameter of Co wires = 100 μm) [12]. Polishing was used to produce relatively flat and smooth surfaces, for good contact with the hard magnetic film. Note that the extrusion approach would be suitable for high throughput fabrication of the μFC patterning process, since one long extruded sample could be sliced to make hundreds or thousands of individual μ-flux concentrators. In order to evaluate the performance of μFC compared to TMP, equivalent pieces of textured NdFeB films were patterned using these techniques. In the case of μFC, a positive field of 7 T and then a negative field of -2.4 T, which corresponds to the coercivity of the NdFeB film, were applied using the superconducting coil of a VSM. In the case of TMP, the NdFeB sample was magnetised in a field of 7 T, then irradiated with a ns-pulsed laser through a photo-resist mask with a 50 μm wide stripe pattern in the presence of a reverse field of -0.5 T. Scanning Hall probe measurements of the stray fields produced by the samples were performed at different scan heights above the surface of the samples (selected data shown in Figure 1). Compared to the TMP sample, the μFC sample shows roughly twice the average peak-to-peak magnetic field intensities at all distances measured, indicating that magnetization reversal is achieved over a greater depth with μFC. While good agreement is achieved between simulation and measurement for μFC at a distance of 10 μm, the measured peak-to-peak values are twice those of the simulated ones at a distance of 55 μm. This discrepancy will be discussed in terms of the assumptions made in simulations. Modelling is also used to predict how to optimize the process further. The high coercivities typical of RE-TM films require the application of relatively strong fields during μFC. However, superconducting coils are not readily available in many labs and the surface area of the sample being patterned may be limited by the bore size of the coil. We thus tested the use of a pulsed magnetic field generator capable of producing fields as high as 10 T [13] as the field source. The compact size of the system allowed the μFC patterning to be carried out beside an optical microscope, which facilitates quick characterization of the patterned film using magneto optic imaging with an indicator film [14]. A μ-flux concentrator was placed on the surface of an isotropic NdFeB film and progressively stronger field pulses were applied. After each pulse, MOIF imaging of the film was carried out before moving to an adjacent virgin zone (Figure 2). The strongest magnetic contrast is observed after the 1 T pulse. For a pulsed of 0.5 T, the central dot is poorly resolved, while for stronger field pulses the contrast from the Co wires fade away. The weaker contrast towards the centre of the array following a pulse of 0.5 T may be due to a reduction in the effective field strength due to the formation of eddy currents inside the Cu matrix. Potential benefits of using compact pulsed field sources for μFC of hard magnetic films for MEMS applications will be discussed.

Since the discovery of $Nd_2Fe_{14}B$ magnets, they are widely used in many fields for their excellent permanent magnetic performance at room temperature, such as the traction motors of hybrid electric vehicles, wind generators and magnetic resonance imaging.[1] In order to reduce the production cost and balance the utilization of rare earth resources, the partial substitution of misch-metal (MM) for Nd in Nd-Fe-B magnets is an effective method to find a balance between magnetic performance and cost due to the inferior intrinsic properties of $MM_2Fe_{14}B$ to $Nd_2Fe_{14}B$. Compared with traditional single alloy method, the dual alloy method has an obvious advantage in preparing high abundant rare earth permanent magnets.[2] Understanding the coercivity mechanism has a substantial impact on developing novel permanent materials. In this work, the stoichiometric composition of $MM_{14}Fe_{79.9}B_{6.1}$ (LaCe-80) and commercial $Nd_{13.5}Fe_{80.5}B_6$ (LaCe-0) were subjected to induction melting, strip-casting, hydrogen decrepitation and jet milling. After blending the powders of LaCe-80 and LaCe-0 with the mass ratios of 0:100(S00), 20:80(S20), 30:70(S30), they were prepared by the rest of the traditional sintering process. The effect of misch metal substitution on the microstructure and room-temperature permanent magnetic properties were studied. Grain alignment and phase constitution were identified by X-ray diffraction. The magnetic properties and the possible interaction mechanisms between two different hard phases were evaluated with the help of the first order reversal curve (FORC) method. Magnetic properties at room temperature were measured by vibrating sample magnetometer (VSM).

GR-06. Nanocomposite Nd-Y-Fe-B-Mo bulk magnets prepared by injection casting technique.

S. Tao[1] and M. Yan[2]
1. China Jiliang University, Hangzhou, China; 2. Zhejiang University, Hangzhou, China

Nanocomposite rare earth $Nd_2Fe_{14}B$ ($Pr_2Fe_{14}B$)/α-Fe (Fe_3B) magnets have obtained considerable interest in exploring potential permanent magnets due to the expected high maximum energy product [1-3]. In general, the coercivity in $Nd_2Fe_{14}B$/α-Fe and $Nd_2Fe_{14}B/Fe_3B$ type nanocomposite magnets originates from the hard $Nd_2Fe_{14}B$ phase, while remanence from the soft α-Fe (Fe_3B) phase or phases. Although, a high remanence in the range of 0.6-1.19 T has been obtained but the coercivity in these magnets is low due to the small volume fraction of hard $Nd_2Fe_{14}B$ phase. The low coercivity tends to reduce the energy product and limit the high-temperature applications of these magnets. Therefore, it is stringent to search for high coercivity nanocomposite magnets. In this work, we have successfully synthesized a new $Nd_7Y_6Fe_{61}B_{22}Mo_4$ bulk nanocomposite magnet with high coercivity by copper mold casting. The phase composition, microstructure and magnetic properties of $Nd_7Y_6Fe_{61}B_{22}Mo_4$ bulk nanocomposite magnets are investigated. Alloy ingots with nominal composition of $Nd_7Y_6Fe_{61}B_{22}Mo_4$ were fabricated by arc-melting in inert atmosphere. Samples in the form of sheets with the dimension of 1 mm in thickness, 5 mm in width, and 50 mm in length were synthesized by injection casting the molten alloy into copper mold in an argon atmosphere. Crystal structure, phase composition, crystallite size and phase volume fraction were determined by the X-ray diffraction technique. Thermal magnetic analysis (TMA) was performed in the present alloys at a heating rate of 20°C/min with an external applied field. Microstructure and composition profiles of the magnetic phases were examined using JEOL-JEM-2010 transmission electron microscopy on thin foils. Magnetic properties were measured using Quantum Design MPMS-XL-5-SQUID with a maximum applied field of 5 T. Fig. 1(a) presents X-ray diffraction pattern for the directly casted $Nd_7Y_6Fe_{61}B_{22}Mo_4$ magnet. It shows Bragg crystalline peaks for phases. The crystalline peaks in XRD pattern were indexed to α-Fe, Fe_3B, $Y_2Fe_{14}B$ and $Nd_2Fe_{14}B$ phases. The α-Fe and Fe_3B are magnetically soft phases while $Y_2Fe_{14}B$ and $Nd_2Fe_{14}B$ are known as magnetically hard phases. The phases observed by X-ray diffraction technique are confirmed by TMA studies. The TMA curve for the directly casted $Nd_7Y_6Fe_{61}B_{22}Mo_4$ magnetic sample is presented in Fig. 1(b). As can be seen, there are four distinct peaks corresponding to $Y_2Fe_{14}B$, $Nd_2Fe_{14}B$, Fe_3B and α-Fe phases. The Curie temperatures for $Y_2Fe_{14}B$, $Nd_2Fe_{14}B$, Fe_3B and α-Fe phases are determined as 215°C, 309°C, 400°C and 760°C, respectively. Fig. 2(a) presents the magnetic hysteresis loop for $Nd_7Y_6Fe_{61}B_{22}Mo_4$ magnet. It shows smooth hysteresis curve without kink in the demagnetizing curve suggesting that the exchange coupling exists in the magnet. The coercivity ($_iH_c$), remanence (B_r) and maximum energy product ($(BH)_{max}$) for $Nd_7Y_6Fe_{61}B_{22}Mo_4$ bulk nanocomposite magnets are 1289 kA/m, 0.51 T and 46.2 kJ/m^3, respectively. To understand the behavior of magnetic exchange interactions between the soft and hard magnetic phases for $Nd_7Y_6Fe_{61}B_{22}Mo_4$ magnets, the δM plot, known as Henkel plot [4, 5] was constructed. The δM is defined as $M_d(H)$-{1-2$M_r(H)$}, where $M_d(H)$ is the reduced demagnetization remanence and $M_r(H)$ the reduced magnetization remanence. For non-interacting phases $\delta M = 0$, whereas nonzero δM indicates the presence of interactions [4]. Fig. 2(b) depicts the δM plot as function of the applied magnetic field for $Nd_7Y_6Fe_{61}B_{22}Mo_4$ nanocomposite magnet. A positive δM is observed confirming the existence of exchange interactions between soft α-Fe, Fe_3B and hard $Nd_2Fe_{14}B/Y_2Fe_{14}B$ phases. The large δM value indicates the existence of strong exchange coupling between α-Fe (Fe_3B) and hard 2:14:1 phases. GR-07. Modeling of piezomagnetic effect in magnetostrictive-electromagnetic hybrid vibration-powered generator.

B. Yan[1], J. Hong[1] and C. Zhang[2]
1. Guangdong University of Technology, Guangzhou, China; 2. Harbin Institute of Technology, Harbin, China

Vibration energy of human activities (like human walking and running) is the by-product of everyday life, can be generated from any perceivable activity. Vibration energy harvesting is the process of converting vibrational energy to electrical energy, which is receiving more global interest and is currently a growing field [1]. Magnetostrictive energy harvester, utilize magnetostrictive material (Tb0.3Dy0.7Fe2 alloy, also called Terfenol-D), exhibit high power density and efficiently, can be safely used to harvest low frequency and huge impact vibration of human walking [2-3]. But single magnetostrictive harvester is still accompanied by low harvesting effect, and its magnitude of electric power generated is always very low. Magnetostrictive-electromagnetic hybrid harvester has larger harvesting effect, can generate more electricity and suit to larger power density design for broadhand vibration impact. Due to its hybrid harvesting effect, the modeling of piezomagnetic effects has two parts: impact-induced and magnetic field-induced. It is still lack of suitable model for design and fabrication of magnetostrictive-electromagnetic hybrid harvester. In this paper, a simplified computational model using for larger piezomagnetic effect design of magnetostrictive-electromagnetic hybrid vibration energy harvester is presented. In the modeling, pizeomagnetic effects in Tb0.3Dy0.7Fe2 alloy are studied as a function of compressive stress and magnetic field, and each effects in ΔB induced by single $\Delta\sigma$ and ΔH are calculated respectively. Then, two methods, pre-loads-based method and impact stress-based method, are used to discuss the optimization of hybrid piezomagnetic effect in the fabrication of magnetostrictive-electromagnetic generator. The model and method is quick and efficient to calculate piezomagnetic effect for hybrid magnetoctrictive material-based harvester, benefit to its optimized target design and the prototype fabricate. Harvesting results calculated by model are in a good agreement with experiments, helps for design and fabrication of high efficient magnetostrictive harvester.

GR-08. Novel thermal stability of coercivity in Alnico 8 alloys with thermomagnetic heat-treatment conditions.

t.J. Zhao[1], l.Y. Sun[1], L. Liu[1], Z. Liu[1], X. Zhang[1] and C. Feng[1]
1. Ningbo Institute of Industrial Technology, Chinese Academy of Sciences, Ningbo, China

The development of Alnico alloys date from 1930s and largely ended in 1970s when Rare-Earth (RE) magnets were discovered [1]. Alnico alloys with Non-Rare-Earth show strong heat resistance properties (up to 600 °C), low temperature of their magnetic properties, and excellent corrosion resistance. Recently Rare-Earth crisis and urgent demands for delicate instrument stimulate researchers to concentrate on Alnico alloys with excellent thermal stability. Not containing rare-earth elements, the method of Heavy Rare Earth Elements compensating temperature coefficient of remanence is not suitable for Alnico alloys, and the study of temperature coefficient of coercivity is very poor. Alnico alloys are primarily composed of two-phases formed through spinodal decomposition during thermomagnetic heat-treatment: an isolated FeCo-rich phase (a1) and a matrix AlNi-rich phase (a2). Considering the BCC structure and thermomagnetic heat-treatment conditions the a1 of rod-like elongates along <001> direction is dispersed distribution in the matrix a2, which means the microstructure is similar with the finite long and linear nanostructured-magnetic-array. So the magnetic anisotropy and hysteresis orginate almost entirely from magnetostatic dipole-dipole interactions [2]. However, the coercivity is much less than the magnetic anisotropy and about one-third of that [3]. The lower coercivity of Alnico alloys enhance viscosity coefficient and prelimit the application. This paper mainly studies the thermal stability of Alnico 8 alloys with thermomagnetic heat-treaatment. The morphology is characterized by Transmission Electron Microscope (TEM), the magnetic properties are measured by the Quantum Design Magnetic Property Measurement System (MPMS) MODEL 6000 equipped with a vibrating sample magnetometer (VSM). During the thermomagnetic heat-treatment Spinodal decomposition occurs to form a1 and a2 with nanostructured. In theory the microstructure is chessboards in transverse direction and infinite long quadrangular in longitudinal direction. The phase and microstructure are showed in Fig. 1 by TEM images of specimen surfaces parallel and perpendicular to the applied. Fig. 1(a) shows a1 is a plate-like of square and hexagon in transverse direction, and the size is 25nm~35nm. Fig. 1(b) shows a1 is a bamboo-like of finite and nonlinear in longitudinal direction, and the size is greater than 300nm. Maybe short temper or uneven components results in the low level of orientation degree and dispersed distribution of a1.The high-temperature magnetic properties of Alnico 8 alloys are listed in Fig. 2. The data shows high-temperature lowers the saturation magnetization (Ms) and remanence (Mr) gradually, but the change rule of coercivity is very unusual. When the temperature goes up to 250 °C the coercivity increases from 1106.778Oe to 1420.29Oe, yet it reduces to 1391.07Oe at 400 °C. Also the reduced rate of coercivity is much less than the increased rate. In addition the temperature coefficient of Ms is less than temperature coefficient of Mr between the temperature zone of increased coercivity and it is opposite between the temperature zone of reduced coercivity. From 0° to 180°the high-temperature angular dependence of coercivity of Alnico 8 alloys is funnel, which means predominant magnetic anisotropy is parallel with a1of bamboo-like in longitudinal direction. And increased coercivity promotes the decline law. The high-temperature reversible reduced curve shows reduced coercivity obviously reduces the values and when the H/Hc is close to the value of 1 there is a faint inflection point. The high-temperature irreversible reduced curve slope shows reduced coercivity improves the peak intensity and shortens the peak width, which means nucleation field is mainly distributed. The predominant magnetic anisotropy of Alnico alloys with BCC structure is parallel with a1 of bamboo-like in longitudinal direction. And the magnetic anisotropy and hysteresis are closely related with magnetic characteristic and microstructure of a1. Maybe the competition effect enhances the magnetic anisotropy to improve the coercivity.

GR-09. Electromagnetic Transient Analysis and Inductance Characterization in Fractional-Slot Concentrated-Wound Interior Permanent Magnet Synchronous Machines under Rotor Demagnetization.

A. Pouramin[1], M. Malekpour[1], R. Dutta[1] and F.M. Rahman[1]
1. School of Electrical Engineering and Telecommunications, University of New South Wales, NSW, NSW, Australia

ABSTRACT: This paper aims to investigate the resultant effect of rotor demagnetization on magnetic and electrical parameters of Fractional-Slot Concentrated-Wound Interior Permanent Magnet Synchronous Machines (FSCW IPMSMs). The distribution of magnetic flux lines, flux density, and self and mutual inductance variations are analyzed under rotor demagnetization by using finite element analysis (FEA). Both healthy and faulty conditions including different distribution of the faulty magnets are investigated. Experimental set up in the laboratory on a prototype FSCW IPMSM is used to verify the finite element model. INTRODUCTION: Fractional-slot concentrated-wound interior permanent magnet synchronous machines (FSCW IPMSMs) have gained a lot of interests in industry. This type of machines has a cheaper manufacturing process, less end winding losses, and greater constant-power speed range [1]. These advantages offer a wide range of applications for FSCW IPMSMs from electric vehicles to wind generation industries. Hence, any malfunction due to the faults such as the rotor demagnetization can be catastrophic. Studying the resultant effects of fault on machine parameters and behavior have been always the concerns of many researchers [2]. Motivated by the above concern, this paper provides a deep understanding of inductance variations of FSCW IPMSMs due to rotor demagnetization. Firstly the accuracy of the machine model in Ansys Maxwell 2D is confirmed with experimental results to build a confidence for the further studies of this paper on the effects of rotor demagnetization. Then the variation of self- and mutual inductances as well as dq- inductances are obtained for the several operating conditions such as no-load and rated load under a maximum torque per ampere (MTPA) trajectory and flux-weakening regime. EXPERIMENTAL VERIFICATION OF THE FINITE ELEMENT MODEL: It is always of great importance to properly model the rotating machine behavior in FEM. Among all proposed modelling techniques, finite element method has proven itself as an accurate and inexpensive technique that gives one an opportunity to study the magnetic behavior of the apparatus under consideration, without any expensive instrument installation. In this paper, a prototype FSCW IPMSM is modelled using Ansys Maxwell 2D considering all material properties, stator and rotor geometries, nonlinearities and saturation effects. disassembled and its parameters such as stator slot geometry, number of stator winding turns, magnet geometries and etc. are measured. The comparison between measured inductances and FEA estimation will be presented in full paper. Fig. 1 shows good agreement between back-emf obtained in FEM and experiment. RESULT AND DISCUSSION: In Fig. 2, the magnetic flux density is shown under both healthy and faulty conditions. As one can see in this figure, asymmetry of flux lines led to less magnetic flux density around the faulted magnets due to the rotor demagnetization. Also the self and mutual inductances are shown in Fig. 3 in which clear distortions can be seen in amplitude. The full paper will provide a broaden results on machine inductances under different operating conditions.

GR-10. Effect of Temperature and Pressure on Electrical Resistivity of Permanent Magnet.

L. Xiao[1], G. Yu[1], J. Zou[1], Y. Xu[1], H. Lan[1], M. Wang[1] and F. Gao[1]
1. Harbin Institute of Technology, Harbin, China

Abstract—This study is focused on the investigation of the effect of temperature and omnidirectional pressure on the electrical resistivity of permanent magnet. And a new setup for electrical resistivity measurements, where strip permanent magnet samples are measured with the four-probe method technique, has been successfully implemented. In order to verify whether the magnetization has an effect on the permanent magnet electrical resistivity, an unmagnetized permanent magnet and a magnetizing permanent magnet were used as the test materials in the experiments. The measured electrical resistivity values of the permanent magnet and the magnetizing effect on the measurements is also discussed in detail. I. Introduction Permanent magnet motors (PMMs) have been widely used in a variety of applications, including aerospace, deep sea submersible, and oil well due to their high power density, high efficiency, high torque density and other advantages [1]. However, the permanent magnet motors in the use and design process, need to face many challenges. Although this type of motors are designed to have a high power density, the resultant losses including winding losses, iron losses and eddy current losses in permanent magnets are inevitable [2]. Among them, the eddy current losses in permanent magnet should pay more attention to the designers, because the eddy losses in the permanent magnets can raise their operating temperature and hence point flux density of the permanent magnets, thus making them may face the risk of partial demagnetization, which affects the overall performance and service life of the motors. To diminish the eddy current losses in permanent magnet and thus improve the overall efficiency, an accuracy and computationally efficient solution for eddy current losses is necessary at the design of the motors. For those permanent magnet motors operating in extreme environments, such as high temperature and high pressure environments, the eddy current losses of their permanent magnets should be taken into account. Inaccurate eddy losses calculation may cause underestimation of the rotor temperature, which in turn increases the risk of demagnetization. Clearly understanding the change of the electrical resistivity of permanent magnet under high temperature and high pressure is the key to accurately calculate the eddy current losses. However, there are few relevant data that meet this condition, and this study is about to solve this problem. II. measurment system 2.1 Definition of the testing materials and specimen geometry In this study, the two most commonly used and different types of permanent magnets in permanent magnet motors were used as the test materials, the specific grades of which were samarium cobalt (Sm_2Co_{17}) and neodymium iron boron (NdFeB), respectively. It is well-known that the permanent magnet materials used in permanent magnet motors are basically magnetized. Therefore, the electrical resistivity of the test samples before and after magnetization are measured, that is, the effect of magnetization on the electrical resistivity of the permanent magnet is analyzed. In view of the brittleness of the permanent magnet materials, the test samples are machined into a simple strip shape. The shape of the test samples are also very advantageous in terms of size. 2.2 Measurement setup and Measurement environment system A carefully designed measurement setup is needed for reliable results based on four-probe method technique [3]. Fig.1 shows the newly designed permanent magnet material resistivity measurement setup, including sliding end, fixed end, baseboard and platen, with voltage contacts and current contacts in the sliding end and fixed end in direct contact with the test sample. Since this study was completed under high temperature and high pressure, the primary solution to this problem is to realize the measurement environment of high temperature and high pressure. And the pressure mentioned in this study is omnidirectional pressure, non-finite axial pressure. III. measured results and discuss Measurement procedures have been completed according to above mentioned measurement setup and measurement method. The measured results show the changes of the resistivity of the two tested samples under the conditions of high temperature and high pressure, respectively. Fig.2 shows the electrical resistivity of Sm_2Co_{17}, the effect of the temperature and pressure on the Sm_2Co_{17} material. And the difference between the resistivity of the magnetized sample and the unmagnetized sample is compared and analyzed, and the influence of magnetization on the permanent magnet material is revealed. Specific measurement results and comparative analysis results will be given in the subsequent full text. IV. conclusion In this study, the electrical resistivity of permanent magnet has been examined under high temperature and high pressure. The influence of magnetization on the electrical resistivity of permanent magnet are analyzed in detail. The measurement results show that when the temperature and the omnidirectional pressure are coupled together, the change of the resistivity of the permanent magnet and the influence of the two environmental factors of temperature and pressure on the electrical resistivity of the permanent magnet respectively. Further explain the role of each factor in the coupling of two environmental factors.

1. State Key Lab of Magnetism, Institute of Physics, Beijing, China

A low cost versatile electrochemical method has been employed to synthesize highly ordered CoPt nanowires (NWs) in anodic aluminum oxide (AAO) templates with average pore diameter of about 100 nm. The structural properties of as deposited NWs have been studied through XRD analysis. Results show that the as deposited NWs are textured along the face centered cubic (fcc) phase with (111) preferred orientation, and magnetic field annealing treatment to NWs can improve the crystalline structure resulting a sharper (111) peak and improved (200) orientation. Magnetic properties at room temperature and lower temperature has been investigated with applied field parallel and perpendicular to NWs axis. The easy magnetization axis is aligned perpendicular to NWs owing to the strong magnetostatic interactions among the NWs due to smaller interwire distance (~15 nm). Furthermore, the as deposited arrays of NWs have been annealed for 2 h at 300 degree Celsius in the presence of 1 T magnetic field applied in the direction perpendicular to NWs axis. Magnetic field annealing gives improved structural and magnetic behavior of these one-dimensional (1D) nanostructures resulting improved crystallinity and increased values of coercivity (Hc) and remnant squareness (SQ). Switching in magnetization reversal mechanism has been observed from curling to coherent rotation for both cases which is quite interesting to study the mixed behavior of magnetic domains on applied field reversal. Furthermore, at lower temperatures significant increase in saturation magnetization, coercivity and squareness has been observed which is mainly due to the reduced thermal fluctuations and contribution of superparamagnetic nanoparticles in blocking state. Superparamagnetic contributions at lower temperature due to presence of fine nanoparticles in blocking state play important role and leads to enhanced magnetic behavior of CoPt NWs.

GR-12. Simplified Magnetic Circuit for Analyzing Demagnetization of Permanent-magnets in PMSMs.

S. Lee[1] and J. Hur[1]
1. Incheon National University, Incheon, The Republic of Korea

Since permanent-magnet synchronous machines (PMSMs) have high torque density and high efficiency in comparison of other electric machines under same volume, they have been widely used in different applications [1], [2]. In the case of PMSMs applied to the actuator or the engine in automobile industries manufacturing hybrid electric vehicles and electric vehicles, their reliability and stability are significantly important because the breakdown of PMSMs may be caused by the potential faults including winding fault, eccentricity, bearing fault, or demagnetization of permanent-magnets (PMs) [3]. When the reliability and the stability are not considered deeply, the faults may lead to critical accident. To ensure the performance of the PMSMs, different methods such as robust machine design, fault diagnosis, and fault tolerance control have developed by many researchers [3], [4]. Nevertheless, it is difficult to apply the methods without the characteristics analysis of PMSMs with faults. This study deals with a simplified magnetic circuit for analyzing the demagnetization of PMs in PMSMs. The demagnetization is one of the most common faults and is affected by current magnitude, current angle, and temperature [5]. When the magnetic flux passing through PMs is increased along with the increase of stator currents, a load line is moved close to a knee-point. Moreover, the temperature affects the knee-point of PMs. According to these variations, the operating point, which is the point of intersection between the load-line and B-H curve of PMs, is decided and it can check whether or not the irreversible demagnetization of PMs is caused, as shown in Fig 1 (a). To make simplified magnetic circuit, this study utilizes the interior-type PMSM using neodymium PMs, and magnetic flux path can be drawn regardless of stator current, as shown Fig. 1 (b). Here, R_s, R_g, R_r, R_T, and R_m are the equivalent reluctance components in stator, airgap, rotor, production tolerance, and PMs, respectively. R_{rip} is the reluctances component generated by the bridge between airgap and barrier. R_{leak} is the reluctances component generated by leakage flux, respectively. F_m denotes magnetomotive force (MMF) generated by PMs. For analyzing the demagnetization of PMs, first of all, the MMF generated by PMs and stator currents are separated for principle of superposition, and then MMF and equivalent reluctance are calculated. In the stator, the current flowing in finite straight conductors induced magnetic fields by Biot-Savart law, as follow. $H_p=NI/(2\times\text{pi}\times p_L)(\cos\theta_{L2}-\cos\,\theta_{L1})a_{phi}+NI/(2\times\text{pi}\times p_w)(\cos\theta_{w2}-\cos\,\theta_{w1})a_{phi}$ (1) where, H_p and N are the intensity of magnetic field in a specified point and the number of turns. p is the length between a conductor and specific point. The intensity of magnetic field in specific one point is proportional to the number of turns, but that in other points is little different because the magnetic flux generated by stator currents have divergent flux paths according to flux points, as shown in Fig. 1 (c)-(d). The divergent flux paths drawn in the schematic diagram also affects the demagnetization of PMs. In particular, when magnetic flux passes through the edge of PM as the case of path 4, the partial demagnetization in the edge can be easily caused owing to the reduction of reluctance. To find the operating point of the PMSM, its load line and B-H curve of PM depend on temperature is necessary. The B-H curve is determined according to PM materials, but reverse magnetic flux should be calculated to obtain the load line. $\Phi_{de\_px}=F_c/((R_{eq}-R_m)(1+\tan^{-1}\theta_x)\times\cos\theta_x)$ (2) where Φ_{de_px} is the reverse magnetic flux which affects the demagnetization of PMs. F_c is the MMF generated by conductors. According to the variation in stator currents and temperature, the demagnetization existence is analyzed by using simplified magnetic circuit and equivalent equations, as shown in Fig. 2. Since this study used a PMSM having neodymium PMs, it has soft spot for the demagnetization under high temperature condition. ■ Future work We will compensate equation expressions and magnetic field characteristics according to different condition such as current magnitude, and current angle, temperature, and then accuracy will be evaluated by comparing the demagnetization degree through results obtained by proposed method and FEM.

GR-13. Polar transformed subdomain modeling for double-stator permanent magnet linear synchronous machine.

R. Guo[1], H. Yu[1], T. Xia[1], X. Liu[1] and G. Yang[1]
1. Southeast University, Nanjing, China

Abstract—The paper presents a developed analytical subdomain model for design and analysis of the double-stator permanent magnet linear synchronous machine (DS-PMLSM) accounting both the primary and secondary end effect. Firstly, the DS-PMLSM is deformed into a ring-segment PMLSM (RS-PMLSM), the solution regions and time are simplified and improved using the analytical model, which is calculated in Polar coordinates instead of Cartesian coordinates. Then, the subdomain method is adopted to analyze the RS-PMLSM model by solving the Laplace's equation and the Poisson equation in each region, and the slot effect is considered by conformal transformation method. The flux density and back-electromotive force (EMF) are calculated based on the developed analytical model. Finally, the analytical results are verified by the finite-element method (FEM) and experiment, the results show that the proposed model can accurately predict the electromagnetic performance, which is useful for the initial design of the DS-PMLSM. I. Introduction The double-stator permanent magnet linear synchronous machine (DS-PMLSM) has been widely used in high speed and long distance movement. However, the thrust ripple of DS-PMLSM mainly caused by the end effect force is an obvious drawback that distorts the magnetic field severely[1][2][3]. In this paper, a developed subdomain analytical model accounting both the primary and secondary end effect is proposed. Firstly, the PS-PMLSM is deformed into RS-PMLSM, the subdomain method is used to calculate this model. Then, analytical field expression of each subdomain is obtained by the variable separation method and Fourier series method, the coefficients in each region are determined by applying the boundary and interface conditions and the analytical solution of each subdomain can be derived. Finally, the distribution of flux density and Back-EMF are calculated, the analysis results are validated by the finite-element method and experiment. II. Model of the DS-PMLSM The model of DS-PMLSM in Cartesian coordinates and the transformed model of DS-PMLSM in Polar coordinates are shown in Fig.1 (a) and Fig.1 (b), respectively. From Fig.1 (a), the magnetic field need to be divided into 13 regions:1,2,2-1…,7. However, the transformed RS-PMLSM in Fig.1 (b), the number of subdomains is decreased to 6 regions which can reduce the computational complexity. III. Predict of magnetic field distribution A. Model of Permanent magnets For the radial magnetization, the magnetization of tangential is zero, and due to consideration of the primary and secondary end-effect problems, the magnetization distribution of radial in mover coordinate is shown in Fig.1(c). The values from $\pm N_p\theta_m/2$ to $\pm\pi$ are zero. B. Analytical solution of magnetic fields The exact analytical solutions in the various regions are determined by applying the boundary and interface conditions. The radial flux density Br and the tangential field strength H are adopted to define the boundary conditions. According to Poisson and Laplace equations, the general solution differential equations of each region can be determined and the final coefficient matrix can be obtained. Through calculating this matrix, the unknown coefficients can be derived; the magnetic field distribution can be calculated. IV. Verified by the Finite Element method The manufactured prototype machine is shown in Fig.2 (a). The magnetic flux density distribution of the air-gap under the no-load condition is plotted in Fig. 2 (b) and the Back-EMF distribution is shown in Fig. 2 (c). As shown in Fig. 2(b), the analytical results are in good consistent with the simulation results. The flux density of air-gap in slot region is about 0.55 T, in three end regions are about 0.25 T. Through the comparison of Fig. 2(c), it can be found that the analytical results match well with FEA and experiment results, the maximum value of the back-EMF is about 14.5 V. V. Conclusion The paper presents a developed analytical subdomain model for design and analysis of the DS-PMLSM accounting both the primary and secondary end effect. The DS-PMLSM is deformed into RS-PMLSM, and the subdomain method is adopted to solve the analytical model. The flux density and Back-EMF are calculated according to this model, and the results show that the analytical results are in good agreement with the FEM simulations and experiment, which is useful for the initial design of the DS-PMLSM.

GR-14. An Analytical and Numerical Hybrid Model for Static Characteristics of a Radial Linear and Rotary Interior Permanent Magnet Actuator.

P. Jin[1], Y. Guo[1] and Y. Zhu[1]
1. School of Energy and Electrical Engineering, Hohai University, Nanjing, China

I.Introduction Recently, linear and rotary permanent magnet actuator (LRPMA) with integrated structure having high dynamic performance, good power/mass ratio, and simple structure has been proposed [1]. A number of numerical techniques are used to analyze its performance while some pure analytical modeling with magnetic scalar potential are also employed by the author and others [2-5]. However, on one side numerical techniques such as the Finite Element (FE) Method are time-consuming and less insightful when looking into the influence of design parameters upon the machine's behavior. On the other entire analytical methods, either directly [2-4] or indirectly [5], just can be used in limited topologies, such as surface permanent magnet mover, but ineffectively for general topologies like interior permanent magnet mover. This paper presents an analytical and numerical hybrid model for static characteristics of a linear and rotary interior permanent magnet actuator (LRIPMA). II.Analytical and Numerical Hybird Model II-A.Structure of the LRIPMA As shown in Fig. 1(a), the LRIPMA prototype with a interior PM array has a tubular mover, on which there are alternately polarized iron poles in the *z*-direction and eight stacks in the *q*-direction, and a stator with eighteen air-cored coils, three stacks in the *z*-direction and six stacks in the θ-direction. Fig. 1(b) and (c) shows the cutaways of the actuator along the linear and rotational directions. Region I ($R_m \le r \le R_s$) is air/winding region and region II ($R_r \le r \le R_m$) is mover region with the PMs and iron poles. In the 3D model, the end effects are not taken into account; the PMs have a linear demagnetization characteristic, and are fully magnetized in the direction of magnetization. II-B.Field Distribution on the surface of the mover A knowledge of the magnetic field distribution on the air region produced by the mover is fundamental to establishing an accurate model of the LRIPMA for design optimization and dynamic modeling. In region I, the static magnetic field is governed by the Laplacian equation only and the boundary on the stator's inner surface where $r=R_s$ is of the Dirichlet boundary condition. In order to obtain the magnetic field distributions in the other boundary where $r=R_m$, a simplified partial 3D FE model contained mover and stator without coils is established. The nonlinear magnetic field of the actuator which can be treated as static field and analyzed by ignoring the eddy current, satisfies the governing equation (1) (equations and functions are all given in Fig. 2) and boundary conditions functions (2), where S_Ω is the outer boundary of the solution domain. A is the magnetic vector potential. H_c is the residual flux intensity of PM. By using the FE method, flux density $B_S(\theta, r)$ in the different points of the mover's surface where $r=R_m$ can be calculated by equation (3) where B_{rS}, $B_{\theta S}$, and B_{zS} are *r*-, θ- and *z*-directions flux density components respectively. By using the 2D discrete Fourier transform, B_{rS}, $B_{\theta S}$, and B_{zS} which are calculated by the FE model, are decomposed into the equation (4) where $\nu=np$ and $\upsilon=k\pi/\tau$; C_{rkn}, $C_{\theta kn}$, and C_{zkn}, are the *k*-*n*th harmonic coefficients of the 2D Fourier Transform. II-C.Field Distribution in the air region In the cylindrical coordinate system, based on the magnetic scalar potential (MSP) ϕ, the magnetic field intensity components can be expressed by equations (5) where ϕ is governed by the Laplacian equation in the air region as equation (6) whose general solution is equation (7) and boundary conditions can be expressed by equation (8). By solving the Laplacian equation in region I subject to former boundary conditions, the Fourier expansions of the flux density components in the *r*-, θ- and *z*-directions in region I in the 3D cylindrical coordinate system can be given. The linear electromagnetic force and rotary electromagnetic torque of the actuator can be subsequently predicted by the hybrid method. III.Verification by Integrated 3D FEM To verify the correctness of the analytical solutions, we calculated magnetic field of the LRIPMA using an integrated 3D FE model. The meshed elements are tetrahedral-shaped and the free mesh algorithm is imposed. The predicted flux densities along the r-direction in an electrical period of the tubular mover and along both the z- and θ-directions with different methods are compared. Some excellent agreements verify the validity of the hybrid model. The electromagnetic torque and electromagnetic force in the rotary and linear directions and the flux linkage of the stator winding are subsequently derived and validated by the integrated 3D FE model in the full paper. IV.Acknowledgment This work was jointly supported by the NSFC (51407061) and the NSF of Jiangsu Province (BK20140854).

Metallic glass represents a new type of materials with new physics. Bulk amorphous Nd-Fe-Al based alloys have shown surprising room temperature hard magnetic properties[1]. It has been suggested that the high coercivity could be attributed to that the moments of Fe-rich clusters with high anisotropy are pinned by non-magnetic nanocrystals [2]. However, up to now, the magnetic characteristics of the ferromagnetic Fe-rich clusters have not been fully understood yet. In this work, Φ2 mm $Nd_{60}Fe_{30}Al_{30}$ rod sample was prepared by a copper mold casting method. The remanence, saturation magnetization, and coercivity of the as-cast alloys are 13 emu/g, 18 emu/g, and 283 kA/m, which suggests the typical hard magnetism. Based on the detailed microstructure analysis, the alloy is actually composed of main amorphous phase and hcp structured nanocrystalline Nd phase. The Fe-rich clusters are well distributed in the amorphous phase and the Hcp Nd could act as the domain wall pinning center. ^{57}Fe Mössbauer spectra were applied to investigate the hyperfine structure of the alloys. According to the refined hyperfine parameters, the distribution of the hyperfine field suggests a normal distribution, which confirmed the amorphous structure of those clusters. The mean hyperfine field and magnetic moments of the Fe atoms in clusters are 23(±1) T, 27(±1) T and 1.5(±0.1) μ_B, 1.7(±0.1) μ_B at 300 K and 77 K, respectively. Fig. 1a shows the magnetic hysteresis loops of the $Nd_{60}Fe_{30}Al_{10}$ alloy after cooling at 5 K with and without an applied magnetic field. The M-H loops for the alloy after field cooling shift upwards compared with the loops for that without field cooling. The corresponding magnetic vectors shown in Fig. 1b suggest that parts of the clusters' moments are blocked by the strong pinning effects of antiferromagnetic coupled Nd atoms, which is difficult to be reoriented under an available applied magnetic field. The present data provide some useful information for understanding the ferromagnetic Fe-rich clusters.

GS-01. Comparative study of magnet flux linkage influence on IPM synchronous machine for high-speed properties.

W. Wu[1], X. Zhu[1] and S. Zheng[1]
1. Jiangsu University, Zhenjiang, China

I. Introduction Automotive industry applications are oriented increasingly toward more energy-efficient and environmentally friendly drive-train technologies. This trend is mainly attributed to the detrimental effects of greenhouse gas emissions causing by vehicle emissions. Thus, the diffusion of pollution-free electric cars in urban environment has become an irreversible trend. As one of the key devices in EVs, the choice of electric drive-train most suited to EV's application is still matter of discussions. In particular, the permanent magnet synchronous machines are widely chosen for their higher torque density, high efficiency and mass saving[1]. II. Design Requirement and Machine Topology In general, EVs require a constant-torque performance at low speed and a constant-power one at high speed, as shown in Fig.1 (a). The continuous torque at low speed is determined by the wanted up-hill behavior, while the maximum continuous power determines the maximum speed of vehicles. Besides, the high efficiency of the entire speed region is extremely desired. To achieve the above requirements, scholars have conducted a great deal of exploration on the innovation of machine structure in past years. Therein, two types of machines are widely reported in literatures. One is a PM-assisted synchronous reluctance (PMA-REL) machine with a low PM flux linkage and the other is a flux intensify interior permanent magnet synchronous (FI-IPM) machine with a high PM flux linkage[2][3]. Both types of machines have been proven to be feasible candidate in EV's driving circle[4]. However, the operating features of the two types of machines are not the same especially in high-speed regions. In this paper, by difference combinations of PM pieces and magnetic barriers in rotors, two IPM machines respectively operating with PM-assisted effect and flux-intensifying effect are established, a comparative study is carried out to clarify the influence of PM flux linkage on the high-speed properties of both of the machines. III. Comparative Analysis The structures of the two machines, named PMA-REL machine and FI-IPM machine, are shown in Fig.1(b) and (c). In PMA-REL machine, the PM pieces are inserted in flux barriers of q-axis, with a magnetization direction opposite to the flux generated by armature reaction. Thus, the main function of the PMs is to saturate the rotor bridges and increase power factor of the machine, and only an assisted contribution is made for the output torque. As for the FI-IPM machine, although the PM piece cuts the flux barriers in the middle, resulting in a marked obstacle for the d-axis flux guide, it should be noted that the magnetic field of d-axis can be intensified by applying a positive d-axis current, which really offsets the reduction of the reluctance torque causing by resistance effect of PM pieces. To deeply explore the property of the two machines, the comparison studies are implemented. Fig.2 (a) and (b) shows the change rules of flux linkage versus current amplitudes of the two machines. Fig.2 (c) and Fig.2 (d) compares the inductance characteristics and torque characteristics of the two machines. Fig.2 (e) and Fig.2 (f) exhibits the torque-speed performance and the loss characteristics of two machines. The results show that the FI-IPM machine possesses a wider constant power speed range with respect to the PMA-REL machine, but emerges a higher copper loss and core loss especially in high-speed regions, and it means a relatively lower efficiency in corresponding regions. The more detailed analysis will be presented in the full paper.

GS-02. Improvement of Air Watt in Single-Phase BLDC Motor for 100,000 rpm Applications.

H. Hwang[1], J. Cho[1], Y. Choo[1], C. Kim[1] and C. Lee[1]
1. Electrical and Computer Engineering, Pusan National University, Pusan, The Republic of Korea

Consumer electronics markets are rapidly changed from conventional to premium home appliances with superior performance, convenience, and better design. As elderly people and dual-income households grow, premium home appliances that are easy to use and help the people with housework are preferred. In line with this, competition among premium products is accelerated in cordless vacuum cleaner markets, but there is a lack of literature and research to support this. A brushless direct-current (BLDC) motor uses an electrical commutating device instead of a combination of mechanical commutators and brushes. Hence, it is widely used in high-speed applications than a dc brush-type motor due to no carbon dust and no maintenance about brush wear. A single-phase BLDC motor is suitable for cordless vacuum cleaners that require more compactness and lighter weight due to its simple electromagnetic structure compared to a three-phase BLDC motor. However, most studies on single-phase BLDC motors have focused on motor design for self-starting and cogging torque reduction for spindle motors or low speed fan motors [1-2]. This paper aims to design a high-efficiency single-phase BLDC motor suitable for handy stick-type cordless vacuum cleaner. In designing a single-phase BLDC motor, since the problem of starting and continuous torque generation is most important, asymmetric air gap structure is generally employed. Figs. 1(a) and 1(b) show cogging torque and mutual torque with and without asymmetric air gap, respectively. As shown in Fig. 1(a), the case of symmetric air gap has dead points at which no torque is generated, and hence, cogging and mutual torque become zero during the dead zone. In this case, it is difficult to generate starting and continuous torque. On the other hand, as shown in Fig. 1(b), there are no dead points due to phase difference between cogging and mutual torque caused by asymmetric air gap. From Figs. 1(a) and 1(b), it is noticed that there is a negative region of cogging torque regardless of symmetric and asymmetric air gap. Since total torque is determined by summing cogging and mutual torque, the magnitude of cogging torque along with its phase shift from mutual torque is critical for continuous torque generation without negative torque. Different from the existing study of single-phase BLDC motors in spindle and fan applications [3-4], the variation of DC battery voltage in cordless vacuum cleaners has to be correlated with the ratio of maximum to minimum air gap in a non-uniform stator pole surface. In this study, a single-phase BLDC motor for cordless vacuum cleaners is designed to satisfy three key conditions of starting torque, continuous torque, and battery voltage fluctuation in case of asymmetric air gap. As shown in Fig.2, another important design specification is the volume miniaturization of a motor assembly having a high-speed fan, a driving inverter, and a housing. The dimension of capacitors in the DC link of a driving inverter should be considered at the same time in designing stator lamination to fit the capacitors into the rest of space, and except for the space, both stator and rotor assemblies are occupied inside their housing. Based on the prototype of a proposed single-phase motor assembly in Fig. 2, its several performances have been measured and/or estimated in motor efficiency, inverter efficiency, the efficiency of air flow, and system efficiency. A step-by-step design procedure will be detailed in the final paper, and from the motor itself to its assembly, the result of experimental tests will be also given to validate the feasibility of a single-phase BLDC motor for cordless vacuum cleaners.

GS-03. Multi-physics and multi-objective optimization of a high speed PMSM for aircraft electric propulsion.

W. Zhao[1], X. Wang[2], C. Gerada[3,1], H. Zhang[1], C. Liu[1] and Y. Wang[1]
1. University of Nottingham Ningbo China, Ningbo, China; 2. Yusheng Group, Ningbo, China; 3. University of Nottingham, Nottingham, United Kingdom

High speed electrical machine has been developed and used for many years, and it is now considered a mature and reliable technology for a number of engineering applications, particularly for direct-drive solutions[1]. With the availability of high specification materials, development of power electronic converters and improvement in the manufacturing methodologies, there is currently an unprecedented effort towards developing electrical machines with very high power density and efficiency, especially for the hybrid and full electric aircraft[2]. When designing such type of machines, the interaction and conflict between the electromagnetic, mechanical and thermal aspects should be considered seriously, since they work at the material boundaries[3]. Moreover, maximum power density and maximum efficiency can not be achieved together generally. There exists an optimal design to obtain a relative high performance for both power density and efficiency[4]. This paper started on the sensitivity analysis of the aspects that will improve the active power density of the electrical machine, including the frequency, slot and pole combination, construction of permanent magnetic and thermal management. These topics will be first researched individually and respective behavioural models developed. They will then be merged within a design cycle of the machine in an effort to attain the target performances of 20 kW/kg (active part) at 20 000 r/min for a 2 MW electric propulsion motor for aircraft. The optimization can be divided into two levels. The slot and pole combination is the first level, while the machine dimension is the second level. Considering the power and speed, as well as the limit of switching frequency, the number of poles are limited to 4 ~ 12, and the number of slots are limited to 36 ~ 48 with distributed windings. Seven variables are selected to determine the machine sizing, as shown in Fig.1, which are stator outer and inner diameter D_{so} and D_{si}, rotor inner diameter D_{ri}, active core length L, thickness of permanent magnet H_p, and slot width and height B_s and H_s. For each slot and pole combination, the best design solution can be given by the second level optimization according to the certain objective. Then, the final optimized result can be obtained by comparing performances between each best solution. During the machine sizing level optimization, some variables are fixed to reduce the optimization dimension. The rotor outer diameter is fixed to 190mm to make sure the rotor linear speed is less than 200 m/s, which is the limit of silicon steel laminations. The airgap thickness is fixed to 2 mm, and the permanent magnet pole embrace is fixed to 0.8, which are reasonable for a surface-mounted PM machine with such speed. The RMS line voltage is fixed to 1.1 kV, and the number of conductors per slot, the number of strands per turn and the strand diameter are selected automatically by the analytical electromagnetic program with the limitation of the fill factor. An analytical mechanical model is integrated in the machine dimension program. Stresses are induced in the rotor due to the interference fit between the magnets and the carbon fiber sleeve, as well as due to centrifugal force[5]. The sleeve thickness is chosen so as to achieve a defined design margin according to the magnet thickness. The sizing program also integrates a simple analytical thermal model with three nodes. The temperature of the stator tooth, yoke and coil can be obtained together with the electromagnetic results. Based on the multi-physical field analytical program, optimization constrains can be proposed from electromagnetic, thermal and mechanical point of view. According to the performance requirement, constrains are set as power density ≥ 20 kW/kg; efficiency ≥ 98 %; current density ≤ 20 A/mm^2; flux density of rotor yoke, stator tooth and yoke ≤ 1.4 T (6.5% Si steel sheet); temperature rise of stator tooth, yoke and coil ≤ 125 K ; stress of the sleeve ≤ 1000 MPa; radial stress of magnet ≤ 0 (pressure stress). A multi-objective genetic algorithm is used in the optimization program to find the optimal solution quickly. Three objectives are chosen, max power density (kW/kg), max torque per loss (Nm/kW), and max torque per loss per mass (Nm/(kw*kg)) to describe the comprehensive performance of power density and efficiency. It can be seen from the sensitivity analysis results, the inner diameter of the rotor, core length and slot height are the most sensitive variables to the power density, while the slot height have a major effect on the torque per loss. The final optimal torque per loss per mass solution comparisons of different number of poles are shown in Fig.2. It shows the 8 poles with 48 slots design can obtain a best comprehensive performance between the power density and the efficiency. It makes sense because increasing the number of poles will increase the power density by reducing both the thickness of rotor and stator back iron, whilst will also increase the iron losses and AC copper losses by increasing the frequency. Finally, the optimal design paraments are listed in this paper, and results meet all the requirements. In this paper, a multi-objective optimization research is carried out based on the multi-physical field simulation. According to the optimization and sensitivity analysis results, the key design issues for high power density and high efficiency permanent magnet synchronous machines are discussed.

GS-04. Design and Characteristic Analysis of High Speed Permanent Magnet Motor for High-speed and High-head Centrifugal Pump.

G. Jang[1], S. Seo[1], C. Kim[1], K. Shin[1] and J. Choi[1]
1. Electrical Engineering, Chungnam National University, Daejeon, The Republic of Korea

Recently, the high-speed rotor system has attracted considerable attention as a special purpose application in the industrial field. High-speed rotating electrical machines are an indispensable technology, especially in high-capacity compact systems such as spindle drives for machine tools, turbo-compressors, and microturbines. Such a high-speed rotating machine is directly coupled to a driver or a turbine without a separate speed-increasing gear to obtain a high rotational torque [1-2]. However, because of the mechanical stress of the rotor due to high-speed rotation, the increase in loss due to high-frequency input power, control technology, bearing, heat dissipation, cooling technology, etc., various electrical and mechanical problems may occur. Compared to a high-speed system using a conventional accelerating gear, a high-speed rotating system using a high-speed machine is more suitable owing to its small size, low weight, and high efficiency because the volume of the system is reduced as compared with a general high-speed rotating system. A high-speed device should be designed not only for the basic electromagnetic design, but also for the mechanical structure design and the dynamic design of rotor shaft to be suitable for high-speed rotation. In addition, a control system and inverter must be designed to ensure the reliability of speed and torque characteristics in a high-speed operation. The design of permanent magnet high-speed motors requires precise electromagnetic design for the calculation of mechanical parameters such as permanent magnet rotors, stator, windings, and other parameters of the device. In addition, the most attention to electromagnetic design is in predicting the loss of the machine. In general, the heat source of the electrical machine is due to electrical loss and can be divided into copper loss and iron loss. The copper loss corresponds to the resistance of the current and the iron loss can be attributed to the eddy current, which is the loss due to the hysteresis of the material and the induction current. In addition, rotor losses due to the non-sinusoidal distribution of air flux density and the bearing frictional hand and wind damage present as mechanical losses can be categorized [3-4]. Because loss is an important factor in determining the operating conditions and efficiency of an equipment, it is very important to accurately predict and design the losses. In particular, because of rotor loss due to time loss resulting from iron loss in the stator core caused by the high-frequency operation, the slot structure of the stator and the time harmonics due to the inverter are very sensitive to the design of the super high-speed equipment This paper presents the application of a gearless pump system using a 12500-rpm, 100-hp high-speed permanent magnet motor in a conventional geared pump system. As mentioned above, when the high-speed motor is directly connected to the high-speed pump, the noise, loss, maintenance, and repair costs can be reduced, and the overall system size can be reduced. To apply a high-speed motor, various design techniques such as electromagnetic design, structural design, and mechanical design of a motor are required. Therefore, in this paper, the design and performance evaluation of a 12500-rpm, 100-hp permanent magnet motor is discussed. Fig. 1 (a) shows the shape of the permanent magnet motor designed based on the finite element analysis method. Fig. 1 (b) shows the results of the torque per unit of rotor volume (TRV) analysis and the design points for selecting the size of the rotor of the permanent magnet motor. Fig. 1 (c) shows the stator and rotor fabricated through the design process. Fig. 1 (d) shows the motor test bed with the permanent magnet motor and pump system combined. The torque meter is used to evaluate the performance of the motor during load. The high-speed motor may fail because of the scattering of the permanent magnet during operation. Therefore, the rotor size should be selected in consideration of the rotor stiffness. Fig. 2 (a) shows the results of the eddy current loss of the rotor, and the core loss of the stator using finite element method (FEM). Fig. 2 (b) shows the stiffness analysis results of the motor rotor during no load and during load. Based on the analysis results, we confirmed that the size of the motor has been selected such that no problems are encountered in the mechanical structure of the motor. Fig. 2 (c) shows the results of the high-speed permanent magnet motor design based on the finite element analysis and the experimental results. When the results of the finite element method did not consider the mechanical loss, the validity of the design results was confirmed through experiments. Acknowledgment This work was supported by the Basic Research Laboratory (BRL) of the National Research Foundation (NRF-2017R1A4A1015744) funded by the Korean government.

I. INTRODUCTION The split ratio of rotor outer diameter to stator outer diameter is one of the most important design parameters due to its significant impact on machine torque capability and efficiency. It has been optimized analytically in existing papers with fixed copper loss only which is reasonable for low-to-medium-speed operating machines [1]. However, for high speed permanent magnet machines (HSPMM), the stator iron loss cannot be ignored due to the inherent high frequency. The iron loss can even be dominant for HSPMM operating at ultra-high speed (>100krpm) [2]. On the other hand, the mechanical constraints should also be considered for the design of HSPMM. The mechanical stress is closely related with the rotor outer diameter thus the split ratio. Hence, it is of great significance to investigate the optimal split ratio for HSPMM by taking the stator iron loss and mechanical constraints into account. II. OPTIMAL SPLIT RATIO FOR HSPMM CONSIDERING STATOR IRON LOSS Generally, a two-term iron loss model can be adopted for calculating the iron loss, where the classic loss and excess loss in the three-term model are combined into a global eddy current loss [3]. This model can be expressed as: (1) where denotes iron loss in watts per kilogram, and represent the hysteresis coefficient and eddy current coefficient, respectively. *f* denotes the frequency of magnetic field. B_{Fe} denotes the flux density of magnetic field. The electromagnetic torque of HSPMM can be further expressed as:(2)(3) where k_w denotes the winding factor. B_g is the air gap flux density. k_s denotes the slot packing factor and N_s represents the number of stator slots. l_a is the active stack length and □□$_{cu}$ denotes the mass density of copper. D_o is the stator bore diameter and *g* denotes the physical air gap length. A_s and A_{Fe} represent slot area and stator stack area, respectively. p_{limit} denotes the total allowable stator loss with certain stator external surface area and cooling method. γ represents the ratio of stator iron flux density and air gap flux density. □□$_{Fe}$ denotes the mass density of stator material. Hence, the optimal split ratio for maximum electromagnetic torque considering stator iron loss can be obtained by solving the following differential as:(4) Fig.1 illustrates the stator loss and electromagnetic torque versus split ratio with and without consideration of stator iron loss. It can be seen that the electromagnetic torque would be considerably reduced when the iron loss is taken into account. This should be attributed to the reduced allowable copper loss thus the electrical loading at each split ratio. In addition, the optimal split ratio for maximum electromagnetic torque has also been reduced due to the decreasing copper loss with the increasing split ratio before reaching its minimum value. The optimal split ratio has to be reduced in order to maximize f(λ). It should be noted that torque variation range is relatively smaller when considering the stator iron loss. The electromagnetic torque decreases slowly after reaching the maximum value. As mentioned before, the copper loss turns to increase mildly which make a compensation for the torque by increasing the electrical loading. Hence, the electromagnetic torque would not drop sharply compared with that when only copper loss is considered as shown in Fig.1 (b). III. INFLUENCE OF DESIGN PARAMETERS ON OPTIMAL SPLIT RATIO As mentioned in Section II, the optimal split ratio considering stator iron loss is significantly related with the allowable copper loss variation trend versus split ratio. On the other hand, the design parameters affecting variation of iron loss will impose the opposite impact on the allowable copper loss when the stator loss is fixed with certain cooling method. In this section, these design parameters such as air gap length, operating speed as well as rotor pole pairs on the optimal split ratio will be investigated in the full paper. IV. OPTIMAL SPLIT RATIO ACCOUNTING FOR MECHANICAL CONSTRAINTS This section investigates the optimal split ratio of HSPMM considering the rotor mechanical constraints. Generally, two fundamental conditions should be satisfied: the tangential stress in the inner surface of sleeve should be within the material limits and the contact pressure between PM and rotor back-iron should be always positive [4]. When the mechanical constraint is taken into consideration, the stator flux density will be significantly reduced due to the increasing air gap length. Accordingly, the stator iron loss will be reduced. In addition, the split ratio at which the stator iron loss reaches maximum is also reduced as shown in Fig.2. It can be seen that optimal split ratio is significantly reduced when the mechanical constraints is taken into consideration. V. CONCLUSION In this paper, the optimal split ratio for HSPMM considering the stator iron loss and mechanical constraints are analysed analytically. The influence of design parameters on the optimal split ratio would be discussed in detail in the full paper. Both the analytical and finite element simulated results reveal that the optimal split ratio is significantly reduced when the stator iron loss and mechanical constraints are taken into consideration.

GS-06. Design and Experimental Validation of High Speed Motor for Electric Turbo Charger Considering the Variation of L/D Ratio.

D. Hong[1,2] and Y. Jeong[1]

1. Electric Motor Research Center, Korea Electrotechnology Research Institute, Changwon, The Republic of Korea; 2. Energy and Power Conversion Engineering, National University of Science and Technology, Changwon, The Republic of Korea

I. Introduction Electrically assisted turbo-chargers enabled by high speed air compressors, high efficiency electric motors, and controllers provide the means for a clean, efficient, and environmentally friendly urban transportation system. Centrifugal supercharger motor also known as e-booster, e-charger or electric blower. The electric motors run at speeds in excess of 100,000rpm. We can drive the compressor of an independent supercharger to create steady boost (and power) mostly during startup, transient and low-speed operation. The motor can be turned on and off as needed. This technology also virtually eliminates turbo lag and enables engine downsizing without compromising engine performance. The ETC (Electric Turbo Charger) consists by a high speed permanent magnet synchronous motor (PMSM), ball or air foil bearings, impeller, controller and power stack and so on. KERI (Korea Electrotechnology Research Institute) is developing a high speed surface permanent magnet (SPM) type of synchronous motor and a PWM-driven inverter. This system operates at a power density of 3kW at 100,000rpm and is intended to fit the 1,600cc diesel vehicles to reduce turbo-lag within 0.5sec. It is important to minimize iron loss considering the used operating speed. Therefore, several materials were used such as amorphous core (0.025t), silicon steel core (0.2t and 0.35t). The core loss and the efficiency of each material were analyzed and compared. The design and experimental validation of the PMSM for the ETC have been developed successfully using resistance load test methodology by reaction torque sensor and multi-physics analyses [1]. II. Loss analysis considering several different materials This paper deals with the comparison of electric core performance in terms with cost and core loss of the each material such as amorphous core (0.025t) and silicon steel core (0.2t, 0.35t). To minimize core loss considering cost and resolve thermal problem based on core loss are a way to commercialize the developed product. Fig. 1 shows efficiency comparison according to the change of the used materials. The amorphous core turned out to be the best in terms of electrical efficiency (98.46%) and core loss (9.85W) at 100,000rpm operating speed. Nevertheless, the silicon steel (0.2t) made by POSCO (korea company) is selected considering the cost of price/performance. Fig. 1 shows schematic diagram of back-to-back dynamo test using reaction torque sensor (Kistler) and resistance load (3kW). Generally, there are many test method to evaluate test motor and driver. However there are no 100,000rpm, 3kW rated torque sensor with the exception one branded product which is very expensive and difficult to handle because the bearings should be operated by oil mist condition. Therefore, reaction torque sensor was applied to back-to-back dynamo system. Also resistance load which one ohm is connected in parallel was adopted considering stray inductance by lead wire cable length and capacitor. Fig. 1 shows performance test results which were well matched with goal and simulation results. III. Response surface methodology for multi-objective optimal design To reduce the response time of electric turbo charger should be considered to customize the variation of rotor L/D (Length/Diameter) ratio. The 2nd order polynomial equations of induced voltage and torque were proposed to use customization design according to the change of D/L ratio. Induced voltage and torque can be estimated and predicted by change with of D/L ratio. Response surface methodology (RSM) was utilized by central composite design (CCD) to make metamodel of 2nd order polynomial equations in Fig 2. The design variables were used length and diameter as shown in Fig. 2. Increased rotor length will cause a critical speed issue and saturation problem in the rotor back yoke. Also, if the rotor diameter is longer, there are problems with linear speed of the rotor, the outer diameter of the stator and the increased inertia of the rotor. Therefore, torque, induced voltage and max. flux density of rotor core were considered according to the variation of rotor diameter and length. RSM is a collection of mathematical and statistical techniques. CCD (Central Composite Design) is the typical method because of easy construction for second-order model. CCD are first-order (2^k) designs augmented by additional central and axial points (2k) to allow estimation of the tuning parameters of a second-order model. Two variables were selected. Hence, variable k is 2 and total number of experiments is 9. Based on selected design variables, 2D FEA had been carried out. Fig. 2 shows overlaid plot (feasible range) considering constraint conditions (induced voltage and max. flux density of rotor's back yoke) according to design variables. IV. Conclusion The core materials such as an amorphous core and a silicon steel core for high speed motor are considered and compared. The design and experimental validation of the PMSM for the ETC have been developed successfully using resistance load test methodology by reaction torque sensor. Further, design, experimental validation and the detailed optimum results will be dealt with in full paper.

1. INTRODUCTION Vacuum technology is necessary for semiconductor industry, medical industry and food industry [1]. The vacuum technology is also necessary for the new space industry and other advanced industries [2]. Turbo molecular pumps with high speed rotors are key technology for these industries. Turbo molecular pumps are usually composed of active magnetic bearings, a high speed rotor and its controllers. Thus, the mechanism is very precise and complicated, which leads to high price. In this study, high critical temperature (T_c) superconducting magnetic bearings (SMBs) [3][4] are tried to apply to a high speed rotor for turbo molecular pump because of some merits. *2. DESIGN OF SMB* *2.1 High speed rotor* Fig.1-1 shows an illustration of turbo molecular pump composed of a rotor with two SMBs, turbine blades and a permanent magnet (PM) motor. The pump has a gas inlet at the top and a gas outlet at the lower side. Usually, the gas inlet is connected to a vacuum chamber using a vacuum hose to exhaust the chamber to a certain degree of vacuum. At the same time, water molecules in the air are trapped on the SMB surface and the turbine blades surface. This is called "trapping effect". The turbo molecular pump with SMBs has some higher performances than conventional turbo molecular pumps due to the trapping effect. *2.2 Rotor model* Fig.1-2 shows the rotor models (Model-1, 2, 3) supported by two kinds of bearings (SMB and pivot bearing). The rotor Model-1 (Length: 192 mm), rotor Model-2 (Length: 232 mm) and rotor Model-3 (Length: 232 mm) are supported by (a) a SMB and a pivot bearing, (b) two SMBs and a pivot bearing and (c) two SMBs, respectively. The magnetic stiffness k =12,990 N/m and damping coefficient c =4.5 Ns/m are applied to these models. The pivot bearing is composed of a small stainless bar (D3 mm ×L5 mm), which is attached to the rotor bottom. *2.3 Simulation* By using the rotor models shown in Fig.1-2, the rotor analysis (finite element method) is performed. In the simulation, the rotor spins up to a speed of 20,000 rpm. Then, the displacements for three models are analyzed. Fig.1-3 shows the relationships between rotor displacement and rotation speed for (a) Model-1, (b) Model-2 and (c) Model-3. The displacements in Fig.1-3(a) are analyzed near the points of pivot bearing, turbine blade and SMB. From the result in Fig.1-3(a), each displacement is relatively small over a rotation speed range except for a speed of 5,000 rpm. From the result in Fig.1-3(b), each displacement is very small (smaller than 0.03 x10^{-3} mm) over a rotation speed range except for a speed of 4,000 rpm. From the result in Fig.1-3(c), each displacement is very small (smaller than 0.02 x10^{-3} mm) over a rotation speed range except for a speed of 4,000 rpm. Hereafter, Model-2 and Model-3 are adopted in our study because of the small displacements. *3. EXPERIMENTAL SETUP* Fig.2-1 shows an experimental setup composed of a rotor with turbine blades, two SMBs, a pivot bearing and a PM motor. The SMB is composed of a doughnut-shaped superconductor $Dy_1Ba_2Cu_3O_X$ (OD48× ID25.6× 15 mm, J_c=3 ×10^8 A/m^2 at 77 K and 1.0 T) and four PMs. The PMs are neodymium (Nd) magnets (OD24 mm ×W4.25 mm, surface magnetic flux density 0.26 T). The magnetic poles of the PMs are arranged with alternate polarities, such as NS-SN-NS-SN. The superconductors are cooled by using liquid nitrogen (-196 ^{o}C). Fig.2-2 shows the schematic illustration of the developed rotor. The rotor is composed of turbine blades, PMs for SMB and a pivot for bearing. The rotor Model-2 and Model-3 measure 590 g in weight. Fig.2-3 shows the photo of the experimental setup. Each part in Fig.2-3 is corresponding to that in Fig.2-1. *4. EXPERIMENTAL RESULTS AND DISCUSSIONS* Spin down tests are performed using the rotor Model-2 and the Model-3. Fig.2-4 shows one of the experimental results of free-run test for the rotor Model-3, showing (a) upper rotor displacement, (b) lower rotor displacement and (c) natural rotation decay curve. Figs.2-4(a) and (b) show that the displacement amplitudes are smaller than 0.04 mm over a wide range except for rotation speeds between 4,000 and 5,000 rpm. From the experimental results, the rotor Model-3 with two SMBs is better than the rotor Model-2 with two SMBs and a pivot bearing. Hereafter, the rotor Model-3 with two SMBs is adopted in our study. *5. SUMMARY* In this study, the rotor Model-1, 2, 3 supported by two kinds of bearings (SMB and pivot bearing) are proposed. From the simulation results, the rotor Model-2 and Model-3 are adopted from the three models because of the small displacements. From some experimental results, it is found that the displacement amplitudes of the rotor Model-3 are a little smaller than those of the rotor Model-2 over a wide rotation speed range.

GS-08. Fast Calculation of PM eddy current loss in IPMSM under PWM VSI supply.

S. Zhu[1], M. Cheng[2] and Y. Zhu[1]
1. Deparment of Energy and Electrical Engineering, Hohai University, Nanjing, China; 2. Deparment of Electrical Engineering, Southeast University, Nanjing, China

I. Introduction When calculating the permanent magnet (PM) eddy current loss (ECL) in the interior permanent magnet synchronous machine (IPMSM) under pulse width modulation (PWM) voltage source inverter (VSI) supply, it is very important to take the high frequency harmonic voltages (HFHVs) in the input voltage into consideration because most of the PM ECL in IPMSM with distributed windings is caused by them [1-2]. However, common finite element analysis (FEA) with sinusoidal current source supply isn't able to take the HTHVs into consideration and the coupled field-circuit time-stepping FEA under PWM VSI supply with fine time step is needed for the calculation, which is very time-consuming especially when conducting 3D FEA to take the end effect and axial segmentation into consideration. A hybrid method with the combination of 2D FEA and analytical method has been proposed in [3] for fast calculating the PM ECL considering axial segmentation. However, the 2D time-stepping FEA with fine time step, which takes several hours for one case study, is still needed for the PM ECL calculation under one load condition with the method proposed in [3]. In this paper, the analytical method in [3] is further developed and applied for the PM ECL calculation of an IPMSM applied in the HEV application [4]. Rather than calculating the PM ECL with the average flux density passing through the PM as input [3], the relationship between arbitrary HFHV and the corresponding PM ECL is established. Hence, the total PM ECLs can be calculated with the FFT results of the input line-line voltage directly without time-stepping FEA at a given load condition. II. Relationship between HFHV and PM ECL The HFHV generates pulsating magnetic flux density variation in the IPMSM [3][5], which is the root cause of the additional PM ECL. The procedure to compute the PM ECLs under different HFHVs and load conditions are shown as follows: 1) One step static FEA with the given *d*-axis current i_d, *q*-axis current i_q and rotor position θ at one load condition is conducted. The incremental permeability in each element of the silicon steel is computed and saved. 2) One step linear frequency FEA with the saved incremental permeability and the coupled field-circuit model shown in Fig. 1 is conducted when neglecting the PM eddy current reaction. The average flux density passing through the PM, B_{av}^{n}, is computed. 3) The same linear frequency FEA but considering the PM eddy current reaction is conducted. The PM ECL and the average flux density passing through the PM, B_{av}^{e}, are computed The rotor is assumed to be motionless during the calculation, and the influence of the rotor speed can be taken into consideration by slightly modifying the frequency of the input HFHV. Because the harmonic currents generated by the HFHVs are very small, the saturation level of the silicon steel is mainly determined by the fundamental current, which can be easily obtained with the static FEA with the fundamental current supply. Hence with the fixed permeability method, linear frequency FEA can be utilized to compute the average flux density variation and the PM ECL caused by the HFHV. Fig. 1 shows the coupled field-circuit model for 2D linear frequency FEA, where U_h is the amplitude of the HFHV, ϕ is the phase angle and the frequency f_h is set in the solver. '-' represents the voltage with positive sequence and '+' represents the negative sequence. Each PM block needs to be modeled as a solid conductor with the zero net current constraint for reasonably calculating the PM ECL with 2D FEA [3][6]. The calculation results show that the voltage sequence and ϕ have no influence on the PM ECL. However as shown in Fig. 2, i_d, i_q and θ have effects on the PM ECLs under the same HFHV, which is because they influence the saturation level of the iron rib and the leakage flux path beside the PM. In addition, for a given load condition and fixed θ, B_{av}^{n} and B_{av}^{e} are both proportional to U_h. B_{av}^{n} is inversely proportionally to f_h, however, the relationship between B_{av}^{e} and f_h is rather complex because of the existing of the flux leakage path. Fortunately, the relationship between B_{av}^{e} and B_{av}^{n} can be described with the model described in (17) of [3]. By conducting several FE calculations with different f_h, the leakage flux factor *p* can be fitted. Then, B_{av}^{e} under arbitrary HEHV can be computed with the analytical model and the corresponding PM ECL can also be calculated with (13) or (21) in [3]. Because the axial length of the investigated IPMSM in [4] is short, the leakage flux path at the axial end of the PM can't be neglected. *p* obtained from 2D FEA needs to be modified when applying in 3D calculation. III. Time-Stepping FEA verification and Conclusion When the rotor speed is 2000rpm, the DC voltage is 650V, i_d is -149.8A, i_q is 132.5A and space vector PWM modulation strategy is used, the total PM ECL calculated with 2D nonlinear time-stepping FEA is 165.8W. The sum of the additional PM ECL calculated with each HFHV in the line-line voltage using the analytical method is 163.5W and the PM ECL under sinusoidal current supply is 4.5W, which shows that the proposed method has very good accuracy. In addition, the total calculation time needed for the proposed method is less than 1min, while it takes about one hour for the 2D nonlinear time-stepping FEA. The results of 3D FEA will be presented in the full paper.

GS-09. Thermal-Loss Coupled Analysis of an Electrical Machine Using Improved Temperature Dependent Iron Loss Model.

S. Xue[1], J. Feng[2], S. Guo[2], Y. Li[2], Z. Chen[2], J. Peng[2] and Z. Zhu[1]
1. Electric and Electrical Engineering, The University of Sheffield, Sheffield, United Kingdom; 2. CRRC Zhuzhou Institute Co. Ltd, Zhuzhou, China

Iron loss prediction is very important for the evaluation of efficiency, temperature and demagnetization of electrical machines. The models developed in [1]-[4] are most commonly used iron loss models for electrical machine analyses. However, none of these iron loss models considers the influence of temperature, which has been experimentally confirmed in [5]. In [6], an improved iron loss model which can consider temperature dependencies of hysteresis and eddy current losses separately is developed. By applying the improved iron loss model, the temperature influence on the iron loss can be fully considered. It is then possible to couple the thermal and loss analyses with each other by utilizing the improved iron loss model, which will be the subject of this paper. The iron loss model developed in [4] is one of the most accurate iron loss models when the temperature is constant with the help of variable coefficients. The iron loss p_{Fe} can be expressed as: Equation(1) where f is the frequency. B_m is the peak value of alternating flux density. $k_h(f,B_m)$ and $k_e(f,B_m)$ are the hysteresis loss and the eddy current loss coefficients, respectively. It should be noted that the iron loss model (1) cannot consider the influence of temperature on iron loss while the temperature influences iron loss significantly. According to the iron loss model developed in [5], both the hysteresis loss $k_h(f,B_m)$ coefficient and the eddy current loss $k_e(f,B_m)$ coefficient vary not only with frequency and flux density but also with temperature. Therefore, the improved iron loss model is then developed and can be expressed as: Equation(2) where $p_{Fe,T}$ is the iron loss density at the actual temperature T. $k_h(T,f,B_m)$ and $k_e(T,f,B_m)$ are the hysteresis loss and eddy current loss coefficients, respectively. In order to evaluate the iron loss models in electrical machines, thermal tests and analyses are carried out in a 12-slot/10-pole IPM machine. The schematic diagram of the test system is shown in Fig. 1(a). The 12-slot/10-pole IPM machine is connected a three phase AC power source. The magnets are removed and the rotor is locked in order to eliminate magnet eddy current and mechanical losses. As shown in Fig. 1(b), four thermal couples are equipped in the electrical machine to measure the temperature at different positions, i.e. the stator tooth, the stator yoke, the rotor magnet slot and the rotor yoke. The temperatures are measured when the electrical machine is powered by the AC power source. For the temperature prediction, the iron losses are calculated by the existing model and the improved model, respectively. The thermal model of the IPM machine is also built in Motor-CAD. The thermal model is then analysed with calculated copper loss and iron losses. The predicted temperatures of the electrical machines can be obtained. Fig. 2 compares the measured and predicted results by the existing iron loss model and the improved model. It can be seen that the predicted temperatures by the existing iron loss model become inaccurate when the temperature is high. This is due to the fact that the existing iron loss model cannot consider the temperature dependency of the iron loss. The input iron loss for the thermal analysis keeps constant while the actual iron loss decreases significantly with the temperature rise. On the other hand, the predicted temperatures keep good accuracy when the temperature reaches 100 degrees Celsius or even higher. This is due to the fact that the improved iron loss model considers the temperature dependency of the iron loss. Input iron losses for the thermal analysis vary with the temperature rise. In other words, the thermal and loss analysis can be coupled with each other by utilising the improved iron loss model, which is more close to the actual condition in electrical machines. The details will be investigated and described in the full paper.

GS-10. Harmonic Iron Losses Reduction for Heat Capacity Improvement in Interior Permanent Magnet Synchronous Motor.

M. Seo[1], Y. Ko[1], Y. Kim[2] and S. Jung[1]
1. Sungkyunkwan University, Suwon, The Republic of Korea; 2. chosun University, Gwangju, The Republic of Korea

1. Introduction Interior permanent magnet synchronous motors (IPMSMs) are usually applied to propulsion systems since their advantages such as high-power density, high efficiency, wide operating range, and small size. However, smaller sizes have a higher loss density and limited heat dissipation surface, which make the cooling of the IPMSMs difficult. Overheating of the machine can cause irreversible demagnetization of the permanent magnets (PMs) and insulation of coils also can be damaged [1]-[3]. Hence, it is necessary to prevent overheating through minimizing losses, which is main heat source, and predict the temperature distribution of machines in the design stage. On the other hand, the harmonic magnetomotive force (MMFs) of the motor cause large harmonic iron losses in the stator and rotor. In particular, inverter induced PWM current harmonics can lead to increase of losses, and rotor losses due to slotting and asynchronous harmonics can cause temperature rise in the rotor. It is therefore essential to minimize losses due to these harmonics [4]. Several papers have been reported on the iron loss reduction and thermal analysis of electric machines [5]-[8]. However, few papers conduct thermal analysis for temperature prediction in various regions of motor along with optimization for iron loss reduction in IPMSMs. In this paper, we propose a novel rotor shape of IPMSM for 170kW urban railway vehicle (URV) by using an optimization method. This optimization minimizes the iron losses, including the core loss and the magnet eddy-current loss of the IPMSM, under the pulse width modulation (PWM) control at rated speed. The effectiveness of the proposed design is discussed from the finite-element analysis (FEA). After that, the temperature rise of optimized model is calculated by empirical-based data and the lumped-parameter thermal-network (LTPN). 2. Analysis Model The motor dealt in this study is applied to an URV powered by a trolley voltage 990V. The rating output power, speed, and torque of this motor is 170kW, 2000rpm, and 812Nm, respectively. This motor is driven by a PWM inverter whose carrier frequency 660Hz. This motor is driven by a PWM inverter with a relatively low carrier frequency of 660Hz, since high voltage specifications limit the switching performance of the power device. Considering that the switching frequency of the EV drive inverter is 10 kHz, it is relatively very low frequency, which can cause the harmonic loss to increase by time harmonics of the input current. Therefore, it is important to reduce the iron losses of URV in terms of shape optimization. 3. Iron Loss Reduction Method The objective of the shape optimization is to minimize the torque ripple, and the iron losses including both the core loss and the magnet eddy-current loss. The constraint is that the torque of the optimization model must be at least 95% of the initial model torque. This optimization is performed by combining the explorative-Particle Swarm Optimization (ePSO) algorithm with the regular time-interval FEA analysis [9]. The optimal design process for reducing the iron losses is shown in Fig. 1. The core loss is calculated from the time variation of the magnetic flux density in each part of the core. From the magnetic flux densities in each finite element, eddy current losses and hysteresis losses are calculated based on experimental iron loss data, which is measured according to frequencies. The harmonic fields caused by the inverter carrier are also take into account to consider time harmonic losses. 4. Thermal Field Analysis Thermal field of the optimized model is calculated, using the LTPN method with the derived loss as input. Conduction and convection conditions are taken into consideration along the heat transfer path between the components and the ambient, and the radiation effect is ignored. End part of winding and gaps between surface of winding and components are also considered. Also, Various thermal contact resistances between components within the motor are obtained from empirical-based data of 130kW URV model, which is equal series with 170kW model, to ensure the accuracy of the calculation. The material and dimension of the other component except active parts, including rotor and stator, are the same conditions. Fig. 2. shows comparison of predicted transient results and measured data of 130kW model.

GS-11. Sensitivity Analysis of Inverse Thermal Modelling to Determine Power Losses in Electrical Machines.

D.G. Nair[1] and A. Arkkio[1]
1. School of Electrical Engineering, Aalto University, Espoo, Finland

1. Introduction Mathematically and statistically based models of iron loss in rotating electrical machines aim to estimate losses both qualitatively and quantitatively. Nevertheless, various manufacturing defects and material peculiarities manifest, making measurements necessary to verify the model's accuracy. When existing models disagree with loss measurements, it is difficult to pinpoint the exact cause of deviation since certain machine parts are inaccessible to local measurements of temperature or flux density. Moreover, no-load measurement of core loss too, is not always accurate – current measurement standards concern only sinusoidal voltage supply, whereas inverters supplied machines are on the rise [1]. The possibility to measure local power loss in machines will be of considerable use in verifying loss models. Given the challenges involved, the concept of inverse thermal analysis is apt for the task. It enables determining the unmeasurable heat source causing a measurable temperature rise in a body. This permits identification of power loss in a selected domain of the motor from available surface temperature measurements. Considerable research dealing with inverse heat conduction problems [2] in simple geometries exists. In electrical motors, the inverse approach was employed to determine stator tooth losses through local temperature measurements [3]. As seen here and most others, it is challenging to measure key temperatures accurately, which impedes the inverse reconstruction. A detailed analysis still needs to be undertaken to choose the best inverse methodology to use with electrical motors as well as its sensitivity to the number and nature of measurements. This work focuses on a 37 kW squirrel cage induction motor whose finite element (FE) thermal solution serves as the forward solution The local nodal power losses are inverse mapped from noisy simulated temperature data. The merits of different inverse solution methodologies – constrained linear least square minimization, conjugate gradient (CG) and direct regularization methods are studied and their accuracy and sensitivity in the motor's power loss mapping compared. The focus is on stator core losses, so the stator core is chosen as the domain of interest. The non-trivial geometry in addition to varying distribution of losses in this particular domain pose interesting challenges to standard inverse methodologies. 2 Methodology 2.1 Forward solution The motor's steady-state forward thermal solution results from a high-fidelity 3-D FE model that uses calibrated thermal parameters [4]. Domain power losses were the model inputs. A separate electromagnetic FE analysis calculates the core losses and rotor resistive losses and were experimentally verified. Resistive loss of stator and mechanical losses were measured. The stator core geometry is separated into yoke and teeth and stator core loss is applied separately to these regions. The temperatures of the yoke and teeth surface obtained from the FE solution are used to obtain the heat flux on the stator core volume in the induction motor. 2.2 Inverse Analysis The inverse model strives to find the unknown heat source x in a linear system $y = Ax$ where, the measured temperature y and the linear operator A are known. Usually the measurements are noisy (y^{δ}) where δ is some noise bound. The system matrix of the FE model and its solution vector are representative of these entities in the motor's thermal solution. Actual measurements are simulated by adding normally distributed random noise (0.01 standard deviation) to the nodal temperatures obtained from the surface of the stator yoke and teeth. Conjugate gradient is a fast converging, robust formulation that returns the unique global minima of the system. It iteratively converges to the unique solution x_* that satisfies the stopping criterion $\|y^{\delta}\text{-}Ax_*\| \leq \|\delta\|$. The diagonally preconditioned CG applied here is faster than constrained linear least squares used in [5] clocking 20 seconds while the latter takes 130 seconds. Direct regularization affords more freedom to the inverse reconstruction as it allows imposing regularization conditions that suppress noise and enhance desired characteristics like smoothness in the source term. Tikhonov regularization is an example of this where the objective function $\|y^{\delta}\text{-}Ax\|^2 + \alpha\|x\|^2$ has an additional term influenced by the regularization parameter α. Figures 1,2 present the reconstructed loss distribution (x_{sol}) on the stator yoke surface from inverse analysis compared against the original loss distribution (x_{tru}). 23 measurements of the yoke surface nodes served as the input to the inverse model. The inverse mapping's accuracy is assessed in terms of relative error norm: $100 \times \|x_{sol}\text{–}x_{tru}\| \div \|x_{tru}\|$. Both are vectors of 4138 elements each; the error expression becomes: $100 \times (\sum_i^n |x_{sol,i}\text{–}x_{tru,i}|^2)^{½} \div (\sum_i^n |x_{tru,i}|^2)^{½}$. 3. Discussion Upon clarifying how different surface or boundary measurements affect the inverse solution, a more faithful stator iron-loss distribution can be used as the starting point. Preconditioned CG is quite effective, as evidenced by the low relative error norm. However, the maximum error in certain nodes were still high. Tikhonov regularization fares worse, but can be improved with better choice of regularizing parameter. Further sensitivity analysis with different number of measurements (at teeth/yoke surface and boundary) is also carried out.

This paper describes the analysis on the Number of Axial Segments of Permanent Magnet in SPMSM for Ultra-High-Speed Application; Electric-Turbo Compound System(E-TCS) for Construction Equipment. E-TCS is a device that combines a turbocharger, which is a regenerative device through exhaust gas, and a compressor to improve the turbo lag. As a result, E-TCS must be able to drive at least 80,000 rpm and require a large torque at low speeds. And because of scattering problem of permanent magnets, so limit to increase the rotor size and shaft length is realatively long. To increase performace of motor, difficulties of permanent magnetization and reduce permanent magnet loss, the segment must be applied in the axial direction on permanent magnet. Design criteria and power loss analysis of the ultra-high-speed motor are described by analytical method, and the results are validated by 3D-finite element method. And then, the prototype motor has been fabricated 3 cases and tested. The experimental results confrimed the validity of the proposed design and alalysis scheme of the ultra-high-speed SPMSM(Surfaced Permanent Magnet Synchronous Motor).

GT-01. Accurate Prediction of Dynamic Hysteresis Loops Using the Modified Jiles-Atherton Model.

Z. Li[1], X. Huang[1], L. Wu[1], J. Ma[1] and Y. Fang[1]
1. College of Electrical Engineering, Zhejiang University, Hangzhou, China

I.Introduction Modelling of dynamic hysteresis loops in the electrical steels reveals the magnetic characteristic of the ferromagnetic materials. Jiles-Atherton (JA) model is capable of describing the hysteresis loops by transforming the physical phenomenon into a simple first order differential equation [1]. M. Hamimid *et al.* introduced hybrid magnetic field in the dynamic inverse model, which gave great prediction of dynamic loops [2]. A. P. S. Baghel *et al.* justified the energy equivalence between the JA approach and field separation theory and validated the usage of hybrid magnetic field [3]. In this paper, a modified dynamic JA model is proposed to predict the dynamic hysteresis loops at different frequency and magnetic induction levels, even when the hysteresis loops become elliptical. More attention should be paid to the excess loss in the model due to its increasing share of iron loss at higher frequency. Comparisons of the measured and predicted hysteresis loops using modified JA model are performed to validate the proposed model. II.Modified JA Model and Validation The dynamic JA model was developed to include the frequency dependence of the hysteresis loop via the additional energy dissipation resulting from the eddy current loss and excess loss. This paper adopts the field separation approach to extend the static JA model to the dynamic model, as it does not lead to non-physical solutions and offers better loop shapes. The static JA model can be manipulated to its inverse form as [3] $dM/dB=(\delta_M(M_{an}-M)+kc\delta(dM_{an}/dH_e))/(\mu_0(k\delta+(1-\alpha)(\delta_M(M_{an}-M)+kc\delta(dM_{an}/dH_e))))$ Then the effective field term in the static JA model can be modified using [2] $H_e=H+\alpha M-(H_{eddy}+H_{excess})$ where H_{eddy} and H_{excess} are the classical eddy current field and the excess field, respectively. The excess loss results from discontinuous Barkhausen jump or bowing of active domain walls in electrical steels and can be regard as a special form of classical eddy current loss [4]. According to the Bertotti's theory, the excess field can be given as [5] $H_{excess}=GS/(\rho*n(t))*(dB/dt)$ The two time-dependent functions H_{excess} and $n(t)$ are not independent. The relations between them are postulated and then validated experimentally [6]. $n(t)=n_0+H_{excess}(t)/H_0$ where H_0 and n_0 characterizes the statistical distribution of the internal domain wall field. These expressions of excess field are used to extract the parameters of the dynamic JA model and predict the BH loops as well as the iron loss. However, as the parameter H_0 of instantaneous excess field is validated in the time average [6], the errors between the measured and predicted loops are introduced. They become significant when the component of the excess loss is large. This paper presents a phenomenological approach to reduce the errors of the dynamic hysteresis prediction without changing the area of the BH loop. Meanwhile it still follows the basic principle that the excess loss is only affected by the rate of change of magnetic induction (*dB/dt*). The modified instantaneous excess field is defined as $H_{excess}=(\sigma GSH_0|dB/dt|)^{1/2}+2H_1\lambda/b^2*(b^2-(dB/dt)^2)^{1/2}(dB/dt)$ where b represent the maximum rate of change of magnetic induction; H_1 represent the maximum error between the measured and predicted magnetic field using original dynamic JA model; λ is a directional parameter, which means $\lambda=+1$ when $d^2B/dt^2 \geq 0$ and $\lambda=-1$ when $d^2B/dt^2 < 0$. For the modified model, the maximum errors between the measured hysteresis loops and the predicted loops using original JA model are calculated to obtain the additional parameter H_1. It is clear that H_1 is proportional to the maximum rate of change of magnetic induction from Fig. 1. Thus the value of H_1 can be obtained at any frequency using linear interpolation method. When the component of the excess loss is large, the prediction error of original dynamic JA model become significant while the modified JA model can accurately predict the dynamic BH loops, as shown in Fig. 2. The advantage of the modified JA model is significant when the frequency of the excitation is high and the shape of hysteresis loop is nearly elliptical, as shown in Fig. 2(a). Fig. 2(b) shows that the errors of the predicted loop using the modified model are less than 5% while the errors using the original model are increasing with the frequency. III.CONCLUSION In this paper, a modified JA model is proposed to predict the dynamic hysteresis loops. As the predicted instantaneous excess field based on the statistical loss theory will bring errors due to the approximation of the number of active correlation regions in the time average. The modified excess loss is proposed based on experimental observation and physical consideration to eliminate the error. The predicted dynamic hysteresis loops using the modified JA model agree well with the measured loops, even under the excitation with high frequency. GT-03. Characterization and local phenomenological model of Barkhausen noise under mechanical and magnetic excitations.

B. Ducharne[1], B. Gupta[1], Y. Hebrard[2] and J. Coudert[2]
1. INSA LYON, Laboratoire de Génie Electrique et Ferroélectricité, Villeurbanne, France; 2. SKF aerospace, Valence, France

ABSTRACT Post-treatment and rescaling, it is possible to plot local hysteresis cycles from the measurement of local magnetic Barkhausen noise. If the material is homogeneous and if similar excitation conditions are imposed, the local hysteresis cycles obtained are comparable to the classical magnetic hysteresis cycles *B(H)* (the cross-section magnetic average induction *B* as a function of the surface tangential excitation field *H*). These local Barkhausen noise hysteresis cycles give interesting clues about the evolution of the microstructure of the magnetic material (internal stresses, level of degradation etc.). This makes it an indispensable tool for the non-destructive evaluation of ferromagnetic steels. In this paper, a phenomenological modeling of the Barkhausen noise from the local modeling of *B* subjected to an excitation field *H* and/or a uni-axial mechanical stress *T* is proposed. The objective is to provide an absolute quantification of the internal residual stresses because of the Barkhausen noise measurements. KEYWORDS Barkhausen noise, magnetic hysteresis loop, model, hysteresis, mechanical stress. MAIN TEXT The use of non-destructive micro-magnetic control techniques such as the measurement of magnetic Barkhausen noise has recently increased exponentially in the industrial environment. This renewed interest is mainly due to the improvement of analog and digital signal processing techniques that have allowed this quality control type to be integrated into the production lines in real time [1]. Micro-magnetic techniques can be used to trace interesting properties of the tested samples (hardness, residual stresses, grinding burns etc.) [2]. Barkhausen noise owes its origin to the magnetization processes of a ferromagnetic material. It is established that a ferromagnetic material, even in a demagnetized state is magnetically divided into finite regions called as domains. Each domain is characterized by its own direction and orientation of magnetization. The process of magnetization consists of converting this multi-domain state into a single domain characterized by a direction and a sense of magnetization very close to the external magnetic field *H* imposed on the material. This process is not continuous but consists of small discrete variations: jump from a pining defect (micro-structural obstacles like precipitation) to another defect of the domain walls (domains boundaries) [3]. This local variations of magnetization states are known as "Barkhausen event". These changes induce pulsed eddy currents near the moving domain walls that develop in all space directions. These abrupt changes in the magnetic structure through the material also induces local and rapid flux variations that can be easily measured using a dedicated local micro magnetic field sensor. In recent publications dealing with the topic, many authors define a new quantity called Magnetic Barkhausen energy (MBN_{energy}) [4]. The MBN_{energy} is obtained from the temporal integration of the square of the local magnetic field sensor voltage output (equation 1). This "post-treatment" technique can be used to trace a hysteresis cycle $MBN_{energy}(H)$ from the local measurement of magnetic Barkhausen noise. At low frequency, if the material is homogeneous and isotropic and after rescaling thanks to a coefficient ν, the Barkhausen cycles obtained are very similar to the usual hysteresis cycles *B(H)*. equation 1. These observations confirm the microscopic origin (wall movements) of the magnetic hysteresis under low frequency excitation. In the extended version of the article, the numerical scheme will be described that is used to return the temporal Barkhausen noise envelope under both magnetic and uniaxial mechanical stress. This numerical scheme is based on both local magnetic hysteresis model and an inverse method linked to magnetic Barkhausen energy. Figure 1. Magnetic Barkhausen noise (left) and simulated Barkhausen envelop under both magnetic and uniaxial mechanical stress excitations. The good simulation results displayed in Fig. 1 are very promising. By correctly anticipating in simulation the material behavior, we will have access to some microstructural information (such as precipitations, local residual stresses). From a non-destructive evaluation point of view, this set of information will allow us to anticipate some failures and ageing issues.

With the rapid development of micro-nano manufacturing technology, there are more and more fields need nano-driven control technology, such as the high-precision positioning systems [1]. Magnetically controlled shape memory (MSM)-alloy actuators serve as the core part of high-precision positioning system on account of their high precision, large energy density, and small volume. The hysteresis nonlinearity of the MSM-alloy actuator, however, severely damages the positional accuracy of the positioning system. In order to research the hysteresis nonlinearity in the MSM-alloy actuator, hysteresis nonlinearity modeling has become a significant hot spot of research [2][3]. The purpose of this study is to structure an excellent hysteresis nonlinearity model to capture the hysteresis nonlinearity in MSM-alloy actuators. The criterion for evaluating modeling performance is that the established hysteresis model can embody the actual characteristic of the actuator. In this study, a novel black-box model composed of the hysteresis-like structure and a nonlinear function is proposed to capture the hysteresis nonlinearity of the MSM-alloy actuator. The proposed black-box hysteresis nonlinearity modeling approach has the advantages of requiring no prior knowledge and internal physical mechanism. The hysteresis-like structure solves the multi-value mapping problem and accurately depicts the major and minor hysteresis loops of the MSM-alloy actuator. The nonlinear function represents the nonlinearity part of the MSM-alloy actuator, which is identified using least squares support vector machines (LS-SVM) on account of its strong approximation capability, high generalization ability, less parameters, and great computing power. The schematic diagram of black-box model is shown in Fig. 1. u(k) is the input current at *k* time, y(k) is the output displacement at *k* time, F[●] is the nonlinear function, H_u[●] is the hysteresis-like part of the black-box model. In the procedure of modeling, u(k) and y(k) are the input values of hysteresis-like part; u(k), y(k), and H_u[●] are the input values of nonlinear function, which is obtained by the LS-SVM. To certify the effectiveness of the black-box model, the simulations are implemented using the obtained experimental data. The simulations show that the modeling error rate of the novel black-box model based on the LS-SVM is 1.37%, which is improved 73.97% in compared with the results in [4]. It is obvious that the modeling precision of the proposed hysteresis model is within the allowable range. The simulation results are shown in Fig.2. The blue solid line is the obtained experimental data, and the red dotted line is the output of the proposed black-box model. As shown in Fig.2(a), the proposed black-box model based on the LS-SVM can accurately describe the major and minor hysteresis loops of the MSM-alloy actuator. The modeling error curve is shown in Fig.2(b). In the future, the proposed black-box model can lay a foundation for designing an adaptive controller to eliminate the hysteresis nonlinearity in the MSM-alloy actuator.

ABSTRACT Accurate and simple magnetic material law is necessary to correctly model the complete electromagnetic systems. In this article, a new formulation based on the scalar quasi-static hysteresis Jiles-Atherton model extended to dynamic behavior using fractional derivative dynamic contribution is proposed. The fractional contribution is solved using convolution which highly reduces the numerical issues. The order of the fractional derivation provides a new degree of freedom and allows to obtain correct simulation results on a very large frequency bandwidth. By using such a formulation, highly space and time consuming space discretization techniques (finite differences, finite elements) are avoided while keeping the global accurate simulation results. KEYWORDS Hysteresis, ferromagnetic material, Jiles-Atherton model, fractional derivatives. MAIN TEXT The development of new electromagnetic designs, such as the improvement of already existing ones require precise simulation tools. These numerical tools can also be used for the estimation of ferromagnetic losses. In the micromagnetic non-destructive testing field, they are used for the understanding and the interpretation of non-destructive control techniques such as eddy current testing, magnetic incremental permeability or magnetic Barkhausen noise [1] [2]. Previous scientific progress in the electromagnetic simulation domain mainly focuses on coupling space discretization techniques (Finite Elements Method (FEM), Finite Differences Method (FDM)) to accurate scalar or vector, dynamic or static hysteresis material law [3][4]. For this material law, the best results come from the extension of a vector quasi-static hysteresis contribution (Preisach model [5], Jiles-Atherton model [6]) to a dynamic behavior as it is defined by the separation losses in the Bertotti's theory [7]. Unfortunately, the usual simultaneous resolution of space discretization techniques and hysteresis models can only be performed by time and high memory space consuming iterative techniques. One of them is the so-called fixed point scheme. If the non-linearity levels are weak, this technique gives accurate results whereas for higher levels (strong hysteresis, saturation) numerical errors are always observed. In this article, an original alternative to space discretization techniques is proposed. In this approach, the space discretization is left behind and the focus is on numerically reproducing the time variations of lump quantities (The cross-section average induction field B, and the surface tangent field H). A few months ago, by extending the Preisach model quasi-static contribution to fractional derivation operators, the authors succeeded in obtaining very accurate simulation results on a very large frequency bandwidth [8]. Unfortunately, the issue here, comes from the Preisach model congruent property, i.e. the similarity of the minor cycles obtained for a given H variations at different levels of B. This property becomes real inconvenient, when we try to plot the butterfly loop required by the magnetic incremental permeability technique [9]. Indeed, using Preisach model is limited to just one curve and exhibits no hysteresis. To improve this, a switch from Preisach's model to Jiles-Atherton's model has been finalized. In this article, we explain with details, how we succeed in simulating the butterfly loop and the B(H) curve on a large frequency bandwidth by extending scalar Jiles-Atherton's quasi-static contribution to dynamic behavior thanks to fractional derivation operators. Fractional derivative is introduced in the lumped quasi-static hysteresis model through a dynamic contribution. Eq. 1. And fig. 1 gives a quick overview of the model equation, n is the fractional order and J.A the Jiles-Atherton model. Fig. 1. Block scheme for the Jiles-Atherton extended dynamic model. Fig. 2 gives a first illustration for the model accuracy by comparing simulation and experimental results for a major hysteresis cycle obtained under dynamic sinus excitation H (400 Hz). In the final version of the article, a large number of comparisons simulation/measure will be provided, the good results obtained for the butterfly loop will also be illustrated. Fig. 2. Comparison of simulation/measurement for Iron/Silicon non-oriented grains under 400Hz sinus excitation field H.

1. Chongqing University, Chongqing, China

Hysteresis is a nonlinear operator that exhibits remanence and selective memory. The effects of the input to the hysteresis system are experienced with a certain delay in time. Thus, the output of the hysteresis system cannot be predicted by current state without the knowledge about the history of the hysteretic system. This phenomenon is originated from magnetic, ferromagnetic and ferroelectric materials. Various methods have been proposed for modeling hysteresis in the last decades, such as the Stoner–Wolhfarth, Jiles–Atherton and Preisach models. Among them, the Preisach model is one of the most practical methods. It is very commonly used for hysteresis modeling in ferromagnetic materials. Preisach model is a history-dependent model, and includes wiping-out property and congruency property, which are the most important characteristics to display the hysteresis phenomenon. The main difficulty of this model is the determination of the distribution function from experiments. Identification of the Preisach distribution function (PDF) is of importance in manifold hysteresis systems. The direct Mayergoyz's method yields an exact PDF reconstruction by collecting the first-order return branches and derivating the obtained Everett function over the Preisach plane. However, this method requires a large number of experience data, and first-order return branches are difficult to be obtained in some cases, such as large power transformers. Centered cycle method [1] is proposed to calculate the PDF by a set of symmetrical waveforms which can be easily obtained in the field. Preisach triangle is uniformly discretized to $n(2n+1)$ cells by n centered cycles and can be determined by the cell-method. Owing to the odd symmetry of the centered cycles, the distribution function is symmetrical to the axis. Therefore only $n(n+1)$ cells values have to be determined. The centered cycle method was validated by experiments and showed the effectiveness for both major and minor cycle modeling. The distribution function is unique, and no optimization method is needed. This method can also be applied to the inverse distribution function determination without any changes. However, there are also some limits for the centered cycle method. When the PDF is identified by centered cycle method and used to calculate hysteresis loops, the errors are relatively large around the knee point due to the large change rate of the flux-current curve around this knee point. If increasing the quantity of center loops in high-curvature region, according to the rules of the centered cycle method, there will be extra tremendous work paid for the low-curvature region, which is not necessary and significant decreases the calculation efficiency. Therefore, this paper proposes an improved centered cycle method using non-uniform discretization to identify the Preisach distribution function. This algorithm enhanced the sensitivity to the region in which the curvature of the hysteresis loops changed more than the other regions, which means that more loops are used for high-curvature regions and less loops for low-curvature regions. Then the distribution function is identified by the non-uniform cell created by the improved center cycle method. Fig.1 shows the anhysteresis magnetization curve and the curvature curve of a sample made of a ferromagnetic material. The curves are divided into three parts by three lines. The value at the right line is H=Hm, which represents the ultimate magnetic field intensity. According to the curvature, these three parts can be named as high-curvature area, low-curvature area and flat area respectively. S1, S2 and S3 are the regions surrounded by H axis and corresponding curvature curve. The area of the regions can quantitatively describe the variation of L. The larger area represents more variation the inductance. As a result, the number of loops selected for identification is proportional to the area in each part. The equidistant loops are measured in each part. Therefore, the Preisach plane are uniformly discretized in each part and non-uniformly discretized as a whole. As Fig.2 shows, there are n loops in the Preisach plane as solid line. And with the dash line, the plane is non-uniformly discretized into many non-uniform cells. The PDF of the innermost part should be determined first by directly using the center cycle method. Then the PDF of the rest part is determined from inside layer to outside layer by the data of two surrounding hysteresis loops. The distribution function of the cell is determined by the difference of the magnetic flux density B of two loops in the same magnetic-field intensity H. Thus, all the cells are determined. However, the non-uniform cells are hard to calculate hysteresis loops. Therefore, for each cell in the Preisach plane, it can be discretized into several squares with the same size. In this way, the entire plane is composed of a large number of small squares. So the non-uniformly discrete plane can be transformed into uniformly discrete plane. The proposed method is validated by laboratory tests, it shows higher precision of predicting the hysteresis loop than center cycle method in the same number of measured loops.

Rate independent hysteresis in magnetic materials has been studied for a long time. The evolution of magnetic flux density *B* depends on the current as well as the past values of input field strength *H*. The Preisach model [1,2] offers a framework for modeling static magnetic hysteresis. Computationally the hysteretic output involves an evolving geometrical quantity that looks like a staircase, and an integral of a two variable Preisach density μ under that staircase. The underlying μ has been treated differently by different authors. Some directly interpolate between values on a grid, while others assume specific functional forms of μ with fitted parameters. Another popular approach is use of first ordered reversal curves (FORC) [3]. Our main contribution is that instead of *a priori* assumption about functional forms, we expand μ in a general form using global basis functions defined on a triangular domain. Nonlinear scalar transformations both precede and follow the Preisach calculation. Fitting results, with our own experimental data, are good. A minor contribution is a transparent state-matrix description of the Preisach staircase and simple Matlab code for incrementing the state. The first nonlinear transformation of *H* uses the arctangent function to map the input to a bounded region. The Preisach density μ is expanded using basis functions defined on that bounded region. An exponential is used to ensure $\mu>0$, as in $\mu(\beta,\alpha) = e^{\sum_i a_i \psi_i(\beta,\alpha)}$, where the basis functions $\psi_i(\beta,\alpha) = \cos(k_i \pi \beta/2) \cos(n_i \pi \alpha/2) + \cos(n_i \pi \beta/2) \cos(k_i \pi \alpha/2)$, where in turn the integers k_i, n_i are nonnegative, either both even or both odd due to symmetry arguments. Integration of μ (see above equation) under the Preisach staircase is done numerically. A final nonlinear transformation of the integral output gives a good fit with the experimentally measured *B*, for both soft and hard loops. A tiny regularization or penalty term is used during parameter fitting to reduce spurious oscillations due to nonuniformly spaced fitting data points. In our experiments, we measured magnetic hysteresis in two different ferrite toroids to obtain *soft* and *hard* types of loops for multi-frequency inputs with multiple partial reversals. The parameters, transformation parameters and basis coefficients a_i, are obtained by minimizing the squared error between the predicted and experimental loops over several datasets. We obtained a good match with 12 shape functions for soft loops, and 20 for hard loops. In total, we used 15 fitted parameters for our soft loops, and 25 fitted parameters for our hard loops. While the number of fitted parameters may at first sight seem large, our approach is general, our data is complex, and our fit is good. Finally, we theoretically and qualitatively demonstrate the necessity of a final nonlinear transform of the Preisach ouput for hard loops. Figure 1 shows the estimated density for soft and hard loops. The high gradients seen for hard loops are easier to capture with the exponential form of μ. Figure 2 shows the match against the experimental data for both soft and hard loops. An excellent fit is achieved for the soft loops. The results for the hard loops are slightly inferior, but still good. Overall, our method is quite general (both soft and hard loops), conceptually simple, and accurate.

I.Introduction The magnetization of a ferromagnetic material can be regarded as a collection of all magnetic particles inside the material. Lots of hysteresis models have been proposed based on different operators (particles) and principles [1]. In the traditional Preisach model, the material magnetization can be assumed as the superposition of a set of rectangular hysteron with a fixed unit magnitude. In the Stoner-Wohlfarth (S-W) model, it is assumed that the ferromagnetic material is composed by a lot of single-domain particles which with uniaxial crystal anisotropy. Bertotti proposed the original concept of elemental operator with biaxial anisotropy and the graphical interpretation method [2]. In this paper, the elemental operator is fully analyzed based on the magnetization mechanism. With the employment of the partial approximate substitution, the drawback of the graphical interpretation method can be addressed, and an improved analytical expression of magnetic field and magnetization on each operator is obtained. Finally, the approach is verified by the experiment on two different ferromagnetic materials. II.Elemental Operator For the ferromagnetic materials, each magnetic dipole in the iron crystal particle is regarded as an elemental operator with biaxial anisotropy on arbitrary crystal plane. Then, it is assumed that the ferromagnetic material is composed by lots of interacting elemental operators, as shown in Fig. 1. Similar to the conventional S-W model, the magnetization orientation of each biaxial anisotropy elemental operator can be obtained by the energy minimization [3]. Similar to the treatment in the case of uniaxial S-W particle, the minimization of the total energy indicates when the orientation of biaxial elemental operator is stable, the equilibrium orientation of the magnetization can be determined. After trigonometrical transformations, the first and second derivatives of the energy equtation can have 4, 3, 2 and 1 real minimal value depending on the magnitude and orientation of the magnetic field intensity. The curve, which separates the regions with different energy extremes, is called as biasteroid or windrose curve[2]. This elemental operator is derived in the form of two dimensions, and can be adopted to model the scalar magnetic hysteresis by restricting the applied magnetic field to vary along one dimension and ignoring the transverse hysteresis component. To represent the bulk magnetization of the ferromagnetic material, the contributions of a collection of elemental operators should be summarized. However, the graphical interpretation method, as discussed above, is fail to describe the relationship between applied field and the resultant magnetization with an analytical expression. This problem largely limits the quantitative analysis of the magnetic properties based on the elemental operator. To address this problem, the partial approximate substitutions approach can be employed. With the new symmetry considerations on the magnetic anisotropy, the anisotropy energy can be a power series expansion of the modulus of the direction cosine. Then the energy minimum of one single operator can be obtained by an analytical way. III.Numerical Implementation After the magnetic properties of one single elemental operator has been fully studied, the bulk magnetization M of a SMC material sample can be determined by integrating the effects of all the elemental operators in the sample with a two- dimensional distribution function. With different parameters of the distribution function, this model can be employed to simulate the hysteresis loops of different materials. In this model the distribution can be described by a two-dimensional Gaussian-Gaussian distribution [4]. The adjustable parameters of distribution function can be determined numerically by fitting the model to the limiting hysteresis loop. Then, the major loops and minor loops can be predicted according to the solved distribution function. IV.Experimental Verification To verify the accuracy and the feasibility of the presented elemental operator, the hysteresis loops (including major loops and minor loops) of two different ferromagnetic materials, soft magnetic composites material SOMALOY™ 500 and non-oriented silicon steel Lycore-140, are measured under alternating magnetic field by the magnetic property measurement system [5]. As shown in Fig. 2, the simulated results agree well with the experiment results in both major hysteresis loops and minor hysteresis loops. V.Conclusion In this paper, the elemental operator with biaxial anisotropy has been introduced based on the magnetization mechanism. With the help of the improved analytical expression, which deduced by the partial approximate substitutions, the scalar magnetic properties of ferromagnetic materials are simulated and compared with the measured results. It can be proved that the results predicted by the model are acceptable. Additionally, the vectorial elemental operator is a feasible method to simulate the scalar magnetic hysteresis of ferromagnetic material.

I. Introduction Direct current (dc) bias is a kind of abnormal working state of power transformer. The presence of dc biased magnetic field in the operation of a power transformer may intensify the vibration and noise in transformer cores because the magnetostriction of electrical steel sheets results in the deformation of transformer core [1-2]. There are some methods and techniques that have been implemented to mitigate and reduce the dc bias' effects. However, in order to make more accurate performance predictions, these procedures require an accurate mapping of the material characteristics under a dc bias's condition. Until now, some significant researches have been conducted on the measurement of such magnetostrictive characteristics in an electrical steel sheet as rotational magnetostriction, anisotropic alternating magnetostriction and its dependence on frequency [3-4]. However, the influence of presence of a dc bias at the magnetized field on the magnetostrictive characteristics has not been well identified yet. In this work, based on an Epstein frame, an experimental setup was built to measure the in-plane magnetostriction and the principal magnetostriction was computed under a dc bias. The influence of dc bias magnetic field on the magnetostrictive property of electrical steel sheet was investigated. Based on the experimental test results, a description of the magnetostrictive behavior in the presence of dc bias was presented by using a back propagation neural network (BPNN) model assisted with the Levenberg-Marquardt (LM) algorithm. This research is helpful to make an accurate estimation to deformation of iron cores under a dc bias. II. Experimental Approach An experimental setup measuring the magnetostrictive property of electrical steel is shown in Fig. 1, in which the Epstein frame, MPG200, Brockhaus in Germany, is employed to magnetize the double-overlapped samples. During the measurement, the magnetic field intensity *H* created by the main winding in the Epstein frame can be superposed with a dc biased field with 0 A/m, 5 A/m, 10 A/m, or 15 A/m and the magnetic induction *B* measured by the second winding can be controlled as a purely alternating *B* with amplitudes of 0.1 T to 1.9 T and 50 Hz. In order to magnetize the specimens along different angles with respect to the rolling direction (RD), the samples were cut at 15° intervals from the RD to the transverse direction (TD). A rosette foil resistance strain gauge is attached to the surface of electrical steel sheet to obtain an in-plane magnetostriction in an arbitrary direction. The strain gauge is connected to the strain bridge box and strain amplifier, then the strain signals are transferred to a NI PXle-6368 data acquisition card and processed by LabView program. The measurements are performed on the samples of a grain-oriented 0.35 mm-thick 3% Si-Fe material. III. Analysis of Magnetostrictive Property Fig. 2 shows the variation of in-plane magnetostriction in any arbitrary direction for one instant of time with the magnetization directions of 0°, 30°, 60°, and 90° with respect to the RD, respectively. In this figure, the elongated strain is depicted as blue lines and its principal strain is λ_p^+ marked with a blue arrow, and the contractive strain is red line and its principal strain is λ_p^- with a red arrow. It can be seen that the principal strain gets bigger with the increase of the magnetization angle deviated from the RD due to more 90° domain wall motions' contribution to the magnetostriction strain, the contractive principal strain is always greater than the elongated principle strain, but the direction where the principle strain occurs keeps constant. As a result, the magnetostriction strain in the grain-oriented steel behaves in anisotropic ways under the alternating magnetizations. Fig. 3 represents the principal strain waveform λ_p^- in one time period with several imposed dc biased fields H_{dc} when the samples are magnetized along the RD and magnetic induction *B* are controlled as 1.2 T and 1.8 T, respectively. In the case of H_{dc} = 0 A/m in Fig. 3(a), the waveform of magnetostriction varies at a frequency of 100 Hz that is twice that of *B* signal (50 Hz). In the presence of a dc bias magnetic field, such as 5 A/m, 10 A/m, and 15 A/m, however, the waveform does not change periodically two times and lose its symmetry at time 0.01 s. We can see that the asymmetry trend increases with the increase of the dc biased magnetic field, and the peak to peak value also increases. However, the symmetry of the magnetostrictive waveform in Fig. 3(b) is restored at high induction *B* of 1.8 T, and the peak to peak value is basically the same. It can be concluded that the influence of the dc biased field on the magnetostrictive strain is little when the samples are magnetized gradually into the saturation stage. One explanation for this phenomenon is that the magnetic domain wall displacement and magnetic torque rotation tend to be completed with approaching the saturated magnetization, which is regarded as the saturated characteristic of magnetostriction. In the full paper, the effect of dc bias magnetic field on the magnetostriction anisotropy of electrical steel sheet will be investigated, in addition, a modeling method of the magnetostrictive behavior in the presence of dc bias will be studied.

The great advantage of HTS coils in magnet is that it can provide large excitation in a limited space. However, under high level excitation condition, especially in the case of fast adjusting process, AC losses will occur and lead to reduction of thermal stability [1], [2]. Therefore, it is necessary to calculate AC loss of HTS coils quickly and accurately. The homogenization method based on H formulation basically meets the calculation requirements of AC loss for a thousand-turn magnet with simple structure [3]. However, for magnets with non-linear ferromagnetic materials such as HTS controllable reactors [4], [5], the non-linear saturation in ferromagnetic domains makes it difficult to calculate AC loss rapidly and accurately with homogenization methods. Three simplified calculation methods of AC loss for HTS magnets have been proposed in this paper. In order to verify the validity of the simplified algorithm quickly and effectively, a two-dimensional axisymmetric model is adopted. The key to reducing the nonlinearity is to quickly calculate the magnetic permeability distribution in the core region. Three methods have been proposed to simplify the calculation. The first method is A+H formulation method. In the A formulation, set the same resistivity through the current flowing area, apply a uniform current density excitation and set BH magnetic properties in the core. In the H formulation, set the nonlinear resistivity decided by E-J characteristic through the current flowing area [6], apply a total current constraint and the magnetic permeability of the core region is from the real-time calculation of the A formulation results. The coupling between the two formulations does not occur during the solution, but the permeability of the core in the H formulation is provided by the calculation of the A formulation. The second method is magnetic permeability transfer of the core region method. Core area is divided into different regions. The magnetic permeability in all the core regions is solved in the A formulation, which is made into a data table. Then the magnetic permeability is applied in the H formulation model as a known item. The third method is A formulation coupling with H formulation method (A&H formulation). A formulation and H formulation share the same model. The PDE module (the control formulation is the H formulation) only contains the superconducting domain and part of the air domain around the superconducting domain. All the domains are contained in the magnetic field module (the control formulation is the A formulation). The core domain is described by the BH curve. The HTS coils are excited by the uniform current density. The section boundary of air domain is shared with the PDE module to transfer the magnetic field strength to the PDE module. The example model is a small iron-containing superconducting magnet, which is modeled with a homogenization method. Considering that the H-formulation method is widely used and supported by a large number of experiments [7], [8], the present example uses the H-formulation results as the benchmark in the error analysis of each method. Fig.1 shows the calculation time with different methods. In the linear discrete model, A+H formulation solves two physical formulations for the whole domain, which has the highest degree of freedom and a 13.5% increase in the number of degrees of freedom compared with other linear discrete models. The A-formulation coupling with H-formulation adopts quadratic discrete and has the highest degree of freedom, which also has the longest solution time. Fig.2 shows the average loss of each method. The average loss of each model with linear discreteness is not much different from that of the H-formulation model and the maximum deviation is 0.527%. The error of the third method using the quadratic discrete is larger, ranging from 11.59% to 20.47%. Both of them are larger than the H-formulation calculation results. In summary, the first method is the first choice when we calculate AC Loss for a HTS Magnet with Iron Core. If the degree of freedom is too large in the model, we can choose the second method. If the AC loss is still difficult to calculate, we need to choose the third method at the expense of a little accuracy. This paper presents three simplified calculation methods of AC loss for HTS magnets, which make it possible to calculate the AC loss of the core-containing superconducting magnet rapidly and accurately. The first two methods have high precision, but they are not suitable for the large-scale model. The third method can calculate the large-scale model quickly, but there is a small amount of error.

I.Introduction Non-oriented silicon steel is widely utilized as main core materials for electromechanical equipment, such as motors and generators, because of their attractive characteristics of high magnetic saturation point, good mechanical strength, little anisotropy, and low cost. Iron loss is the key index especially for high speed motor, which could take a larger share in the total loss compared with low speed motor. Considering the high speed motor could operate in the higher temperature environment, temperature dependent iron loss model is one of the focus recently. There are a lot of iron loss models based on loss separation principle, such as three-term model, two-term model. Considering the frequency and temperature effect, there are constant coefficient models and variable coefficient models[1]. Regarding the model fitting, someone uses the multi-frequency loss curves to fit all coefficients, but someone not. Up to now, accurate measurement of motor iron loss is very difficult. Furthermore, research papers published recently use ring specimen and Epstein frame to validate the temperature dependent iron loss model. Too many iron loss models make people a little bit confusing, iron loss calculation and validation on motor is still an open question. This paper aims to examine those temperature dependent models based on a stator core(product-level) and ring specimen(sample-level) in a wide range of frequency and temperature. II.Temperature Dependent Iron Loss Models The initial expression for the iron loss in magnetic materials was proposed by Steinmetz [2], where iron loss is a sum of hysteresis loss and eddy current loss. In [3], a third term in the iron loss expression was introduced by Pry and Bean. The iron loss is divided into hysteresis loss, classical eddy current loss and excess loss. By improving the modelling of the excess loss, an iron loss model was proposed by Bertotti et al. in [4, 5]. Since the Bertotti model has a good physical background, it has been evolved into many different expressions and is widely adopted for iron loss calculation. However, it is pointed out in [6] that the contributions of classical eddy current loss and excess loss couldn't be easily separated by an Epstein frame or a ring specimen test. Alternatively, a new two-term approach is developed in [6], where the classical eddy current loss and excess loss in Bertotti's three-term model are combined into a comprehensive eddy current loss. Since this two-term model is easy to implement and has an equal accuracy for non-oriented silicon steel, it is widely used in electrical machine design and optimization [7-8]. The above mentioned iron loss models are based on constant coefficients. However, the iron loss coefficients change with the flux density and the frequency [9-10]. Therefore, the iron loss models containing variable hysteresis and eddy current loss coefficients are developed by Xue et al[11]. These models are used for the iron loss predictions in [12-13]. III.Experimental Validation Due to difficulties on loss separation, especially the existence of stray loss and frictional loss, it is difficult to directly validate the iron loss model on a motor. So, as a first step, only alternative magnetization is involved. This paper plans to evaluate the iron loss model on a stator core, with slot, teeth and variable axial length. To avoid the uncontrolled factors from specimen, we bought the silicon steel directly from the WISCO, China, then tailored the silicon steel into ring sample and stator lamination, respectively. Stacked ring sample is used to fit the iron loss model coefficients, whose outer diameter is 40mm, inner diameter 32mm. Stator lamination is used to build a product-level core and evaluate the iron loss model. All the specimen preparation and wire cutting is done within the laboratory. Non-metallic fixture is customized to avoid the undesirable electromagnetic loss, shown in Fig. 1(a). Firstly, DC and AC magnetic property of ring sample is measured at 0~400Hz, 0.1~1.9T, RT~200 Celsius degrees. Secondly, DC conductivity measurement was carried out in the same oven, shown in Fig. 2. With these measured data, we can fit various iron loss models mentioned in Section II. During the specimen measurement, back EMF of secondary winding become non-sinusoidal when magnetic induction is larger than 1.7T. Therefore, we use the time domain loss expression to fit these experimental data, if waveform factor of secondary winding EMF exceeds 1.11±0.01. Thirdly, the wound stator core will be put into the same oven to obtain the iron loss. Only massive validations can lead to a practical research result. In order to fully validate these models and eliminate exceptions, the measurement is implemented on 1 piece, 5 pieces, 10 pieces and 20 pieces, respectively. Measured iron loss should be proportional to number of pieces, and this criterion is used to justify the measured stator iron loss. The prediction of stator iron loss is implemented based on FEM software JMAG, where the flux density of each element is exported to MATLAB workspace so as to obtain the iron loss values of different models. Now, the specimen measurement and fitting is finished, partial result is shown in Fig. 1(b). The stator core measurement is being done and the comparison of model prediction result will be given in full paper.

Introduction Numerical methods and mostly finite element analysis (FEA) are popular in electromagnetic modeling because they are standardized methods and because of the availability of a large number of commercial software. However, the computation time may be prohibitive, especially for 3D models. Analytical models are fast but restricted in terms of magnetic saturation evaluation and geometry complexity. Magnetic Equivalent Circuits (MEC) are an excellent compromise as they are fast and take into account magnetic saturation. They are not as generic as FEA and if parameters vary, MEC models have to be readjusted [1-6]. Thus, model development durations are longer for MEC than for FEA. For more genericity, authors in [7-9] have demonstrated the equivalence between the equations of reluctance network (RN) and FEA method and the possibility to form RN matrix system by means of FEA. This paper presents the load analysis of a Permanent Magnet Linear Machine (PMLM) as a case study for a direct flux tube MEC method using an automatic Mesh Based Generated Reluctance Network (MGRN). The aim is to show that it is possible to quickly build a semi-numerical model of studied structures with an automatically generated MEC with accurate results on global and local quantities. Comparisons of iron losses evaluated by the use of the MGRN model show that results are in a very good agreement with those obtained by Ansys-Maxwell FEA [10] used as a reference. This approach can be used in a tool that allows the automated processing of an arbitrary geometry providing an accurate model in a shorter amount of time than needed for building a dedicated model. *MESH BASED GENERATED RELUCTANCE NETWORK* Geometry is discretized in a number of bidirectional elementary reluctance blocks (Fig. 1). The model is divided into zones according to geometry and material proprieties. Discretization can be made finer or coarser according to the desired precision. Central nodes of element blocks are connected via their branches. The advantage of using bidirectional block elements is that no previous knowledge of flux paths is necessary. Each mesh of the network of the final MEC will describe a possible path for flux to go through. The second advantage is to have access to normal and tangential components of local quantities such as flux density and magnetic field. Thus, forces can be evaluated using the Maxwell stress tensor and iron losses by means of Bertotti model [11]. Scalar magnetic potential is used to formulate and solve the nodal based matrix equation: $[U]=[P]^{-1}[\Phi_s]$ [P] Permeance matrix [U] Scalar magnetic potential in each node $[\Phi_s]$ Sum of flux sources for each node n Total number of nodes The approach for solving the equation system as well as PMLM proprieties are given in [12]. A non-linear B-H curve is used for the ferromagnetic material and saturation is addressed with an iterative method as the value of permeability is adjusted in every ferromagnetic block element till convergence of the algorithm. The framework for space discretization, boundary conditions and PM sources assignment are explained in [13]. The PMLM is supplied with a 3-phase sinewave current and distribution of sources of magneto-motive force (MMF) due to coil currents is determined at each step. Fig 1 illustrates the geometry of the PMLM and the MMF distribution. *Sources distribution* MMF sources due to PM need to be placed on the branches of the magnetization direction (y axis) in the elements through all layers of the PM zones. Similarly, MMF sources due to coil currents are distributed on all elements of the teeth and slots. Total MMF according to position (along the x axis) is the sum of the MMF created by each coil. The ratio (height of element block to height of coil zone) is used to weight the MMF sources on each branch in each block of the winding zone (Fig. 1) : $mmf_{elem}=(1/2)\times(E_h/Z_h)\times\varepsilon(x_{node})$ ε Total mmf according to position x_{node} Position of the central node of block mmf_{elem}: MMF on the branch of the block E_h Element height Z_h Zone height *Saturation* The permeability in the reluctances of the blocks in the ferromagnetic parts is initialized with the linear part of the B-H curve. Convergence criteria is magnetic energy in each block as a product of flux density and magnetic field at each step is compared to the one of the previous iteration till the difference no longer exceeds a pre-defined value. At each displacement step, the magnetic permeability value of the block elements are those of the previous magnetic state in the whole model i.e. the previous displacement step. *Motion* A relative moving zone is defined including mover, PM and lower airgap region. The airgap is discretized in a way that the desired movement step is equal to the size of an element block in the airgap. This avoids non-conformal meshing problems and makes it easier to handle changes in matrix topology. *Iron losses* The total iron losses In the MGRN model are calculated in post-processing and are the sum of hysteresis losses, eddy current and excess losses as shown in the equation: $P = k_h f B_m^2 + (\pi\sigma d^2 f^2/6)\int(dB/d\theta)^2 d\theta + (\pi\sigma d^2 f^2/6)\int|dB/d\theta|^{1.5} d\theta$ Flux density values in each node of each reluctance block element are evaluated in the MGRN model using the same B(H) curve and material proprieties as implemented in the Ansys-Maxwell FEA model. Fig 2 shows comparisons of total iron losses (in all ferromagnetic parts i.e. stator and mover) vs frequency for the MGRN and the FEA models used as a reference at I_{max}=5A. It is shown that the results are in very good agreement.

Abstract–In this work, in order to get adaptive Jiles–Atherton (JA) model parameters, an algorithm is proposed and assumes JA parameters to be the functions of magnetic field intensity H, or magnetic flux density B. These parameters are considered by using response surface model (RSM) which is based on the moving least squares (MLS) approximation. The RSMs of the JA model parameters are built based on the simulation results of Preisach model. Numerical example is involved to demonstrate the improvement in the accuracy of the modified JA model. Comparison of its predictions with measurements and with traditional JA model is also shown in this paper. I. Introduction In many engineering applications such as electromechanical actuators, piezoelectric, and magnetostrictive, magnetic materials are widely used [1]. The relationship between induced magnetic flux (B) and magnetic field (H) is shown by he hysteresis loop. Efforts have been made by developing different types of static hysteresis model for study of the hysteresis phenomenon. One of the best known is JA model [2]. The implementation of JA uses five parameters, and four of them are numerical and one is experimental. These parameters usually are identified based on an iterative procedure which may introduce convergence problems [3]. The determination of JA parameters is critical and it is numerically sensitive and does not systematically converge. Another one of the most famous phenomenological hysteresis models is Preisach model [4]. The contribution of infinite number of hysteresis operators is handled with the Preisach triangle, the staircase line and the Everett function. Since the distribution function is defined with H and the accessional iteration is required to find H from B, the classical Preisach model is not suitable for B-oriented method [5]. The classical Preisach model encompasses the basic features of hysteresis phenomena in a conceptually simple and mathematically elegant way. For a given operating condition of the machine, the magnetic fields of any point can be calculated using finite-element method (FEM). The FEM employs single value magnetization curve of iron so it cannot directly calculate hysteresis loss. So in this paper, the analysis results obtained by FEM for constructing the JA parameters are used with static scalar Preisach model. To evaluate the accuracy of the proposed adaptive JA model, numerical tests will be obtained. It is also compared in terms of computational time with traditional JA models and Preisach models. Finally as an example of application, a high-frequency transformer, made of ferrites, is also studied. II. Classical Loss Separation By reports of Bertotti, hysteresis loss P_h, classical eddy current loss P_{ed}, and excess loss P_{ex} consist of the iron losses in terms of the statistical property of Barkhausen effects [6]. P_h can be either segregated and interpolated via measurements or simulated by the proposed adaptive JA model described in Section III. Ped is generally determined from the magnetic field distribution. At low frequency, the induced eddy currents will not significantly affect the external magnetic field distribution, and P_{ed} can be computed from (1) of Fig. 1(a). When the operating frequency is sufficiently high, conventionally, the problem is handled by the introduction of a skin effect factor K_c which is formulated as (2) of Fig. 1(a). By the introduction of magnetic objects with related *n* and *V* which are the statistical parameters determined through measurement, the computation of P_{ex} is simplified as (3) of Fig. 1(a). In general, P_{ex} is always approximated as an optimization approach to formulate the identification problem based on the least square approach as equation (4) of Fig. 1(a) [7]. III. Presentation of the Hysteresis Loss Model The magnetization consists of two terms which are irreversible and reversible components in the JA model of hysteresis. The irreversible component indicates the irreversible domain wall motion. And the reversible magnetization corresponds to the reversible domain wall bending. The magnetization is outcome of the effective magnetic field intensity. In (5) of Fig. 1(a), the energy loss density which is generated by the irreversible domain wall motion is considered. The supplied energy in energy equation is equal to magnetic energy changes and the hysteresis loss as (6) of Fig. 1(a). Suppose c is a dimensionless reversible coefficient, then by introducing c the reversible magnetization can be taken into account as (7) of Fig. 1(a). The *jth* value of the magnetization evaluates the (*j*+1)*th* step the hysteresis characteristic by (8) of Fig. 1(a). The adaptive JA model is proposed according to the regulation of the classical JA model. The JA model parameters are determined as the response surface models (RSM) based on the field analysis by Preisach model. The flow chart of the proposed algorithm is shown as Fig. 1(b). IV. Numerical Examples The 2-D model of the ferromagnetic ring which is shown in Fig. 2(a) with measurement in cylindrical coordinate system has been used to verify the proposed algorithm. Fig. 2(b) to Fig. 2(d) shows the comparison of the measured and simulated hysteresis curves. V. Conclusion In this paper, the hysteresis loss is elaborated and solved via FEM. By using the adaptive JA modeling of hysteresis loss, it is capable of identifying the excess loss in a more accurate analytical form. The validation shows that the proposed method is able to reach an accurate result.

GT-14. A Self-adaptive Play Model with Input-dependent Shape Functions for Hysteresis Loss of Electromagnetic Devices.

X. Liu[1] and *W. Fu*[1]

1. Electrical Engineering, The HongKong Polytechnic University, Hong Hom, Hong Kong

Abstract–Play models are capable of representing minor hysteresis loops of a silicon steel sheet. This paper presents an identification method which can automatically detect the number of play hysterons needed for the simulation. Single sheet tester is applied to get the symmetric B-H loops and first-order reversal curves to identify the play models. Two types of play models are employed in this work. Simulated minor loops, representation of errors, and symmetric B-H loops are presented to verify the accuracy of the proposed method. I. Introduction For the high accurate calculation of core loss, analyzation of the hysteretic properties for magnetic materials is an essential topic. Complex minor hysteresis loops can result in higher time harmonics. Since the computational process of the play model is equated with the nonlinear Preisach model, its representation of minor-loop is constrained by the property of equal vertical chord. Therefore, it is necessary for complicated magnetic field to have a precise representation of minor loops in analysis of iron core for motors. The play model with an input-independent shape function has already been proved equated with the static scalar Preisach model [1]. Nonlinear Preisach model has the hysteretic property. So one of the identification methods is to use the second-order reversal curves of for this property [2]. For this method, all second-order reversal curves are required to be measured for identification, so it needs heavy labor load and is difficult for application. In the study of play model, the product form of an input-dependent shape function is applied. And based on this type of shape function, an identification method of the play model is proposed [3]. II. Play Models with Input-dependent Shape Functions Between the magnetic flux density *B* and the magnetic field *H*, the hysteretic relationship is described by the play model. As the Preisach model, it provides an output using the inverse distribution function method. A discrete form of the play model is shown as (1) in Fig. 1 [3], where p_z is the play hysteron operator; z is the width of the operator; p_{z0} is the value of p_z at the last time-point; N_p is the number of play hysterons; f_m is the piece-wise input-dependent shape function for p_{zm}; and B_s is the saturation B. Play model constructed by input-independent shape function can be identified from the Everett function [4]. The input-dependent shape function has a product form as (2) in Fig. 1. The Everett function from symmetric loops is presented as (3) in Fig. 1. The play model represents a hysteretic function precisely by using (1) in Fig. 1 which should have the coherent property required as the Preisach model. This property is used to determine an optimal weight function $w(B)$ of the piece-wise shape function. A simple weighting function is employed in this work as (4) in Fig. 1. A piecewise linear shape function as (5) in Fig. 1 is used for identification. III. Self-adaptive Play Models with Input-dependent Shape Functions B-H loops are simulated by the symmetric loops identified play model. Increase in the number of hysterons used will elevate the accuracy of the play model. But choosing the number of play hysterons is usually based on experience. In this work, a self-adaptive play models with input-dependent shape functions is proposed. A preset condition is employed to control the process. The process is shown as below: Step 1. Measure the saturation magnetic field H_s. Set M and determine condition d_0. Step 2. Suppose m=m_i. Step 3. Calculate the piecewise linear shape functions using (5) in Fig. 1, and the weight function w(B). Step 4. Calculate the magnetic field H_i by (6) in Fig. 1, and d_{Hi} by (7) in Fig. 1. If d_{Hi} is smaller than d_0, then accept and output the result. Else $m_{(i+1)}$=m_i+1 and go back to step 2. Step 7. Determine whether the number of m_i reaches the M. If yes, then output the final result. Else go back to step 2. IV. Representation of symmetric BH loops Identification uses the symmetric B-H loops can give accurately representation of symmetric BH loops. The play model uses the methodologies (1)-(3) as [5] for identification. The simulated symmetric B-H loops are shown as the Fig. 2(a)-(c). (1) Everett function method employs the symmetric BH loops. (2) Everett function method employs the reversal curves from saturation. (3) Least-squares method employs both symmetric loops and the reversal curves from saturation. Another example as [3] is to compare the simulated and measured reversal curves of the steel sheet 30P105. These curves are first-order and are from negative saturation along rolling and transverse directions. The results are shown as the Fig. 2(d) and Fig. 2 (e). V. Conclusion This paper has proposed a self-adaptive play model with input-dependent shape functions. This method constructs the piece-wise shape function of magnetic field without preset of number of play hysterons while keeps the simulation accuracy. Results in Fig. 2 show that the method is feasible.

GT-15. Skin Effect and Eddy Current Loss in Electrical Steel Sheets under Applied Excitation Fields.

J. Li[1], Q. Yang[2,3], S. Wang[1] and Y. Li[2]
1. State Key Laboratory of Control and Simulation of Power System and Generation Equipments, Tsinghua University, Beijing, China; 2. State Key Laboratory of Reliability and Intelligence of Electrical Equipment, Hebei University of Technology, Tianjin, China; 3. Municipal Key Laboratory of Advanced Technology of Electrical Engineering and Energy, Tianjin Polytechnic University, Tianjin, China

Abstract Body: By applying electromagnetic diffusion equation, skin effect in electrical steel sheets in the condition of alternating excitation is analyzed based on Maxwell electromagnetic field theory. Due to skin effect is more significant mainly at high frequency, non-dimensionalized treatment for the diffusion equation is produced and eddy current loss is calculated by considering or not skin effect, respectively. Meanwhile, broadband magnetic losses and separation of typical electrical steel are obtained by using a 3-D magnetic properties testing system to bring to light the emergence of skin effect under rotational excitation. The simplification of magnetic constitutive equation is proposed and introduced into the diffusion equation, which is solved by employing finite elements coupled to Fredholm's equation. An approximate expression for the rotational eddy current loss component with skin effect is eventually written. 1. The simulations show that due to the influence of skin effect, non-uniform distribution of induction flux density within electrical steel sheets will become more and more significant, the flux density and field intensity nearby the surface are larger than that in the centre of the sheets [1, 2]. And with increasing of alternating excitation frequency, the inhomogeneity of induction flux density will be extended and growing more inhomogeneous, due to the smaller skin depth and a small increase of anomalous loss in the total core losses, as shown in Fig. 1. 2. Therefore, alternating eddy current loss P_{ae} as functions of the peak mean alternating flux density B_{ma_mean} and the alternating excitation frequency f_a can be deduced as follows: $\lim_{v\to\infty} P_{ae}(B_{ma\_mean}, f_a) = [2\omega_a(B_{ma\_mean})^2/3\rho\mu v^2 = (\sigma\pi^2 d^2/3\rho)(f_a)^2(B_{ma\_mean})^2$ *(no skin effect)* [W/kg] (1) $\lim_{v\to 0} P_{ae}(B_{ma\_mean}, f_a) = [4\omega_a(B_{ma\_mean})^2/\rho\mu v = (4\sigma^{1/2}\pi^{3/2}d/\rho\mu^{1/2})(f_a)^{3/2}(B_{ma\_mean})^2$ *(considering significant skin effect)* [W/kg] (2) where, ω_a is the angular frequency; $v = 2\delta_e/d$, δ_e is the skin depth, d is the sheet width; ρ, σ and μ are the mass density, conductivity and permeability of magnetic materials, respectively. 3. Based on the total 3-D rotational experimental core losses of cold-rolled NO electrical steel sheet 50A1300 (thickness d = 5.00e-4 m, density ρ = 7.85e+3 kg/m^3, conductivity σ = 5.70e+6 S/m), which are fulfilled by using a 3-D magnetic properties testing system [3-6], the emergence of skin effect can be described according to the comparisons between the experimental and separated values of the mean micro-vortex current losses per cycle *vs*. the square root of rotational excitation frequency, as shown in Fig. 2. 4. The rotational eddy current loss component is evaluated by integration on the sheet thickness of the square of the current density modulus derived from the numerical computation of the curl of H fild. Then, an approximate expression for the rotational eddy current loss with skin effect can be written, as often done with the alternating regime. $P_{re}(B_{mr\_mean}, f_r) = (3\sigma\pi^2 d^2/4\rho)(f_r)^2(B_{mr\_mean})^2\{\delta_e[\sinh(d/\delta_e)\text{-}\sin(d/\delta_e)]/d[\cosh(d/\delta_e)\text{-}\cos(d/\delta_e)]\}$ *(considering significant skin effect)* [W/kg] (3) where, P_{re}, f_r and B_{mr_mean} are rotational eddy current loss, excitation frequency and mean peak flux density, respectively. Conclusion: The skin effect and eddy current loss under alternating and rotational fields are interpreted and deduced based on electromagnetic diffusion and magnetic constitutive equations. The emergent of skin effect in the condition of rotational excitation at high frequencies, the analysis and calculation methods of alternating and rotational eddy current losses, *etc.*, will promote the experimental verification and in-depth study of eddy current loss in the practical engineering applications.

GT-16. Efficient Deperming Protocols Considering Magnetic Coercivity Distributions in Magnetic Stealth of Warship.

S. IM[1], H. Lee[1], H. Chung[2] and G. Park[1]

1. Electrical and Computer Engineering, Pusan National University, BUSAN, The Republic of Korea; 2. Agency for Defense Development, Changwon, The Republic of Korea

I. Introduction Demagnetization is to reduce the residual magnetization in magnetic materials. It is used in various industries such as HDD and VFD to record and erase data. Especially, in national defense, it is very important since there are fatal hazards such as magnetic mines if warship has high magnetic flux inside it [1]. In order to demagnetize it, alternating and decreasing magnetic fields are applied through external coils surrounding the warship as shown in Fig. 1(a). These magnetic fields are called the deperming protocol and generally there are three kinds of protocols such as Anhysteretic Deperm, Deperm-ME and Flash-D. Several studies have shown that Flash-D has better performance than Anhysteretic. In Flash-D, unlike Anhysteretic Deperm, it is composed of three stages, and the importance of the second stage is greatly emphasized by previous studies. If Stage 2 is performed at a high Priesach density region, the result will be excellent [2]. However, there is a lack of research on the factors that determine the most effective deperming protocol. Therefore, it is needed to develop a protocol that determines the start and end magnetic fields of Stage 2 for demagnetization. In this paper, Preisach model was used to analyze theoretically for an effective deperming protocol. According to Preisach model, magnetic domains with various size of coercive and interaction force are distributed to represent magnetic properties [3]-[5]. The results of the demagnetization are determined according to the state of the particles with various coercive force. In consideration of this, deperming protocol that can affect half of the particles in the warship is proposed. Preisach density distributions are obtained from the hysteresis curves to determine the magnetic fields that can affect the target particles. To validate the proposed one, as shown in Fig. 1(b), a solenoid coil was designed and two specimens of SM45C and SS400 were tested in a scale-down MTF test room. II. Process for deperming using Priesach model A. Conventional Flash-D protocol Flash-d protocol consists of three stages which is to decrease, increase and then decrease again. Stage 2 gradually increases the magnetic field unlike other deperming protocols. According to the previous studies, it was proved that the demagnetization performance is excellent when Stage 2 is determined as a region with a high Preisach density distribution. However, there is a limit to determine the current of Stage 2 depending on the characteristics of the materials. B. Proposed process and Flash-D protocol In this paper, the process of determining the start and end currents of stage 2 in flash-d protocol for effective demagnetization was analyze and proposed by using Preisach model. The basic concept is that stage 2 operates, like the previous study, in the region where the Priesach density is high. However, the development of a protocol that can perform the most effective demagnetization in the high density region was proposed. First, the B-H curve of the magnetic materials was measured. By differentiating the measured B-H curves, a curve of the Gaussian function was obtained, as shown in Fig. 2. It represents the density distribution curve of the particles having different coercive force in Preisach model. Most of the particles have a coercive force similar to that of the B-H curve, and the particles having large and small coercive force are less distributed. From the density distribution curves, the current I1 and I2 at the beginning and end of Stage 2 were determined by selecting the area corresponding to 50% of the magnetic particles, as shown in Fig. 2. When the proposed protocol was applied, 50% of the particles in the warship were affected once more. Therefore, the particles are effectively affected by the protocol at each stage, and thus the result of demagnetization was excellent. III. Experiment Result In order to verify the proposed protocol, the SM45C specimen was used as a warship equivalent model. The experimental procedure was as follows. First, the magnetic flux density according to earth magnetic fields was measured at a sensor located 18cm below the specimen. The measured result is 1929 nT. After applying proposed protocol, the magnetic flux density is 99 nT, which is 5% of the induced magnetic field. Therefore, the demagnetization was performed very well. Likewise, the experiment was carried out using the SS400 specimen. The protocol was adapted to the material properties of SS400 and finally 22 nT was measured. Detailed experimental equipment and experimental results will be shown in full paper. IV. Conclusion This paper proposes an efficient deperming protocol considering the characteristics of the magnetic materials. It was analyzed by using Preisach model and proved through experiments. Therefore, by using this process, it is possible to establish an effective deperming protocol considering the hysteresis characteristics of the warship.

GU-01. Electromagnetic-Mechanical Analysis of a Balanced Armature Receiver by Considering the Nonlinear Parameters as the Function of Displacement and Current.

Y. Jiang[1], D. Xu[1] and S. Hwang[1]
1. Mechanical Engineering, Pusan National University, Busan, The Republic of Korea

1. Introduction Balanced armature receiver is widely used in hearing aid and earphone because of the small size and high sensitivity. Balanced armature receiver is a product which covers multi-physics. It contains the electromagnetic, mechanical domain and the property such as current and displacement can affect each other. In one hand, the current in electromagnetic domain will take effect on the force which determines the displacement in mechanical domain. In the other hand, displacement change can contribute to the change of back electromotive force (EMF) which affects the current. So the current and displacement are coupled and need to be considered at the same time to analyze the balanced armature receiver. In terms of equation, current and displacement are coupled in the voltage equation which involves the nonlinear parameters such as inductance, speedance, and force factor. Based on lumped parameter method, the nonlinear parameters were calculated as functions of displacement in balanced armature speaker [1]. By using finite element method, Lee et al. analyzed the nonlinear parameters as the function of displacement in microspeaker [2]. In this study, the displacement and current are both considered in the nonlinear parameters to analyze the performance of balanced armature receiver by using FEM. 2. Analysis method The balanced armature receiver is modeled with different deformation which means different vibration displacement. Then different current is input and then the flux density can be solved through electromagnetic FEM simulation. Based on the flux density, force generated on the vibration armature can be obtained by Maxwell stress tensor method. In this way, the nonlinear parameters can be described by several displacement and current as shown in Fig.1. The inductance is defined as the derivative of flux linkage to current. And speedance is defined as the derivative of flux linkage to displacement. The inductance and speedance can generate the back EMF. And the force factor is defined as the force divided by the current. It can relate the current and force. In mechanical domain, the displacement of receiver can be obtained by using forced vibration FEM simulation with a given input force. But the input force in mechanical simulation is not related with the current in electromagnetic domain, so coupling analysis is needed by solving the voltage equation. Before solving the voltage equation, the current will be set as a initial value and displacement will adopt the value from mechanical simulation. With the assumed current and displacement, the nonlinear parameters can be determined as a specific value in Fig.1. So the current can be calculated by solving the voltage equation. Even though current and displacement are not true values in the very beginning, current and displacement can converge and be accurate after iteration. By this way, current and displacement are both considered in the analysis. Furthermore, according to the 3D modeling, the balanced armature parts has been manufactured and assembled. The displacement of receiver is tested by laser in Klippel system. And the current is detected by current sensor in Klippel system. And the simulation results are verified by experiment result, just shown in Fig.2. 3. Conclusion Balanced armature receiver is a product which contains multiphasic problem. Current and displacement are the performance criterion in electromagnetic and mechanical domain separately. These two performance criterion are affected by each other and needed to be considered together. In the work, a more comprehensive multiphysic coupling analysis method has been presented by considering displacement and current. The analysis result are verified by experiment.

GU-02. Performance Analysis of Superconducting Coil Impregnated with Epoxy Resin.

Z. Chen[1], G. Geng[1] and J. Fang[1]
1. Beijing Jiaotong University, School of Electrical Engineering, Beijing, China

I. INTRODUCTION The second generation high temperature superconducting (HTS) coated conductors (CC) have lower AC losses and higher current density than the first generation wires[1], but its weak mechanical properties limit its application in large storage magnets. Because of high field and high current density, Lorentz force effects mechanical stability of superconducting magnet greatly [2]. To improve the stability of the magnet, a coil winding technology has been developed for bonding wires together by impregnating epoxy resin. After the coil is impregnated with epoxy resin the structure size is changed. Therefore the resin insulation layer also affects the inductance and the actual current-carrying capacity of the superconducting coil [3]. The impregnation curing process conditions will produce thermal stress, due to differences in the thermal expansion coefficients of various engineering materials for HTS magnets [4], [5]. In this work, we modified the distance between the turns of the coil and investigated the distance influence on the inductance of the coil, then analyzed thermal stress induced by impregnation curing process on superconducting coil. II. SELECTED AND DESIGN OF MODEL COIL The thermal stress of each unit double-pancake coil is independent of each other in solenoid magnet so the two-dimensional axisymmetric model can be applied [6]. A double-pancake coil model is designed by using four parallel YBCO tapes in this study. The model of magnet structure and coil section is given in Fig.1 (a) and Specification of parallel YBCO tapes and coil is shown in Fig.1 (b). III. CALCULATION AND ANALYSIS OF MODEL COIL A 12 turns of coil with insulation thickness of 0.18mm was studied the effect of the insulation on electromagnetic characteristics. Fig.2 (a) shows the distribution of magnetic field of coil. The inductance of each turn of coil with difference thickness of the resin insulation layer is shown in Fig.2 (b), and g is the thickness of the resin insulation layer increased from 180 μm to 380 μm. As presented in Fig.2 (b), the inductance of each turn in the middle of the coil is larger than the inductance of each turn in both sides of the coil. Fig.2 (c) gives the simulation result, coil inductance decreases with the thickness of the insulation. When the resin insulation layer thickness, g, increases uniformly by 1μm, the inductance of superconducting coil decreases uniformly by about 1.097nH. According to Fig.2 (c), in order to gain larger energy storage capacity, the coil needs to be wound as compactly as possible but because of the higher produced self-field, the critical current in a tight coil is lower than in a loosely wound coil. When the critical current is reduced, allowed transport current decrease and the energy storage amount decrease. In next step we will analysis and evaluate of the magnetic field produced by each turn of coil. This work will help decrease the degradation of the superconducting characteristics such as critical current of the superconducting magnets. The influence of thermal stress on magnet structure was analyzed by Finite Element Method (FEM) software COMSOL. The analysis of thermal stress contains two aspects, First, thermal stress analysis of magnet during impregnation curing heat treatment (293K-413K); Second, thermal stress analysis of magnet during the pre-cooling process (293K-20K). As presented in Fig.2 (d), the superconducting tape maximum deformation is 0.23% and the thermal stress does not damage the superconducting tape under the impregnation curing process. During the pre-cooling process the maximum strain of superconducting tape is 0.0039% and the maximum strain of the epoxy resin is 0.02%. In cooling stage of impregnation curing process (413K-293K) the maximum strain of superconducting tape is 0.0078% and the maximum strain of epoxy resin is 0.01%. Under pre-cooling process epoxy resin exerts some shrinkage pre-stress on the superconducting tape and reduces the strain of the superconducting tape. IV. CONCLUSIONS In this study, the electromagnetic and stress analysis of the superconducting coil impregnated with epoxy resin was carried out by finite element simulation software. The inductance of each turn in the middle of the coil is larger than the inductance of each turn in both sides of the coil and the coil inductance decreases with the thickness of the insulation. Thermal stress does not damage the superconducting tape under the impregnation curing process, and the epoxy resin can provide some pre-stress for the superconducting tape in pre-cooling process. This work can help the design and optimization of solenoid energy storage magnets impregnated with epoxy resin. ACKNOWLEDGEMENT This work is supported by National Science and Technology Major Project of the Ministry of Science and Technology of China (Granted No. 2016YFE0201200).

I. Introduction Amorphous core transformers (AMT) have the major advantage of higher power efficiency due to lower iron loss (W_i) compared with that of grain-oriented silicon steel (GO) cores used in conventional transformers (SiT) [1]. Some studies have attempted to increase the power capacity of AMTs to over 5 MVA [2]. However, the enlarged amorphous core, made from stacked foils 25-mm thick, is vulnerable; it requires structures to support its weight. Additionally, the saturated magnetic flux density (B_S) and the lamination factor of the amorphous core are approximately 18% and 10% lower, respectively, than those of the GO core. This results in the amorphous core having a larger cross-sectional area than that of the GO core with same the specifications. To enable the use of an amorphous core with lower W_i in large capacity distribution transformers, we investigated the practicality of a hybrid-configured annular core consisting of an amorphous core combined with a GO core, which has the advantages of a higher B_S, lamination factor, and mechanical strength than the amorphous core. The distributions of the magnetic flux density and W_i in the hybrid core were measured and calculated with electromagnetic analysis using the three-dimensional finite element method (FEM) while the two individual cores, amorphous and GO, were excited simultaneously. We then designed a prototype 5-MVA single-phase hybrid core transformer (HBT) on the basis of our investigation results. The prototype had improved power efficiency due to its lower W_i and reduced size enabled by the increased amplitude of magnetic flux density, B_m. II. Experimental and analytical methods As the schematic diagram in Fig. 1 (a) shows, we stacked two cores: a 2605HB1M amorphous wound core [3] with a lap-joint part and a frame-shaped 30P105 GO [4] stacked core with step-lapped parts at four corners. The two cores had net masses of 500 and 150 kg, respectively. They were both 2.0 m long, 0.5 m wide, and the core window's dimensions were 1.8 × 0.3 m. The geometric cross-sectional area of the amorphous core and the GO core had a ratio of 8:2. We applied a 60-Hz sinusoidal voltage to the excitation coil wound around the two cores. We measured B_m and W_i averaged in the hybrid core as a whole and in each individual core by measuring the current in the excitation coil and the induced voltages in the search coils wound around the two cores and each individual cores. The calculated results with FEM on a three-dimensional hybrid core model were compared with the experimental results. III. Results Fig. 1 (b) shows the changes in amplitude of the magnetic flux densities in the amorphous core ($B_m^{(A)}$) and in the GO core ($B_m^{(G)}$) as functions of the averaged B_m in the hybrid core as a whole. The measured and calculated results have good agreement. The GO core was hardly excited, and the amorphous core had higher $B_m^{(A)}$ than the GO core in lower averaged B_m due to the difference in the material's permeability and reluctances between the two cores. $B_m^{(A)}$ approaches saturation asymptotically, while $B_m^{(G)}$ increases noticeably as B_m increases. It is possible that the GO core prevented over-saturation in the amorphous core. Averaged B_m in the hybrid core as a whole is 1.58 T when $B_m^{(G)}$ reaches 1.70 T, the upper limit of conventional SiT. These results show that the HBT could operate at B_m approximately 10% higher than the upper design value of B_m in AMT. The cross-sectional area of the HBT core was also smaller than that of AMT. An image of the core structure and a photograph of the exterior of a prototype 5-MVA single-phase three-leg type HBT is shown in Fig. 2. The core of the HBT consists of four sets of the hybrid core shown in Fig. 1 (a). The prototype HBT has a net mass of seven tons, including a winding and support parts. We developed and applied a structure and assembly process that protects the vulnerable amorphous cores from the stress of their own weight and of fixing force. Standard performance tests were performed by immersing the prototype in an insulation oil tank. The cross-sectional area of the HBT's core was 8% smaller than that of an AMT designed with same the specifications, and W_i was reduced to less than half that of a conventional SiT. IV. Summary To use amorphous cores in larger-capacity distribution transformers, we measured and calculated the distributions of the magnetic flux density and iron loss in a hybrid-configured core consisting of an amorphous core combined with a GO core with higher B_S and mechanical strength. The GO core prevented over-saturation of the amorphous core. The hybrid configuration enabled approximately 10% higher amplitude of magnetic flux density than configurations with an only amorphous core. Operation tests on a prototype 5-MVA single-phase HBT demonstrated its higher efficiency and reduced size. Acknowledgements This work was supported by the Ministry of the Environment of the Japanese Government.

GU-04. Inductance analysis for the multi-unit permanent magnet synchronous machine in different operating situations.

D. Zeng[1], J. Zou[1], Y. Xu[1] and F. Liu[1]
1. Harbin Institute of Technology, Harbin, China

1.intorduction The inductance is a key parameter for the electrical machines since it has a significant impact on the performance. The inductance components of the multi-unit permanent magnet synchronous machine (PMSM) depend on the winding configuration and the machine structure. Thus, many inductance calculating methods and analysis between different calculating methods have been researched. These methods mainly include the analytical calculating method and finite element method (FEM). To analyze the inductance of the different machines, some analytical calculating methods and models have been proposed. Based on the basic winding function method, the inductance of interior permanent magnet machines has been analytical calculated in [1], the inductance of brushless slot-less machines with surface inset magnets has been analytical calculated in [2]. Based on the Maxwell's equations, the inductance of the surface inset permanent magnet machines with high saliency ratio has been analytical calculated in [3], the inductance of the permanent magnet linear synchronous machines has been analytical calculated in [4], the inductance of the fractional-slot concentrated-winding machines has been analytical calculated in [5]. These calculation results are all compared with the results calculated by FEM. These inductance analytical methods are all focus on the three-phase electric machine. The inductance of the multi-unit PMSM has been introduced in [6]. However, the analysis for the inductance of the multi-unit PMSM in different operating situations has not been done. In different operating situations, the coupling of the different phase effect on the inductance has not been analyzed. The calculation and analysis for the inductance of the multi-unit permanent magnet synchronous machine in different operating situations are presented in this paper. 2. Inductance calculation model This model is established under the assumptions and restrictions listed as follows: 1) Stator and rotor cores are infinitely permeable and end effects are neglected. 2) Each phase is composed of identical coil groups (or phase belts) and has the same winding turns. 3) Each phase distributes symmetrically around the stator circle. 4) The effect of the end windings on the inductance is neglected. Based on the winding function method and the reluctance circuit, the analytical calculating model for the inductance of the five units PMSM with 40 poles and 45 slots for instance is shown in Fig.1. The winding configuration is used as the first step. The air gap and magnets can be modeled as the lumped reluctance component, the leakage reluctance component, and the reluctance component of the stator teeth are all illustrated in Fig. 1. These reluctance components are obtained by the specific size and the material characteristic of the PMSM. The operating situations of multi-unit PMSM mainly include the full-unit operating situation, the part-unit operating situation, and the operating situation that some unit-motors operate as motors and some unit-motors operate as generators. The full-unit operating situation is the normal state, the part-unit operating situation is the fault-tolerant state, and the operating situation that some unit-motors operate as motors and some unit-motors operate as generators is the no-mechanical-load-test state. The different operating situation can be considered with the coupling factor of the magnetic circuit. Its value is different in different operating situations. The relation between the magnetic flux of the phases and the magnetic flux of the circuits is presented in equation (1). And the self inductance of this multi-unit PMSM can be calculated by equation (2). The mutual inductance of this multi-unit PMSM can be calculated by equation (3). 3. Result and discussion To analyze the inductances of the multi-unit PMSM in different operating situations, two multi-units PMSM prototypes with concentrated windings are designed. Both the two machines are equipped with surface mounted NdFeB permanent magnet on their rotors. The two multi-unit PMSMs are designed with the different number of units to validate the inductance matrix in both odd and even units PMSMs. Both the two machines have the same dimensions and rotor structure. They differ only in their slot pole combinations. The linkage flux with the permanent magnet of each phase in all the three machines should be same to guarantee the inductances of the three machines are calculated at the same saturation. And to obtain the same value of the linkage flux with the permanent magnet of each phase in the two machines, the numbers of coil turns N of the two machines are calculated. The inductances of the two machines in different operating situations are calculated. The characteristics of the inductance in different operating situations are discussed. 4. Conclusion In this paper, the inductance of the multi-unit PMSM in different operating situations are calculated, the inductance matrix of the multi-unit PMSM is different in the different operating situations.

GU-05. Characteristics Analysis of Electric Motor using Ring Core Test and its Experimental Verification.

D. Kim[1], J. Chin[1], M. Lim[1] and J. Hong[1]
1. Department of Automotive, Hanyang University, Seoul, The Republic of Korea

The initial magnetization curve (B-H curve) and iron loss of electrical steel sheet are essential data for predicting the electric motor performance. Typically, the Epstein frame test is adopted widely, to acquire these magnetic properties. However, for the rotating electrical machines with small geometry, the ring core test can be preferred. In this paper, B-H curve and iron losses are measured by Epstein frame test and ring core test. Each result applied in finite element analysis (FEA) of the fabricated electric motor. Furthermore, using these FEA results and *d-q* equivalent circuit, prediction of the electric motor performance is done. As the future work, the electric motor test will be done, and the result will be compared with predicted results. I.Introduction Generally, magnetic properties of electrical steel sheets are acquired by Epstein frame test according to IEC 60404-2 international standard[1]. Also, supplied data of electrical steel sheets from the manufacturer is usually obtained from the Epstein frame test. However, the ring core test can be preferred for predicting the rotating electrical machine with the small geometry for several reasons below[2]. -Closed magnetic circuit without any airgaps -No need of any special measurement set -Simple to prepare test samples -Geometry is similar to stator yoke of electric motor In this study, a non-oriented electrical steel sheets (50PN470) are prepared. For the ring core test, stacked ring sheet is prepared for the specimen. To exclude the effects of processing, the wire cut is adopted for cutting. Furthermore, the outer diameter of the ring core specimen does not exceed 1.4 times the inner diameter, ensuring the reliability of the test result[3]. Using the sample, initial magnetization curves and iron losses were measured. From these magnetic properties and supplied Epstein frame test result, prediction of the electric motor performance is done through the FEA. To verify the prediction results, an electric motor is introduced. As the future work, the no-load test and the load test will be conducted for the adopted electric motor. The error between the test results and simulation results will be investigated. II.Magnetic Properties of Electrical Steel Sheets A.Experiment on Electrical Steel Sheets The primary winding of the ring core specimen and Epstein frame is connected to the AC voltage source controlling magnitude and frequency. Also, it is connected to B-H analyzer for measuring the magnetic field intensity. The secondary winding of each test frame is connected to the B-H analyzer to measuring the magnetic flux density using the induced voltage. NF high-speed power amplifier was used for the AC voltage source, and IWATSU SY8258 B-H analyzer was used for measuring B-H curves and iron losses. B.Initial Magnetization Curve The tests were conducted in the range of magnetic flux between 0.1T to 1.6T and accordingly, field intensity range between 35.61A/m to 4956A/m. Initial magnetization curves obtained from Epstein frame test and the ring core test is depicted in Fig. 1. C.Iron Loss Measurement of the iron loss was conducted with the same method of the initial magnetization curve, but measuring frequency was changed. The tests were performed in the range of magnetic flux density from 0.1T to 1.8T, and range of frequency from 50Hz to 1000Hz. To predict the electric motor performance, iron loss surface of interpolated and extrapolated from each test is shown in Fig. 2 using Steinmetz's equation and least square method[4]. III.Prediction of Electric Motor Performance A.Iron Loss Analysis Using the previously acquired iron loss data from two tests, iron loss maps according to frequency, and magnetic flux density was constructed. From these maps, iron losses are analyzed under the various load conditions. FEA was used to calculate the magnetic flux density for each meshed element of proposed models as the rotor was rotated. Next, using the Fourier series, the magnitude of the fundamental and harmonic component was analyzed. From the iron loss map, iron losses according to frequency and magnetic flux density were calculated for harmonic components of each element. Finally, iron losses of all the element were added to assess the iron loss of the machine[5]. B.Performance Prediction The performance of the electric motors was predicted by the *d-q* axis equivalent circuit of the permanent magnet synchronous motors (PMSMs) considering the iron loss from the section *A* in chapter III. Using the FEA, *d*-axis and *q*-axis inductance were calculated for the range of the phase current and current phase angle including harmonic components. While the inductance calculation process, for the same range, linkage flux of the armature winding is calculated. After finishing the parameter calculation process, solve the *d-q* axis equivalent circuit of PMSM for the speed and torque range, considering DC link voltage and current limitation. Finally, the electric motor performance maps are created for Epstein frame and the ring core test data[6]. IV.Future Work As the future work, loss separation will be done for the fabricated electric motor. Using the electric motor with the non-magnetized permanent magnet, the mechanical loss will be measured. Furthermore, to validate the prediction of electric motor performance, load test will be conducted. After that, the comparison of prediction result from Epstein frame test and ring core test will be done.

GU-06. Improving the transmission efficiency of wireless power transfer systems in electric vehicles by using magnetoplated aluminum pipes.

Y. Bu[1], S. Endo[1] and T. Mizuno[1]
1. Shinshu University, Nagano, Japan

1. Introduction Wireless power transfer (WPT) technology is becoming increasingly popular because it enables the transmission of electrical energy without the use of connecting wires, which makes the transmission process convenient and safe. Currently, researchers are in the process of developing transmission powers greater than 3 kW for charging electric vehicles (EVs). Some car manufacturers have even started making prototypes using the WPT system. The charging operation tends to be much better in the WPT system because there are no direct electrical connections. The car needs only to be parked at the charging station; subsequently, the WPT system automatically carries out the electrical connection. In the WPT system for EVs, the devices typically use the electromagnetic induction produced between a pair of coils; one coil is for transmitting power, and the other coil is for receiving power. To improve the electromagnetic induction efficiency at high frequencies in the range of 81–90 kHz, a Litz wire of 1000 or more strands is used to reduce the AC loss. The use of a Litz wire reduces the AC impedance resulting from the proximity effect and increases the *Q* value. Therefore, Litz wires are used in almost all high-power WPT coils [1]. Litz wires can improve performance because they have a greater number of strands than solid wires; they also have low diameters. These attributes, however, also increase the cost of the Litz wire coils. Using a solid wire coil instead of a Litz wire will reduce costs, but the associated high-frequency losses will reduce the efficiency of the coil. Therefore, in this paper, we propose a magnetoplated aluminum pipe (MAP) with a special magnetic layer to improve the transmission efficiency. As compared with the solid wire, the MAP is very light and cheap. Therefore, it is possible to replace the Litz wire with a MAP. 2. Structure of MAP coil Fig.1 shows the MAP coil structure used as the transmitting and receiving coil in our evaluation experiments. Fig.1 (a) is the plan view of the coil. It is a spiral coil with eight tight winds, and the outer diameter of the coil is 380 mm. A Ferrite core is attached to a coil plane that has one side of length 410 mm; and the coil plane has a thickness of 4 mm. Fig.1 (b) is a cross section of the MAP coil structure showing the transmitting coil and the receiving coil, which are placed facing each other in the WPT system. Fig. 2 shows the MAP structure that we used in this experiment. To reduce the exchange loss caused by the proximity effect, we made a 0.4 mm magnetic layer on the concentrated part of the magnetic flux on the surface of the aluminum pipe (AP). We used this magnetic layer with low loss amorphous iron powder. From Fig. 2, it can be seen that because of the different distribution of the magnetic flux lines, the coating positions are not the same at the center and the periphery of the coil. We use FEM analysis to obtain the magnetic flux of the coil. 3. Experimental result We made coated (i.e., MAP) coils and uncoated (i.e., AP) coils and measured their AC resistance and transmission efficiency using an Impedance Analyzer. At the drive frequency of 85 kHz, the AC resistance, inductance, and quality factor *Q* of the AP coil were 126mΩ,32.3uH, and 149, respectively. For the same frequency, the impedance, inductance, and quality factor *Q* of the MAP coil were 115 mΩ,33.2uH, and 157, respectively. The MAP coils had up to 5.4% better *Q* values and AC resistance reduced by 8.7% as compared with the AP coils. We measured the transmission efficiency when the transmitting coil and the receiving coil were separated by 150 mm. The transmission efficiency was 92.6% for the AP coils and 93.4% for the MAP coils. The proposed MAP coil could increase efficiency by 0.8%. Although the effect is not great, however the MAP coil has strong practicability because the coil heating can be suppressed. In the future, we will improve the trial process to improve the effectiveness of this method.

GU-07. Accurate Calculation of Eddy Current Loss in Litz-Wired High Frequency Transformer Windings.

Z. Liu[1], L. Zhu[1] and J. Zhu[2]

1. Tianjin Polytechnic University, Tianjin, China; 2. University of Technology Sydney, Sydney, NSW, Australia

I.Introduction The winding power loss of a high frequency transformer is strongly influenced by the high frequency eddy current skin and proximity effects. The litz-wire can reduce effectively the eddy current effects. The precise loss calculation method of litz-wire remains however a difficulty. At present, the Dowell model [1] and Ferreira model [2-3] are two commonly used methods to calculate the winding loss. The Dowell model is originally derived to calculate the eddy current effects in foil conductors and later on extended to packed windings composed of litz-wire by introducing a porosity factor [4]. The accuracy however declines quickly when porosity factor reduces, and the characteristics of eddy current distribution is not adapted to the litz-wire. On the other hand, the magnetic field of round conductors analyzed by Ferreira model is excellent, but the error become significate at high frequency at high porosity factor [5] because it neglects the interaction between conductors in the same layer [6]. In this paper, an improved model is proposed for calculating the eddy current distribution in litz-wire windings due to the skin and proximity effects. This model can have much more accurate prediction of eddy current distributions in the cross-section of a round litz-wire conductor, and can be used for electromagnetic design of high frequency devices. II.Calculation analysis A.The skin effect The traditional Ferreira model is based on the Bessel function to analyze the eddy current skin effects in a round conductor. Considering the skin effects, the eddy current per unit length can be calculated by (1) As shown, the eddy current density can be reduced effectively as the diameter of a strand of litz-wire becomes far less than the skin depth. B.The proximity effect The proximity effect is on both strand and bundle levels. The current distribution in a conductor strand can be influenced by the internal magnetic field, H_{int}, and the external magnetic field, H_{ext}, generated by the currents flowing in other strands of the same bundle and currents flowing in wires of other bundles. In a litz-wire, the internal magnetic field due to the currents flowing in other strands of the same bundle can be obtained by the Ampere's law as $H_{int}=Ir/2\pi r_c^2$, where I and r_c are the current and the radius of a bundle of litz-wire, respectively. The external magnetic field produced by currents flowing in strands of different bundles can be obtained by the per unit layer current, I_{pl}, and numbers of conductor layers, m, as $H_{ext}=(m-1)I_{pl}$. The resultant proximity effect can then be calculated by the total magnetic field. The proximity effect due to litz-wires in different layers presented in (2) can identify the eddy current distribution caused by other conductors. The winding in the same layer can also influence a lot, which is not considered in Ferreira model. The eddy current distribution caused by the windings in the same layer can be obtained from the (3), which highly depend on the porosity factor. C.The eddy current loss of a twisted litz-wire Considering the twisting effect, the total loss can be calculated by integrating the local magnetic field along the bundle length. The magnetic field can be assumed to be rotating along an untwisted bundle. Assume p_i is the pitch length when the strand back to the original position. Obtained from (4), if the pitch p_i is far smaller than the wire length with a perfect twist, the litz-wire can almost eliminate the proximity effect due to the rotating magnetic field. However, the litz-wire in practical use can hardly be perfectly twisted, and therefore the winding power loss can be calculated by $P=(\sum\int J_i \times J_i)/2\sigma$, where σ is the conductivity of the conductor, and J_i the current distribution. III.Experience Verification A KMC-40 gapped core was used in the experiment. The core material was amorphous alloy. The cross-sectional area of the winding is 4.05 cm^2. The outer diameter of the litz-wire is 1.35 mm. It is made by twisting 100 wires of diameter 0.10 mm. Fig.1 compares the litz-wire AC resistance obtained by the Dowell, Ferreira, and proposed models with the experimental results. As shown, the modified Dowell model present in [4] has good precision in the case of high porosity factor, and the Ferreira model has good precision at low porosity factor. The proposed method takes into account the proximity effect caused by the same layer, and therefore can yield much more accurate predictions than the other two models. IV.Conclusions From the analysis above, we can observe that twisting the strands can effectively reduce the proximity effect due to the external magnetic field. A perfectly twisted litz-wire can almost completely eliminate the proximity effect. The litz-wire in practical use, however, can hardly be perfectly twisted. The proximity effect loss caused by the litz-wires in the same layer is affected by the porosity factor. In this paper, an improved model is proposed to take into account the proximity effect caused by the litz-wires in the same layer in addition to those acounted for by other models in the eddy current loss calculation. The theoretical results of new model are compared with those obtained by the two best-known methods, and validated by the experimental measurement. It can be seen that for both small and large porosity factors, the new model yields more accurate calculation results.

GU-08. Applying Response Surface Method to Oil-immersed Transformer Cooling System for Design Optimization.

Y. Zhang[1], S. Ho[1] and W. Fu[1]
1. Department of Electrical Engineering, The Hong Kong Polytechnic University, Hong Kong, Hong Kong

In this paper, response surface methods (RSMs) are applied in the design optimization of oil-immersed transformers. A 3-D computational fluid dynamics (CFD) model is constructed firstly with all the design variables parameterized. Solutions derived by numerical method are fed into RSM, which generates a surrogate model for the original problem. A preliminary study of predicting maximum temperature rise for oil-immersed transformer shows promising results. The optimization solution based on the approximation model will be compared with that of direct optimization method. I. Introduction Analytical methods with empirical coefficients are widely used in oil-immersed transformer cooling system design [1]. The entire transformer is divided into several sections according to the heat path or oil flow path. These sections are solved separately with corresponding formulations and parameters. Generally, the application of these analytical equations and empirical coefficients is limited to certain categories of transformers. Computational fluid dynamic (CFD) method, as a supplementary tool or the major approach, has been introduced into the transformer design and analysis process [2 - 5]. The application of CFD ranges from conducting the cooling system design optimization of certain section [2 - 4] to optimizing the entire cooling system of a transformer [5]. CFD is capable of modeling complex geometry and nonlinear material characteristic, the computational effort, however, is tremendous, which limits its extensive application in inverse problems. Response surface method (RSM), as an efficient approximation tool, has been adopted in many engineering problems, such as electromagnetic device design [6], prediction of material properties [7] and thermal analysis of multichip module [8, 9]. In this paper, several types of RSMs are introduced into the oil-immersed transformer cooling system design with their performance compared. To generate a set of input and output data for the RSM, 3-D CFD modeling of the oil-immersed transformer is established firstly. The overall performance of response surface optimization method on accuracy and efficiency is evaluated through comparison with solutions of direct optimization method. II. Analysis Model and Methodology A. CFD modeling The CFD model of a three-phase oil-forced transformer is built based on some simplifications and hypotheses. Influences of insulation and structural parts are neglected, and the analysis focuses on the dimension optimization of oil channels, which is shown in Fig 1. As the flow and temperature distribution are not consistent for three phases, parameters for one phase are independent from others. Moreover, separated coils are considered in the analysis to handle high temperature rise. There are three objectives for this optimization problem: minimizing the volume of oil, pressure drop and maximum temperature rise. B. RSM Central composite design is employed to choose a universal set of design points for the RSM. These design points are solved by numerical method consecutively, solutions of which are used as the training data combined with the values of design variables. Several categories of RSMs based on different algorithm, such as Kriging, second order polynomial function, genetic aggregation and non-parametric regression, are introduced to estimate the problem and to generate an approximation model to replace the original CFD model. Generally, the response surface derived with the initial design points is not accurate enough, and adding more proper refinement points could further improve the performance of the response surface. Several parameters, such as coefficient of determination, root mean square error and relative average absolute error, are computed to determine the performance of the approximation model. After deriving the approximation model, the final optimization is easily implemented and repeated for different objectives. Optimized solutions derived by response surface optimization will be compared with the direct optimization method. III. Numerical Results A preliminary study on the maximum temperature rise estimation of a three-phase oil-immersed transformer was conducted with four types of RSMs. As the 72 design points (including 57 refinement points) and 10 verification points used in these four methods are the same, their performance could be evaluated through comparing the goodness of fit, which is shown in Fig. 2. It can be found that genetic aggregation and Kriging method achieve better performance on fitting the design points and predicting the verification points than other approaches. The maximum predicted error of genetic aggregation is 2.2 degree centigrade for these ten verification points. IV. Conclusion The application of several categories of RSMs in oil-immersed transformer design optimization is presented in this paper. A simple numerical example of oil-immersed transformer temperature rise prediction is tested, which shows promising results. The optimization solutions of response surface optimization and direct optimization will be compared in the full paper.

1. Introduction Wireless power transmission can be applied to a wide range of fields requiring electric power from smartphones to electric cars and is expected as a next generation innovative technology. Currently, the mainstream of practical applications is the electromagnetic induction method, and it is used as a power feeding to multifunctional small electronic devices typified by mobile terminals. However, this method is limited to charging in a very close state, and has a disadvantage that it is vulnerable to displacement between transmission and reception coils. In order to solve those problems, magnetic field resonance method was announced from MIT in 2006 [1)]. In this system, high efficiency transmission over long distances is enabled, and since the influence of positional displacement is relative small, it is possible to construct a charging system with high usability. Our laboratory aims at establishment of a local high usability power supply area finally. Specifically, it is the construction of the "unnoticed charging area" in which the transmitting coil is embedded in the floor or wall, and the user's device is unconsciously charged by the receiving coil mounted on the device automatically. However, in order to maintain high efficiency in the resonance method, it is necessary to change the optimum driving frequency with respect to the transmission / reception distance. For that change, accurate grasp of the distance and frequency changing function are required for power supply equipment, so the system becomes complicated. For the above reasons, we tried to realize a stable power supply by using a Helmholtz type coil which can obtain a uniform magnetic field between the coils on the transmitting side. As a result, although it was inferior to the conventional type in terms of maximum efficiency, we succeeded in maintaining constant efficiency between the coils. 2. Transmission system using Helmholtz coil Receiving side coils are subject to various restrictions such as size and thickness depending on the target application. We focused on the transmission side, which has a relatively high flexibility of design as compared with the receiving side. In order to increase the output power, simply by increasing the input power and multiplying the transmission side coils, the desired output can't be easily obtained for the above-mentioned reason. Therefore, by using a Helmholtz coil, we attempted to not only increase the output but also stably supply power to the receiving side. In constructing a local charging area, which is our final objective, it is reasonable to place a transmitting coil on the ceiling and the floor. As a space where people can actually work, at least 2 m is required for the height. However, it is very difficult to fabricate a coil of a size to realize it. For this reason, we first confirmed the effectiveness of the approach using Helmholtz coil and conducted basic experiments with coils of comparatively easy size to produce. The configuration of the experimental system is shown in Fig. 1. When the distance H between two transmission coils and the radius R of each coil are equal to each other, the coil has a uniform magnetic field on the central axis connecting the coils. Two circular spiral coils (coil end: open, winding pitch width: 3 mm, 2 turns, radius: 300 mm) were used on the transmission side and the distance between coils was 300 mm. For the receiving coil, a circular spiral coil (coil end: short, winding pitch width: 4 mm, 10 turns, radius: 75 mm) assumed to be mounted on a tablet computer was used. The resonance frequency is 9.5 MHz for all coils. The distance d which is from one of the transmitting coils to the receiving coil was changed at d = 5 to 25 cm. The vector network analyzer (VNA, ADVANTEST, R3755A) was used for measurement of transmission efficiency. The measurement result is shown in Figure 2. As a comparison, the result (single) when only one transmission coil is used is also depicted. The efficiency in the case of using the Helmholtz coil decreases about 20% in maximum efficiency compared with the single, but maintains stable efficiency even if the distance d changes. This tendency can't be confirmed by merely setting up a plurality of transmission coils. This shows that the uniform magnetic field by Helmholtz coil always maintained a constant resonance state at any position between the coils. In this way, simplification and cost reduction of the system can be realized only by designing and arranging the coils without additional function to the power supply unit. 3. Summary and Future Plans In this time, we could confirm that stable power supply can be realized to a specific closed space by using Helmholtz coil. For next step, we will tackle to create a large Helmholtz coil with a radius of 2 m for our final goal. In order to achieve that, after evaluating the performance using electromagnetic field simulation software JMAG (JSOL Corp.), we will examine the fabrication. Additionally, in addition to the no-load test by the VNA, we are also planning to measure the transmission efficiency and the maximum transmittable power with the actual load on the receiver side.

GU-10. Calculation of Magnetic Inductance of the Spiral Coils Including Ferrite Core for Remote Field Energy Transfer Devices.

Y. Jang[1] and G. Park[1]
1. School of Electrical and Computer Engineering, Pusan National University, Busan, The Republic of Korea

I. Introduction In recent years, researches on induction heating (IH) and wireless charging (WC) have been actively carried out [1]-[5]. IH and WC systems have something in common. The first is the use of spiral coil to reduce the volume of the entire system, and second is the use of ferrite core at the bottom of the coil to minimize the leakage flux and increase the efficiency of the system [2], [4]. One of the most important factors in design process of IH and WC systems is to design spiral coil and ferrite core considering the limit of system inductance. In case of spiral coil, the inductance is determined by coil diameter, turn interval, outer diameter, and number of turns of the coil. The inductance also changes due to the thickness, area of the ferrite core, and distance from coil to ferrite core. Since the parameters affecting the inductance vary and it is difficult to obtain the inductance value through fabrication and measurement for all cases, calculation of the inductance depends on the finite element analysis in most research and design process. However, the disadvantage of calculating an inductance using finite element analysis is take a long time to modeling and analysis if the structures are complicated. And unlike the solenoid coil with iron core whose magnetic path is determined, it is also unreasonable to apply a magnetic circuit in spiral coil because the magnetic path is diverse, and the leakage flux is large. Therefore, in this paper, analytical calculation of inductance is proposed by using image coils. First, the inductance calculation method using finite element analysis is introduced, and then the inductance calculation by using image coils is presented. The inductances obtained by the above two methods are compared with each other. II. METHOD OF INDUCTANCE CALCULATION *A. Finite Element Analysis* Fig. 1 (a) shows the cross section of the entire structure about the spiral coil and ferrite core. d_w is diameter of the conductor cross-section which current flows, D_{outer} is outer diameter of the spiral coil, SP_t is the turn interval, and N_t is the number of turns. The thickness and radius of the ferrite core are assumed to be infinite (or large enough). Since the ferrite cores are a soft magnetic material, the permeability is high, and the conductivity is low. If the current flowing in the coil is I_c, flux density vector B and magnetic field H vector of the entire analysis region can be obtained from the finite element method. In this case, the inductance of system is calculated by, $L=1/(I_c)^2\int_V B\bullet H dV$ (1) where, *V* is volume of the entire analysis region. *B. Analytical Method* If the thickness and radius of the ferrite core are infinite (or large enough), an image coil can be placed instead of the ferrite core. Fig. 2(b) is shown the reference coil and the image coil [5]. In this case, the structure of the image coil is the same as that of the conventional spiral coil, and the magnitude of the current flowing is shown in (2), $I_i=I_c\times(\mu_r-1)/\mu_r$ (2) where, μ_r is permeability of the ferrite core. If the spiral coil is simplified by circular coil which have the same center axis and the number of coil is same to number of turns, the magnitude of the magnetic field at point (r, z) in cylindrical coordinate system is shown in (3), $H_{(r,z)}=\sqrt{(H_r^2+H_z^2)}$ (3) where, $H_r=\sum^{N}_{tn=1}(-1)/2\pi[\int^{2\pi}_0\{(z\times I_c/A)+(z+2d)\times I_i/B\}R_n\cos\alpha d\alpha]$ (4) $H_z=\sum^{N_t}_{n=1}1/2\pi[\int^{2\pi}_0\{(I_c/A)+(I_i/B)\}R_n(R_n-r)\cos\alpha d\alpha]$ (5) $A=(r^2+R_n^2+z^2-2R_n r\cos\alpha)^{3/2}$ (6) $B=(r^2+R_n^2+(z+2d)^2-2R_n r\cos\alpha)^{3/2}$ (7) $R_n=D_{inner}+n(d_w+SP_t)$ (8) Then, the calculated inductance is (9), $L=\mu_0/(2I_c)\times\sum^{N_V}_{vi=1}H_i^2\bullet\Delta dV_i$ (9) where, μ_0 is the permeability of free space, N_V is the number of volume elements, H_i is the magnetic field intensity of the ith volume element, and ΔdV_i is the volume of the ith volume element. III. COMPARISON FEA WITH ANALYTICAL METHOD The magnetic field distribution and inductance values obtained by FEA and Analytical Method are shown in Fig. 2. The specifications of the spiral coil are d_w=3mm, SP_t=1mm, D_{outer}=271mm, and N_t=21turns. The relative permeability of the ferrite core μ_r=1000. Applied current I_{peak}=10A, and the input frequency f=20kHz. Fig. 2(a) is a graph showing the magnetic field distribution at z=8mm when the distance of spiral coil and ferrite core is 5 mm. Fig. 2(b) is a graph showing the inductance value according to the distance between spiral coil and ferrite core. IV.CONCLUSION A method of calculating inductance in a spiral coil through the image coils is studied in this paper when the thickness and radius of the ferrite core are infinite (or large enough). The structure, position and applied current of image coils were determined, and magnetic field and inductance were calculated from reference coils and image coils. To verify that the proposed method is suitable, we compared the magnetic field distribution and inductance obtained through FEA. As a future work, we will study how to calculate the inductance of a ferrite core with a finite core thickness and radius. And we will also study when the center of the ferrite core is empty for cooling.

GU-11. Magnetostriction impact noise and vibration on power transformer characteristic via PSO method.

C. Hsu[1,2] and Y. Huang[2]
1. Department of Mechanical Engineering, Oriental Institute of Technology, New Taipei city, Taiwan; 2. Department of Mechanical Engineering, National Central University, Taoyuan, Taiwan

1. Abstract: Electromagnetic design of the power transformer to reduce the noise based on the magnetostriction variation, it should be faced it very closely due to the resident people paid a great attention recently. Actually, it is well-known that magnetostriction of the power transformer is caused by the exciting variation of the magnetic core. This study, it presented an optimization method to reduce the noise of the power transformer that also performed the factory testing before delivery and after that to install on-sited downtown power station, is a main objective. A novel method particle swarm optimization (PSO) is use to reduce noise level of transformer and also effective to decrease total cost reduction. This paper discusses a main magnetic property of magnetostriction dependent on the transformer operated at full-load tests. Also, this study is presented that a lot of transformers with capacities, 15 MVA to 60 MVA / high voltage (HV) 132kV to low voltage (LV) 33 kV around six units. Actually, a full loading testing for transformer characteristic is to lead a key point for reduction of the noise and vibration. A tricky noise source of the power transformers for no-load (core/magnetostriction) and full-load (winding/displacementε) testing results compared with simulation and measurement data, are performed. The difference between the simulated and the measured sound levels is limited around 3dB range especially for higher capacity and successfully developed in this case. 2. Introduction It is well known that power transformers operate at a low-frequency generated the noise response. Even the overall noise response can be smaller than that as usual no-load operation condition, but due to a kernel point magnetostriction characteristic, it still generate a lot of confuse noise to the resident people. This is because noise variation dependent on the magnetic field variations in the laminations of the core. Magnetostriction can be regulated due to a key point which is the magnetic material and core structure [1]. For normal comment sense in core lamination structure, it can be understood that although the total change in length is as a small micrometers. The stress response based on the electromagnetic reactive from magnetic flux variation can be obtained. Before aforementioned the reason will cause the deep noise and hum wave response. This is because resonance frequencies, for example, included as, 120 Hz, 240 Hz and 360 Hz, etc., which are harmonics of the 60Hz excitation current of the transformer in Taiwan, is obtained. The noise level increases with higher magnetic flux density, higher capacity of the MVA rating and higher electromagnetic force for the power transformer, is significant. This study will discover a useful method to get a great resolution in reduction of noise and vibration by using finite element analysis (FEA) method. Both magnetostriction of the core and electromagnetic force effect of the winding in design and testing for power transformer are success performed. 3. Simulation and Experimental Results In general, the total noise level of transformers is mainly influenced by magnetostrictive variation of the core and electromagnetic forces of the windings, and also consider rigid-structured of the tank walls, respectively, is addressed. These studies have presented serval magnetic material to fabricate transformer core. Truly, the magnetostriction variation as a function of the core properties has been presented [2] as 30Z140, 27ZH100, 27PH100, 30ZH105 and 30P120, respectively. A 3D model of the power transformer is calculated to simulate the noise and vibration variables through by FEA, adding with a useful optimization method PSO, as shown in Figure 1(a). It presented the magnetic flux density distributed in the core and to show the noise amplitude of the core is significant. Based on this reason, it also discovered a new evident reason that the winding displacement (m/m) is relative with the electromagnetic force and current density, is obtained. This study, it will perform each transformer (six units) between 15 MVA to 60 MVA / high voltage (HV) 132kV to low voltage (LV) 33 kV, extremely-lowed noise development and test environment, as shown in Figure 1(b). This study, it presents an optimization method to calculate lower magnetostriction variation due to serval material application for transformer. The effect of magnetostriction-induced core magnetomechanical stress and electromagnetic force of winding variation on noise and vibration for power transformers, are presented. Generally, a great magnetic property of the magnetostriction of grain-oriented Si steels should be chosen. Then, both electromagnetic force and flux displacement of the winding with different magnetic materials are calculated. In Figures 2(a)-(b), the simulated and measured results for magnetic core and rigid winding in magnetic flux and electromagnetic force is analyzed. This is fundamental work and should be performed before reality transformer implements and also success development.

1. Xuji Power Co. Ltd., Xuchang, China; 2. School of Electronic and Electrical Engineering, Nanyang Institute of Technology, Nanyang, China

Research on wireless power transmission is a hot area at present [1-3]. Coil design is one of the key technologies in wireless power transmission [3-6]. A core goal of coil design is to study how to improve coupling coefficient. Higher coupling coefficient means greater transmission power and higher efficiency under the same conditions. Many types of coil have been designed, such as square coils, circular pad, four-square coils, DD coupler, DDQ coupler [4-5]. A comparison is made between circular and elliptical coils by studying the shape of the magnetic field and the path of magnetic flux with a concept of flux pipe [5-6]. Experimental results show that, in terms of the type of coil, coupling coefficient of the circular pad and DD coupling coils is higher and the cost is lower. Most of the existing researches focus on the practical application and comparison of various types of coils, and rarely compare the characteristics of the two basic circular and square coils. In this paper, the basic characteristics are studied about the two types of the most basic coil, which provides the basis for how to use two kinds of basic coils. For the two most common types of circular and rectangular coils, the structure is axisymmetric. For any one of the above two types of coils as a transmitting coil, the case of a magnetic field coupling is considered using two types of coils in the single turn as receiving coil, respectively. There are three cases: (1) the area of the two receiving coils is equal; (2) the circumference of the two receiving coils is equal; (3) the outer diameters of the two receiving coils are equal in space. It is easy to know that the maximum area of the rectangle coil is square under the same circumference of coil, and so we use square and circular coils for comparative analysis. The circumference, area and outer diameter of the circular coil are equal to the square coil, respectively, when the area and circumference of the square coil are kept constant, as shown Fig. 1. Magnetic field characteristic analysis : For the circular and square transmitting coil with given structural parameters, the curves of the similar Magnetic flux density B can be obtained by numerical calculation and electromagnetic simulation, as shown in Fig. 2a. For cases where the area of the two receiving coils is equal in Fig. 1a, the magnetic flux is equal in the area where two receiving coils overlap. For the non-coincident part, the magnetic flux of the circular coil will be greater than the magnetic flux of the square coil, according to the results of fig.2a. From the above analysis, it is easy to know that the magnetic flux of the circular coil will be greater than the magnetic flux of the square coil for the same circumference of the two coils as shown in Fig.1a. Because the area of the circular coil in Fig.1b is larger than the area of the circle coil in Fig.1a, the fig.1b has a result similar to that of Fig.1a. For the case of the same outer diameter shown in Fig. 1c, the magnetic flux of the square coil is larger than the circular coil because the square coil completely contains the circular coil. through the above analysis, the circular receiver coil flux greater than the square coil flux in the case of equal area or equal perimeter, namely in these two cases, the circular receive coil mutual inductance is greater than the square receive coil. the simulation results of the normalized coupling coefficient of three types of coils at different offset distances according to the design parameters of the electric vehicle wireless power supply coil are shown in Fig.2b. The cost and loss of the circular and square coil are equal when the circumference is equal. The mutual inductance of the circular coil is obviously better than that of the square coil, so the efficiency is higher. When the enclosed area is equal, the cost and loss of the circular coil is lower than that of the square coil, and the mutual inductance is slightly larger than that of the square coil, so the efficiency is also higher than that of the square coil. Therefore, it is the best choice to choose a circular coil with no space constraints. Under the condition of limited space, the square coil can achieve greater mutual inductance, but the cost and loss of the coil will be higher than that of the circular coil.

I.INTRODUCTION As an emerging technology, wireless power transfer (WPT) has attracted substantial attention in many applications, such as electric vehicles, portable electric devices and medical instruments [1]. Generally, the WPT system possesses the advantages of safety, high reliability, low maintenance, and electrical isolation [2]. As one of the most prominent technologies, the WPT is changing the conventional usage of energy in daily life for human being. The key element in the WPT system is a pair of magnetically coupled coils [3-5]. When delivering power in a large area, multiple coils can be adopted to form a single uniform magnetic field. Also, in the multifrequency WPT system, a single transmitter can be used to feed multiple receiver coils with different resonant frequencies [6]. Usually, the coreless planar coil is preferable to achieve better ability of tolerance to misalignment than that with ferrite core. Since the circular coil has the problem of limited coverage, the rectangular coil is preferable in the multiple-receiver WPT system. However, in order to provide the desired power transfer capability, the size of this kind of system is usually very large and thus the system flexibility is reduced. Normally, a single-layer planar coil is used for both the transmitter and receiver, which will significantly increase the system complexity and occupied volume. This paper focuses on the design and analysis of multilayer rectangular coil structures, dubbed as cubical compact coils, for those multiple-receiver WPT systems desiring compact size and good power transfer capability. In order to make sure that the mutual inductances of the multiple receivers are the same, the magnetic field distribution over the transmitter should be uniform enough. This paper proposes three different types of cubical compact coils, namely the spiral type, concentrated type, and uneven compound type. Their designs and analyses are elaborated. Apart from assessing their magnetic field distributions, the corresponding electric potential distributions are analyzed at different currents to provide the guidance for selection and arrangement. II. METHODOLOGY The proposed cubical compact coil structures are shown in Fig. 1, which are the spiral type, the concentrated type and the uneven compound type. These three coil types can be applied to both the transmitter and receiver. For exemplification, the peripheral dimensions are 200 mm and 140 mm. The Litz wire with 165×0.1 mm is adopted to make up all coils. For the spiral type, all turns of the coil are distributed evenly with two layers. Meanwhile, for the concentrated type, all turns of the coil are bundled together with two layers. By combining the advantageous features of both the spiral type and concentrated type, the uneven compound type is proposed where five turns form one bundle with two layers and the pitch distances between every two bundles are not the same, namely, S_1=3 mm, S_2=5 mm, and S_3=7 mm. Once the system parameters are predefined, the mutual inductance between the transmitter and receiver becomes the major determinant of the system performance such as power transfer capability and efficiency. Generally, the uniform magnetic flux density makes the mutual inductance keep constant, thus improving the ability of misalignment tolerance. Therefore, the magnetic field distribution can be utilized to analyze the system performance. Based on the same peripheral dimensions, the magnetic field distributions and electric potential distributions of all three types of coils are analyzed by using the finite element method based software JMAG. As a result, the spiral type of coil essentially provides the magnetic field distribution in a conical-like shape as shown in Fig. 2(a), whereas the concentrated type of coil presents a rectangular concave-top distribution as shown in Fig. 2(b). Meanwhile, the uneven compound type can provide much more uniform magnetic field distribution than both the spiral and concentrated types. Focusing on the magnetic flux densities at the middle plane as shown in Fig. 2(c), it can be found that along the horizontal displacement, the uneven compound type can exhibit much more uniform field and hence achieve better tolerance for the misalignment. Moreover, for this kind of multilayer structures, the proximity effect should be analyzed. As shown in Fig. 2(d), the maximum electric potential of the concentrated type of coil is simulated, which is well below the breakdown voltage of 1400 V of the Litz wire. Finally, an experimental prototype has been constructed and tested to verify the feasibility of the proposed system. More experimental results including the power transfer capability and misalignment tolerance will be given in the full paper. III. CONCLUSION In this paper, three cubical compact coil types of transmitter and receiver for WPT have been proposed and implemented. They are particularly suitable for those multiple-receiver WPT systems desiring compact size and good power transfer capability. By newly combining the spiral coil type and concentrated coil type, the uneven compound coil type can provide more uniform magnetic field distribution, hence minimizing the difference of magnetic flux densities that can be picked up by multiple receivers. Moreover, the electric potential distribution is analyzed to ensure that the maximum electric potential is well below the breakdown voltage of the Litz wire. I.INTRODUCTION As one of the most prominent technologies, wireless power transfer (WPT) has attracted substantial attention in many applications and is changing the conventional usage of energy in daily life for human being [1]-[2]. In recent years, automatic guided vehicles (AGVs) are highly demanded with the fast-increasing transportation and logistics market [3]. In order to alleviate the problem of their short driving range, more batteries or frequent charging are inevitable [4]. Rather than increasing the size of batteries or the number of charging ports, the use of WPT for AGVs can greatly facilitate the charging process [5]. Most importantly, because of the absence of metallic contacts, possible electrocution during the charging process can be totally eliminated [6]. Since the AGV usually needs to operate continuously, it is highly desirable to be wirelessly charged during moving. Namely, an array of power transmitters is embedded beneath the workplace while a receiver is mounted at the bottom of the AGV. Another problem for AGV application is that it desires a large number of sensors embedded under the workplace to navigate these AGVs, which will significantly increase the system complexity and hardware cost. This paper proposes and implements a new move-and-charge (MAC) system for AGVs. Essentially, the proposed rail transmitter not only serves to wirelessly charge the AGV, but also to navigate the AGV based on the variation of mutual inductance. Thus, it can significantly reduce the battery size, while eliminating the risk of electrocution and the guiding sensors embedded under the workplace. The key is to make use of the DC-DC converter to keep the equivalent resistance constant. When the AGV is misaligned with the rail transmitter, the receiver current will be varied so that the steering part of the AGV will perform the correction of direction to maintain the received power. Consequently, both dynamic charging and navigation can be achieved simultaneously. II.METHODOLOGY The proposed MAC AGV system is shown in Fig. 1(a), which includes the rail transmitter designed with 180 mm width and the pad receiver. The rail transmitter is embedded just beneath the ground while the pad receiver is mounted at the bottom of the AGV so that the airgap between them is 80 mm. The rail transmitter design involves only a long primary coil supplied by a single power inverter, which takes the definite advantages of lower investment cost and lower installation complexity than the pad transmitter design for feeding multiple AGVs. For the sake of better flexibility, maintainability and scalability, the rail transmitter design usually adopts the sectional arrangement in which it uses one power inverter per section to feed multiple AGVs. Normally, the rail transmitter should be compensated with capacitors as shown in Fig. 1(b), and the system operation frequency is set at 85 kHz according to the SAE J2954 wireless charging standard. Since the wireless power from the transmitter to the receiver is proportional to the surface area where the magnetic flux passes through, the ferrite based pad receiver is adopted to provide magnetic flux guidance, hence minimizing the flux leakage. In order to provide the effect of navigation without relying on guiding sensors, the DC-DC converter is used to regulate the charging voltage and current, aiming to keep the equivalent resistance constant. If the AGV is not aligned with the rail transmitted, there will be a difference between the received current and reference current. This difference will cause the steering part of the AGV to control the AGV in such a way that the alignment can be restored. In order to predefine this reference current, the magnetic field distributions at different situations are calculated by using finite element analysis software JMAG. A 200 W MAC AGV system has been designed. As shown in Fig. 2(a), when the pad receiver of the AGV is exactly aligned with the rail transmitter, the magnetic flux density at the height of 80 mm is symmetrical without requiring any correction of direction. When the AGV comes across the right corner rail, the magnetic flux density is shown in Fig. 2(b), where the total effective flux passes through the pad receiver is reduced and hence the received current decreases to 5.5 A so that the right correction is needed. As shown in Fig. 2(c), the current drops fast with respect to the misalignment. It can be observed that the received currents when the pad receiver is above the straight rail and corner rail are 6.6 A and 6.0 A, respectively. Thus, the current of 6.0 A can be regarded as the threshold value to conduct the correction of direction. Finally, an experimental prototype has been constructed and tested to verify the feasibility and controllability of the proposed system. More experimental results including the system efficiency will be given in the full paper. III. CONCLUSION In this paper, a new MAC system has been proposed and implemented for AGVs, which not only performs wireless charging, but also automatically navigates the AGV without using guiding sensors. By newly adopting the equivalent resistance adjustment circuit and current threshold control method, it can simultaneously provide wireless power and misalignment correction, hence achieving the desired traction. Most importantly, it can significantly reduce the battery size and hence cost of each AGV, while eliminating the risk of electrocution. GU-15. Design and Optimization of Quasi-constant Mutual Inductance for Asymmetric Two-Coil Wireless Power Transfer System With Lateral Misalignments.

Z. Li[1]
1. College of Traffic Engineering, Hunan University of Technology, Zhuzhou, China

I. Introduction Magnetic resonant wireless power transfer (WPT) is an emerging technology that may create new applications for wireless power charging[1]. However, the output voltage fluctuations resulting from lateral misalignments are main obstructing factors for promoting this technology. In this paper, an asymmetric two-coil WPT system is presented. The mathematical model of the proposed topology with lateral misalignments is built based on equivalent circuit method. The expression of the output voltage is then derived by solving the system equivalent equations. In addition, a method of optimization parameters is proposed. The mutual inductance between the receiving coil and the transmission coil is nearly constant by the proposed method with lateral misalignments. Therefore, the output voltage can be kept nearly constant. The asymmetric two-coil WPT system via magnetic resonance coupling is designed. Simulation and experimental results validating the proposed method are given. II. Analysis of Optimization Method The output voltage V_L is only dependent on the mutual inductance between transmission coil and receiving coil when the parameters (*R, L, C*) of each coil and the load are given. The mutual inductance may be changed with the variations of lateral misalignments, and the parameters of each coil. In this section, a method of optimization parameters is proposed. The mutual inductance can be kept nearly constant with lateral misalignments by using the proposed method. The process of the proposed optimization method is as follows: 1) Parameters setting: the resonant angular frequency is set to be 85kHz. The mutual inductance should be larger than 6.0μH. The transmission distance is set to be 15cm. The diameter of copper is set to 1.75mm. The outer diameter of Tx is changed from 0.25m to 0.30m in a step of 2.0mm. The outer diameter of each receiving coil is changed from 0.2m to 0.25m in a step of 2.0mm. The number of turns of Tx is changed from 17 to 40 in a step of 1. The number of turns of each receiving coil is changed from 6 to 10 in a step of 1. 2) Calculated mutual inductance: According to (1) and (2), the mutual inductance between Tx and each receiving coil can be obtained with different lateral misalignments. M_{10} is the mutual inductance between Tx and each receiving coil when lateral misalignment equals to 10cm; M_0 is the mutual inductance between Tx and each receiving coil when lateral misalignment equals to 0cm. 3) Compared to ε (ε=(M_0-M_{10})/M_0) at a given outer diameter of Tx, outer diameter of each receiving coil, the number of turns of Tx and the number of turns of each receiving coil, the optimum ε is obtained(The smaller ε is, the smaller the variations of mutual inductance becomes). 4) According to the optimum ε, the optimum parameters of Tx and each receiving coil can be obtained. III. Simulation & Experimental Verification To validate the proposed structure and optimization method, the prototype model of the system has been built, as shown in Fig.1. It is composed of the DC voltage source, a transmission resonant coil, a receiving resonant coil, H-bridge inverter, a full-bridge rectifier, and the load. The value of the DC voltage source is 48V. The DC voltage source is shown in Fig. 1(a). The transmission resonant coil is shown in Fig. 1(b). The receiver resonant coils are shown in Fig. 1(c). The outer diameter of the transmission resonant coil is 0.6m with a pitch of 0cm for approximately 17 turns according to the optimization method. The outer diameter of each receiving resonant coil is 0.2m with a pitch of 0cm for approximately 10 turns according to the optimization method. All coils are made from 300-strand AWG 38Litz-wire. H-bridge inverter is used at the transmitter side to provide AC excitation, as shown in Fig. 1(d). It contains four MOSFETs (IRF3207), a full-bridge rectifier is used at the receiver side to convert AC to DC. In future research, the power level of the prototype will be increased and those full-bridge rectifiers will continue to be used in high power system. The full-bridge rectifier contains four diodes (HFA15TB60) with a voltage rating of 600V, which can also be used in high power system. Fig. 2 shows the measured mutual inductance between transmission coil Tx and receiving coil Rx placed at different positions. It can be seen that the mutual inductance M is changed from 6.89μH to 6.63μH as the misalignment is varied from 0cm to 10cm. The difference between M_0 and M_{10} is 0.26μH. ε is equal to 3.77% according to ε=(M_0-M_{10})/M_0. The variations of mutual inductance are very smooth as the misalignment is varied from 0cm to 10cm. IV. Conclusion In this paper, an asymmetric two-coil WPT system is presented. The mutual inductance between Tx and Rx is changed with the variations of lateral misalignments, and the parameters of each coil. In order to decrease the variation of the mutual inductance, the turns of Rx and the diameter of Tx should be increased. And the turns of Tx and the diameter of Rx should be decreased. In addition, a method of optimization parameters is proposed. The optimum parameters of each coil can be obtained by using the proposed method for given constraint conditions. The experimental results show that the mutual inductance is changed from 6.88μH ($M_{\_0}$) to 6.63μH ($M_{\_10}$) as the lateral misalignments is varied from 0cm to 10cm. The optimum ε is only 3.7%.

GV-01. Thinning Defect Evaluation and an Application for Thickness Measurement by Eddy Current Testing.

S. Nagata[1]
1. Faculty of Engineering, University of Miyazaki, Miyazaki city, Japan

This paper presents an eddy current non-destructive evaluation system that can detect the thinning defect on metal specimen. Detection of a thinning is a diffcult problem for the eddy current testing (ECT). Especially, when surface of thinning defect is flat and smooth, induced eddy current inside specimen does not be perturbed by the defect, therefore, signal indicating the thinning defect is very small. We studied on an ECT for radiator structures, and concluded that in case of such structures, it is comparably easy for detecting thinning defect[1]. We clarified that the frequency characteristics of signal of single fin showed valid dependencies on the radiator thicknesses. Finally, we determined a thinning detection method using an additional metal bar, instead of single fin. A small piece of metal bar, namely called marker, is mounted opposite side of specimen, then ECT evaluations are performed. Multi-Frequency Excitation and Spectrogram Method (MFES) is used. Figure 1 shows an experimental result when specimen made of aluminum, thickness 2.0mm. Signal indicating the marker appears arround at position 0mm. In this result, a frequency of the maximum signal is arround 2.0kHz. According to the specimen becoming thinner, this frequency shifts higher one. Figure 2 shows the relation between the frequency and maximum signal. The experimental results show good relationship between signal of the marker and the specimen thickness. The present method indicates not only the validity for the detection of thinning, but also availability of an application to measuring metal specimen thickness.

GV-02. Seismic circuit breaker with electromagnetic contactor.

T. Mifune[1] and K. Nishimura[1]
1. National Institute of Technology, Suzuka College, Suzuka, Japan

We reported a vibrational circuit breaker using ferromagnets and repulsive magnets [1]. The breaker has the advantages of auto-detection and does not require a battery. In previous studies have two problems. First, we used a moving parts with a slightly larger inner diameter than the axis. However, with this, there was friction between the shaft and the moving parts, and there was variation in the operating point. By using sliding bearings to solve this problem, the variation of operating points due to friction was reduced. Second, it was created for low current electronic circuits. For scenes actually used for home and industrial use, high voltage and high current are expected. It is necessary to investigate the allowable ampacity for high-current. Because it is effects of electromagnetic field when we apply the current over tens of amperes to it. In addition if high current is passed directly to the permanent magnet, temperature rise will occur. This may cause the magnetic force of the permanent magnet to disappear. In this digest, we propose to utilize an electromagnetic contactor shown in Fig.1. It is an electrically controlled switch used for switching an electrical power circuit, similar to a relay. We experimentally measured operating acceleration responses for the circuit breakers when we applied and didn't apply current. We obtained a similar result shown in Fig.2. These responses have resonant frequency of about 4 Hz. Responses of seismic intensity also are similar responses. If it can correspond to the seismic intensity such as 5 upper, 6 lower, it will be applicable as a seismic circuit breaker. The detail of how to correspondence to the seismic intensity is presented at the conference.

GV-03. Marker-free coil-misalignment detection approach using TMR sensor array for dynamic wireless charging system of electric vehicles.

X. Liu[1], W. Han[1], C. Liu[2] and P. Pong[1]
1. Department of Electrical and Electronic Engineering, the University of Hong Kong, Hong Kong, China; 2. School of Energy and Environment, City University of Hong Kong, Hong Kong, China

I. Introduction Dynamic wireless charging (DWC) technology for electric vehicles (EVs) has obtained increasing attention recently [1] because it enables on-road EVs to be powered wirelessly so that EV driving range can be further extended. However, one main problem of the DWC system is that the receiving coil mounted on EVs should be well-aligned with the primary coil embedded under lane [2]. The transferred power and energy transmission efficiency drop significantly when there exists a large lateral misalignment. The existing vehicle-tracking techniques can be classified into two categories: marker-based approach and marker-free approach. The marker-based approach typically uses the radio-frequency identification (RFID) reader or magnetic sensor to detect the RFID tags or magnetic markers over/under lane [3-5]. However, the dense configuration of RFID or magnetic markers leads to high construction costs. The marker-free approach can overcome this drawback. Currently, marker-free approach is implemented with search coils which are installed underneath a vehicle body to detect the lateral misalignment; however, search coils suffer from their complicated installation (due to out-of-plane configuration) and bulky size (due to large turn number) [6, 7]. Its algorithm to determine the misalignment position by observing the change in voltage phase of search coil is unreliable and time-consuming [6]. Moreover, its actual applicability is largely restricted by the non-linear relationship between misalignment distance and search-coil voltage. In this work, a marker-free approach to detect the lateral coil-misalignment for DWC system using a tunneling magnetoresistive (TMR) sensor array is proposed (Fig. 1a). The compact-in-size TMR sensor array in-plane with the receiving coil is used to detect the magnetic field generated by the primary coil and to determine the coil-misalignment position, which makes the installation convenient. Computation process is straightforward, and coil-misalignment position can be easily obtained by analyzing the output amplitude of TMR sensors. II. Operating principle The magnetic field distribution on the plane of receiving coil can provide coil-misalignment information. Fig. 1b shows the diagram of magnetic field distribution at sensing position A. Since position A is at the center and on the same plane as receiving coil, the magnetic field generated by receiving coil at position A does not have component in the y-axis direction. The magnetic field at position A in the y-axis direction only depends on its relative position with respect to primary coil, as expressed by Eq. (3) in Fig. 1c. By adopting typical EV DWC parameters, the width of primary coils is set to 0.8 m, the gap length between primary coil and receiving coil 0.2 m, and the current flowing through primary coil 10 A_{RMS}, B_y at different sensing positions can be calculated according to Eq. (3), as depicted in Fig. 1d. There exists a sensing position where B_y equals to zero. The magnitude of the magnetic flux density is on the order of tens of μT which is well within the detection limit of TMR sensors. The lateral misalignment of receiving coil will lead to a shift of magnetic field distribution compared to the original field distribution without misalignment (Fig. 1d). Therefore, it is feasible to determine the misalignment position by employing a TMR sensor array to measure the flux density in the y-axis direction and analyze the sensing position where the flux density is minimum. III. Simulation analysis and experimental validation A 3D FEM simulation of magnetic field distribution at the sensing positions was performed to validate the theoretical field-calculation model. Fig. 2a shows the dimension of the primary coil and receiving coil. The simulated magnetic flux density in the y-axis direction is shown in Fig. 2b. When the receiving coil is well-aligned with primary coil, the minimum value of B_y occurs at the sensing position of 0 mm. The minimum value occurs at the sensing position of -30 mm when the receiving coil is misaligned 30 mm towards the left side; whereas that occurs at 30 mm when the receiving coil is misaligned 30 mm to the right side. An experimental prototype (Fig. 2c) is also established according to the simulation parameters. The prototype was composed of the magnetic-resonant-coupling-based wireless power transfer system which adopted the series-series topology. Its operating frequency was chosen as 20 kHz. The power source was provided by an AC power supply. A sensor array consisting of 9 single-axis TMR sensors uniformly distributed in an interval of 15 mm is mounted on the plane of receiving coil. TMR2001 sensor is employed due to its high sensitivity (80 mV/V/mT), small size (3×3×1.5 mm) and wide dynamic range (up to 1 MHz) [8]. The outputs of the sensor array were amplified 50 times by differential amplifiers (AD620) and then sampled by a DAQ card into a computer. The measured field results in the y-axis direction are shown in Fig. 2d. It is easily observed that the minimum output of the sensor array occurs at the sensing position of 0 mm when no misalignment exists. The minimum output of the sensor array occurs at the sensing position of 30 mm when the receiving coil is misaligned 30 mm towards to the left side. The minimum output occurs at -30 mm when the receiving coil is misaligned 30 mm to the right side. The experimental results are in good agreement with the theoretical analysis and the simulated results. More detailed analysis results will be presented in the final paper.

1. Technology Research Center, Sumitomo Heavy Indurstries, Ltd., Yokosuka, Japan; 2. Oita university, Oita, Japan; 3. Oita Industrial Research Institute, Oita, Japan

In order to improve magnetic properties of non-oriented electrical steel sheets, effects of heat treatment in a magnetic field to control crystallographic orientation were studied. In this paper, we report on the effects of the amplitude and direction of the magnetic field applied during the heat treatment in comparison to magnetic properties of samples, which the longitudinal direction is parallel to the rolling direction (RD) or rolling transverse direction (TD). To clarify the effects of heat treatment in a magnetic field on the magnetic properties of the electrical steel sheets, heat treatment without magnetic field was firstly carried out and a change rate, defined as a value obtained by dividing the iron loss value after the heat treatment by the iron loss value before the heat treatment, was used in the evaluation. Fig. 1 shows a schematic view of the heat treatment apparatus. The heat treatment apparatus consisted of an electric furnace at inner diameter of a superconducting magnet (10 T - CSM) and a quartz glass tube inserted into the furnace. The quartz tube was depressurized to less than 10^{-3} Pa with a turbo molecular pump. The heat treatment temperature was controlled at 1023 K, 1123 K, and 1273 K. 10 mm × 50 mm sized samples were prepared by cutting a non-oriented electrical steel sheet, 50A470 (JIS C 2552), with electrical discharge machining. Samples were cut so that their longitudinal direction was parallel to the rolling direction or rolling transverse direction. The samples were placed at the center of the magnetic field in the quartz tube using a holding jig made of quartz in a way that the direction of the magnetic field would be parallel to the longitudinal direction of the samples. The strength of the applied magnetic field was set to a maximum of 10 T. Fig. 2 shows iron loss change rate of the samples heat treated at 1273 K with respect to iron loss before heat treatment. In Fig. 2, for example, “RD-10T” means the sample with longitudinal direction parallel to the rolling direction and applied magnetic field during the heat treatment of 10 T. The vertical axis represents the change rate and the horizontal axis represents the amplitude of the excitation magnetic flux density controlled by the sinusoidal wave of 50 Hz with a small-sized single sheet tester. As shown in Fig. 2, both the RD- and TD-samples heat-treated without magnetic field (0 T) under the temperature condition of 1273 K showed a remarkable change in the magnetic properties. The grain growth was accelerated by the heat treatment, the iron loss was reduced, and the permeability under low excitation conditions was improved. Contrarily, the permeability at 1.6 T or higher decreased. It was also found that the effect of the heat treatment on the reduction of the iron loss was greater in the TD-samples. As for the results of heat-treatment in magnetic field, the iron loss of the RD-sample was reduced after heat treatment in 10 T. On the other hand, the iron loss of the TD-sample increased after heat treatment in 10 T. It was also found that application of the strong magnetic field of 10 T throughout the heat treatment, i.e. during the heating and cooling, caused increase of the iron loss and decrease of the magnetic permeability regardless of the direction of the material. The cause of this phenomenon is possibly the contraction of the polycrystalline specimen in the strong magnetic field. The details will be discussed at the presentation and in the full version of this paper.

GV-05. Analytical Modeling of Multi-layer Permanent Magnet Eddy Current Brake With Hybrid Secondary.

B. Kou[1], *W. Chen*[1,2], Y. Jin[1] and X. Zhao[1]
1. Harbin Institute of Technology, Harbin, China; 2. Harbin University of Science and Technology, Harbin, China

I. INTRODUCTION Eddy current brake has been widely used in various kinds of industrial applications due to its outstanding performance. Compared with the electric excitation brake, permanent magnet eddy current brake has the advantages of compact structure, high efficiency and high reliability[1]-[4].In the eddy current brakes, the secondary according to the material can be divided into the non-magnetic reaction material and the magnetic reaction material. The secondary of non-magnetic reaction material with high conductivity is generally used for low-speed braking. The magnetic reaction secondary with high permeability is widely used in high-speed braking, such as high speed train braking systems. However, in the ejection experiment, it is necessary to brake the ejection object from high speed to low speed in order to avoid the ejection object broken. The hybrid secondary eddy current brake is the combination of the non-magnetic reaction secondary and the magnetic reaction secondary eddy current brake, which can make the secondary have higher braking force in both high speed and low speed. In this paper, a multi-layer permanent magnet linear eddy current brake with hybrid secondary was presented as shown in Fig.1(a). First, the structure and working principle were introduced. Then, the nonlinear analytic model was derived using the Maxwell's equations. The iron secondary was split into thin sheets of constant permeability, determined by an iterative procedure. The analytic model takes into account higher harmonics and secondary saturation. Therefore, the accuracy is observably improved. Finally, the accuracy of the analytical model is verified by the finite element method. II. FUNDAMENTAL STRUCTURE Fig. 1(a) shows the structure of the multi-layer permanent magnet linear eddy current brake with hybrid secondary. The primary part consists of the primary core and permanent magnets (PMs). The polarity of adjacent permanent magnets on the same row is opposite. Besides, the magnetized direction of the permanent magnet on the same column is the same. The two short hybrid secondary is made of copper plate with high conductivity and iron plate with high permeability material. III. ANALYTIC MODEL The hybrid secondary linear eddy current brake analytic model is simplified, as shown in Fig. 1(b). Because of the independence of the iron secondary and copper secondary flux, they can be divided into two regions separately. Since the model is symmetrical about the middle plane of each secondary, we can only study the half symmetric region and use the second kind of boundary conditions to simplify the structure. The copper secondary analytic model is divided into four different regions, primary iron core, permanent magnets, air gap and secondary copper plate. The iron secondary analytic model is shown in Fig.1(c). Considering secondary saturation, the iron plate is divided in fictitious layers whose permeability is determined by an iteration procedure. Then, the two analytic models are derived using the Maxwell's equations. IV. MODEL VALIDATION The finite element analysis is used to verify the validity of analytic model. Fig. 2(a) and Fig. 2(b) compare the air-gap flux density obtained by the FEM and analytical method. We plot the magnetic-flux density map inside the device with the speed of 20 m/s and 200m/s. It can be seen that the air-gap flux distortion due to higher harmonics. Fig. 2(c) is the iron secondary and the copper secondary braking force characteristic. The maximum braking force of the copper plate appears at a low speed range (about 5m/s). As the speed increases, the braking force decreases rapidly. The maximum braking force of the iron plate appears at a high speed (about 50m/s) and keeps constant as the speed increases. Fig. 2(d) shows the resultant braking force of the two conductor plates. The secondary braking force maintains a stationary value from high speed to low speed. Therefore, we can verify that the analytic model can reasonably take into account higher harmonics and secondary saturation. V. CONCLUSION In this paper, a multi-layer permanent magnet linear eddy current brake with hybrid secondary was presented. The magnetic field distribution is calculated by using the Maxwell's equations. The expression of braking force is derived based on the Maxwell stress expressions. The agreement between analytic model and finite element method is very good. It verifies the validity and universality of the analytical model.

GV-06. Parametric Design of Vehicle Horn Employing Rolled Silicon Steel Sheets Based on Its Analytical Approach.

J. Sim[1], K. Jung[1], D. Kim[1] and J. Hong[1]
1. Automotive Engineering, Hanyang University, Seoul, The Republic of Korea

I. Introduction Vehicle horn is an electromechanical energy conversion device which can be equipped with a variety of vehicles such as automobiles, motorcycles, trains, and trams. It is usually driven by a built-in electromagnet connected to a sinusoidal voltage source. Furthermore, the electromagnet produces an oscillating magnetic flux, vibrates a circular diaphragm, and makes a sound. This operating principle is similar to an electric bell or a buzzer. It plays a major role in calling attention to a collision risk or forewarning other people of a vehicle's presence and approach. The majority of countries legally regulate that all the vehicles should have the horns. As a result, their demand becomes gradually high as the vehicle market is expanded every year [1]-[4]. The carbon-steel-based solid cores are often used for all the components of the conventional vehicle horns such as body, diaphragm, pole, and armature. Such cores are a lot excellent in terms of cost-effectiveness, reliability, and productivity. On the other hand, they exhibit lower penetration depth and higher magnetic reluctance than the silicon-steel-based laminated cores when exposed to a time-varying magnetic field [5]-[7]. It is since the former has higher electrical conductivity than the latter. As a result, the traditional vehicle horns have the issues in extreme losses, inferior electromagnetic forces, and exposure to high temperature environment. This paper thus suggests a vehicle horn with novel structure employing rolled silicon electrical steel sheets as a solution for the aforementioned phenomena. The silicon electrical steel sheets surround the pole and armature of a conventional model. Such cores, 50A470, play a role in penetrating a time-varying magnetic field uniformly, preventing the eddy current from flowing in closed loop, and reducing the eddy current loss. In addition, the input current and the joule loss in copper winding are reduced thanks to the increased equivalent iron loss resistance. The corresponding equivalent magnetic circuit model is also developed to palliate a lot of computational burdens. The specific nonlinear analysis procedure and the circuit parameter extraction methods are referred to. The circuit model is used for the parametric design procedure of the novel vehicle horn. As a result, an optimum model with minimum loss and equivalent performance is obtained. Finally, it is manufactured and experimented in order to justify its effectiveness compared with the conventional vehicle horn. II. Rolled Silicon Electrical Steel Sheets In the case of the carbon-steel-based solid cores, the eddy current and the consequent loss are mainly induced at the skins of the pole and the armature due to their high electrical conductivity. However, the silicon-steel-based rolled cores exhibit lower electrical conductivity and higher magnetic permeability than such solid cores. The silicon electrical steel sheets, 50A470, are rolled around pole and armature of a conventional model. The silicon steel sheets prohibit the eddy current from flowing in closed loops and decrease the consequent loss. Furthermore, by means of the increased equivalent iron loss resistance, the input current and the joule loss in copper winding are also reduced. III. Analytical Approach Its analytical approach is introduced to represent the interconnection between an axisymmetric vehicle horn and an AC voltage source as described in Fig. 1 [1]. The circuit model is expressed in phasor forms because the sinusoidal time variations of the voltage source will generate the sinusoidal variations of electric and magnetic fields with the same frequency in the time harmonic fields. Also, it composes of the excitation coil resistance, the equivalent iron loss resistance, and the system effective reluctance. IV. Parametric Design In this parametric design, the two major design parameters were the excitation coil turns and the armature diameter to which the conventional one and the supplementary silicon steel diameter belong. In addition, the armature height, the pole diameter, and the pole height were set as the dependent design variables to keep up the weight of the driving part, i.e. the armature and the diaphragm, and the length of the air-gap as the armature diameter changes. The objective functions were the following four electromagnetic characteristics; force, input current, copper loss, and iron loss. In this case, the constant AC voltage condition was applied to. As a result, so as to maintain the electromagnetic force and minimize the other objectives and the coil turns, the armature diameter should be changed from 10mm to 18mm. The coil turns also changed from 150turns to 95turns as in Fig. 1. V. Experimental Verification The two prototypes and its experimental setup are shown in Fig. 2. The coil resistance, the active power, the reactive power, the amplitudes and the phases of the input voltage and current were measured for the condition above. The measured data could be used to calculate the copper loss, the iron loss, and the back electro-motive force, which were compared with those from the analytical approach for the two models. Such validation gives the approximately accurate estimation of the performance and the effectiveness of the novel model compared with the conventional model.

GV-07. Analytical Modeling of Angular Misalignment for Axial Flux PM Machines: Effects on Cogging Torque.

B. Guo[1] and y. huang[1]
1. School of Electrical Engineering, Southeast University, Nanjing, China

Abstract: In this paper, an improved semi-analytical model is proposed to investigate the cogging torque of axial flux permanent magnet (AFPM) machine under angular misalignment. First, the axial and circumferential flux density in the airgap under healthy condition is developed by Maxwell's equations and Schwarz–Christoffel (SC) mapping. Second, the SC mapping in MATLAB toolbox is modified to consider the angular misalignment which could improve the accuracy. The results show that the analytical predictions agree well with the finite element (FE) results, also, the model is verified via the performance of experimental results. The main contribution of this paper is that the approach developed in this paper is more accuracy for angular misalignment, especially for the flux densities in the airgap. I. INTRODUCTION Axial flux permanent magnet machines (AFPMMS), due to their compact mechanical structure and high power density, are widely used in industrial applications, such as the fly wheel energy storage system. However, the contact area between the rotor plate and shaft is relative small, which makes the rotor predisposed to angular or axis misalignment. The misalignment of AFPMMs may cause serious problems, for instance, the unbalance magnetic force and mechanical vibration[1]. Therefore, these manufacturing imperfections should be detected quickly in order to avoid accidents. A significant amount of work has been done concerning the eccentricity for HSPMMs. Mark Thiele study the cogging torque via FE approach[2], while Antonino investigated manufacturing dissymmetry effects based on field functions in order to reduce computational time[3]. Nevertheless, these models are still based on the FE method and time consuming. In [4], the author adopted the lateral force approach to study the static angular eccentricity considering slot effect. This technique is convenient and simple. However, it neglects the tangential components of the air gap flux density. As previous study, [5] deal with several types of eccentricities. However, the magnetic flux densities of the static declined eccentricity in [5] do not match very well with the FE results. This paper is organized as follows. In Section II, the parameters of AFPM machine with Halbach array is provided. Section III will introduce the electromagnetic calculations used in this paper. The angular misalignment model and its solution strategy will be presented in Section IV. Afterward, the cogging torque is then discussed in Section V. In section VI, the experiment results are presented and compared with the results of model. At the end, conclusions will be presented. II. PROTOTYPE PARAMETERS The prototype construction of AFPMMs is a 5 phase, 2 pole pairs, 10-slot AFPMM with Halbach arrays, the basic dimensions and key design parameters are listed in full paper. III. DESCRIPTION OF ANALYTICAL MODEL Based on the separating variable method, the general magnetic vector potential solution for region I and II (shown in Fig. 1) can be written and solved by Matlab [6]. Using the Schwarz–Christoffel (SC) mapping technique [7], the flux densities of center airgap are calculated. The results shows that the analytical results agree well with the FE results. IV. MODEL OF ANGULAR MISALIGNMENT In this paper, to improve the accuracy of the magnet flux calculation, the structure of static angular eccentricity is directly draw by the SC Matlab toolbox. In order to reduce the computational time, the flux densities within only half period is calculated. Afterwards, the permeance function could be calculated. The flux densities at the mean radius are calculated by both the proposed method and FE method. Good agreement of both axial and circumferential flux densities are shown in Fig. 2. It can be seen that the accuracy is improved than approach shown in [5]. VI. EXPERIMENTAL RESULTS The rotor disk and the stator of the AFPM prototype are shown in full paper. The experimental setup and devices are carried out. In the test bench, the prototype is coupled with an inductance motor via belt system. The inductance motor is driven by an inverter. VII. CONCLUSION The high speed AFPM has been emerging in many industrial applications due to their compact structure and high power density. However, it has a critical problem with assembling process because of the imperfect manufacturing. Thus, this paper has a significant contribution in that the model developed in this paper has improved the accuracy, and the computation time can be reduced remarkably. In addition, it is notable that the cogging torque under normal and angular misalignment is investigated in this paper. Consequently, the approach proposed in this paper can be regarded as an effective analysis tool for AFPM machine under such condition. More information could be seen in the full paper.

I. Introduction In general, traction motors for the electric vehicles (EVs) and hybrid EVs have to offer the characteristics, such as high torque, wide speed range, high efficiency, high controllability, and maintenance-free operation [1]. To achieve these goals, our research group is studying a new rare-earth-free motor that combines two driving principles. In a previous paper [2], an electromagnet-assisted ferrite magnet motor (EMaFM) was proposed, and its electromagnetic performance was investigated on a 1.5-kW radial-gap EMaFM (RG-EMaFM). The EMaFM is a motor in which the torque due to a ferrite magnet motor is assisted by the variable magnetic force of an electromagnet motor. In the EMaFM, a flux-modulating synchronous motor (FMSM) [3], which does not require brushes and slip rings, was used as the electromagnet motor, and a surface permanent magnet synchronous motor (SPMSM) was used as the ferrite magnet motor. From two-dimensional (2-D) finite element analysis (FEA) and experimental results, it was found that the torque can be controlled widely by the armature current or field current. In this paper, an axial-gap EMaFM (AG-EMaFM), which achieves high torque in the EMaFM, is newly proposed, and its electromagnetic performance is investigated by using three-dimensional (3-D) FEA. II. Proposed AG-EMaFM Figure 1(a) and (b) shows the topologies of the EMaFM, namely the conventional RG-EMaFM and the proposed AG-EMaFM. In the conventional RG-EMaFM, the motor base housing becomes longer in the axial direction than that of the proposed AG-EMaFM in order to rotatably support the rotor and rotating shaft. Moreover, there are problems such as a decrease in the conductor areas of the inner armature winding (W_{a1}) and difficulty in cooling the W_{a1}. However, with the proposed AG-EMaFM, these problems can be solved at once. In the after-mentioned performance analysis, the air-gap lengths and the sizes of active parts for torque production of the RG- and AG-EMaFMs are designed to be the same for easy comparison. Additionally, as shown in Table I, the slot-fill factors of the two armature windings (W_{a1} and W_{a2}) and field winding (W_f) in the AG-EMaFM were designed to be almost the same, and the conductor areas of the W_{a1} were increased. III. Results of Performance Analysis Figure 2 shows the magnetic flux density distribution in the AG-EMaFM under i_d = 0 control. In the figure, i_d and i_q are the d- and q-axis currents, respectively, I_f is the field current, and N_r is the rotating speed of the rotor. From Fig. 2, it can be seen that the magnetic saturation is more likely to occur in the stator teeth of the FMSM side. Figure 3 shows the torque waveforms of the RG- and AG-EMaFMs under i_d = 0 control. As can be observed from Fig. 3, the average torque (T) of the AG-EMaFM is 1.39 times higher than that of the RG-EMaFM when the magnetomotive force of the W_f is the same. IV. Conclusion As described above, the proposed AG-EMaFM is better than the conventional RG-EMaFM in terms of downsizing the motor base housing and cooling the windings. In addition, its torque density can be improved by increasing the conductor areas of the windings.

INTRODUCTION Several researchers have recently focused on core loss reduction of the motor based on core with nanocrystalline magnetic materials (NMM) [1, 2], which offer low iron losses [3]. Previous studies have shown permanent magnet synchronous motors (PMSM) by use of “only stator core” made of NMM have low core losses [1, 2]. Here, in order to realize low loss motor system, it is necessarily to understand core loss properties of “both stator and rotor cores” with NMM. However, there has been no report on the motor by use of “both NMM stator and rotor cores”. In this study, the core losses of PMSM with the NMM stator and rotor cores under pulse-width-modulation (PWM) inverter excitation are evaluated based on both experiments and numerical simulations. The comparison with PMSM made of conventional non-oriented (NO) steels is also performed. In addition, we discuss the core loss repartition by using numerical simulations. MOTOR CORE AND ITS MEASURMENT SYSTEM Fig. 1 shows the appearance of the rotor and stator cores and the completed PMSM motor. The nanocrystalline alloy ribbons consisted of Fe-Si-B-Cu-Nb are laminated and impregnated with acrylic resin to make the block core. The laminated block core is then cut in the shape of the rotor core using electric discharge machining. The rotor core with an outer diameter of 74 mm and a thickness of 47 mm is constructed. The space factor of the rotor core is about 82%. See Ref. [4] for the details of the NMM stator, NO rotor, and NO stator cores. From here on, the PMSM with NO (NMM) stator and rotor cores is called NO-PMSM (NMM-PMSM). Fig. 1 also illustrates the set-up of PMSM measurement system, which consists of a three-phase voltage source PWM inverter with IGBT, under no-load condition. A power analyzer (Yokogawa PX8000) is used to measure the phase voltages, the phase rms currents and then the input active electrical power P_{in}. Conventional vector control is used for the speed control. Under these conditions, the PMSM total iron losses W are calculated by $W=P_{in}-P_{cu}-P_{m}$, where P_{cu} is the copper loss and P_{m} is the mechanical loss. See Ref. [4] for the details of measurement system. In our numerical simulations, 2D-finite element method (FEM) with A method is performed. In our simulations, iron losses of the soft magnetic cores are calculated from Steinmetz equation and then, the magnet losses are calculated by using the electrical conductivity and the analyzed eddy current density. See Ref. [4] for more details of numerical simulation methods. RESULTS AND DISCUSSION Fig. 2(a) shows the experimental results of core losses of both the NO-PMSM and the NMM-PMSM. The measurements have been done at 750, 1500, and 2250 rpm that correspond to electrical frequency of 50, 100, and 150 Hz, respectively. The core loss increases with the increase of the rotational speed. The core loss of the NO-PMSM (NMM-PMSM) is about 2.3, 5.2, and 8.0 W (1.1, 2.6, and 3.9 W) at 750, 1500, and 2250 rpm, respectively. In average, under PWM inverter excitation, the total core losses of the NMM-PMSM are about 60 % lower than those of the NO-PMSM. In order to discuss the core loss repartition, we do the numerical simulations. Fig. 2(b) shows core loss repartition between the stator, rotor and magnets of NMM-PMSM and the NO-PMSM by numerical simulations. Here, the numerical core losses are fit to the measured iron losses at 1500 rpm. The average rotor loss of NMM-PMSM and the NO-PMSM cores accounts for 16% and 18% of the total core losses, respectively. The average decrease obtained by using NMM instead of NO in only the stator (rotor) core is about 62% (56%). Here, replacing the NO rotor and stator cores of the proposed PMSM by those cores with NMM leads to a reduction of the core losses. The core loss reduction depends not only on the stator core but also on the rotor core. These results confirm the benefit of using not only NMM stator core but also NMM rotor core to reduce the motor core losses. CONCLUSIONS We for the first time developed and examined PMSM by use of “both stator and rotor cores” made of NMM. The core loss of the NO-PMSM (NMM-PMSM) was about 2.3, 5.2, and 8.0 W (1.1, 2.6, and 3.9 W) at 750, 1500, and 2250 rpm, respectively. In average, under PWM inverter excitation, the total core losses of the NMM-PMSM were about 60 % lower than those of the NO-PMSM. The average decrease obtained by using NMM instead of NO in only the stator (rotor) core was about 62% (56%). The core loss reduction depended not only on the stator core but also on the rotor core. These results open the way to further research in ultimate low loss motor system based on both rotor and stator cores made of NMM. ACKNOWLEDGMENT This work was partly supported by the New Energy and Industrial Technology Development Organization (NEDO) and the Ministry of Education, Culture, Sports, Science and Technology Program, Japan, for private universities.

GV-10. An Approach Combining Analytical Calculation and FEA for Evaluation of Rotor Strength of IPM Motors.

M. Hsieh[1], J. Lai[1] and C. Li[1]
1. National Cheng Kung University, Tainan, Taiwan

1. Introduction and Research Method This digest proposes a FEA-assisted approach for evaluation of the mechanical strength of interior permanent magnet motors (IPM motors). The rotors of IPM motors can be structurally weak due to inevitable bridges or ribs that should be as narrow as possible to mitigate flux leakage. An ideal design is such that the motor can maximize the electromagnetic performance while keeping the rotor just sufficiently safe. However, common ribs/bridge design is usually conducted with experiences, intuition or alternatively, using only structural analysis, which completely ignores the effect of electromagnetic force. To maximize the motor performance, an over safe design, i.e., wider ribs/bridges than needed, should be avoided. To do this, coupled electromagnetic-structural simulations would be necessary so that the mutual effect of the rotor structure (i.e., rib/bridge width) and electromagnetic performance can be fully investigated. Also, the forces acting on the rotor and causing stress contain centrifugal force and electromagnetic force. This should also be simulated using coupled simulation; however, this is very time consuming and would prolong the development process. The method developed here is to predict the structural safety using solely structural analysis without the coupled simulation while maintaining the electromagnetic effect and keeping sufficient accuracy. The Maxwell stress tensor is employed to calculate the electromagnetic force on rotor surface for different load conditions. A modification factor is then determined by the ratio of the calculated electromagnetic force plus the centrifugal force obtained using FEA to the FEA centrifugal force [i.e. (Fem_cal+Fcent_fea)/Fcent_fea]. This facor is greater than or close to one and can be used to compensate the error caused by the structural simulation only. Note that the structural simulation can directly obtain the stress on the rotor ribs/bridges so that the added electromagnetic force is assumed to linearly contribute to the stress levels. This can then be used to inspect the rotor mechanical strength with a reasonable accuracy. 2. Target Motors A group of IPM motors with different rotor diameters (from 48 mm to 110 mm) and power ratings (from 3 kW to 12 kW) but similar torque-per-unit-rotor-volume are investigated. One prototype is built and tested based on the previous analysis. Then, the experiments are performed to validate the simulations and the developed approach. 2.1 Computation of Electromagnetic Force As previously stated, the Maxwell stress tensor is used to calculate the rotor surface electromagnetic force. This is then compared with FEA (sample in Fig. 1) for validation. This will be detailed in full paper and part of the results will be presented along with structural analysis. 2.2 Structure Simulation The centrifugal forces are calculated using ANSYS simulation. The results do not consider electromagnetic effect. However, as previously stated, the modification factors obtained from the results in Sections 2.1 and 2.2 will be added to the structural simulation so that the electromagnetic effect can be included. Sample results are shown in the following figures and will be explained later. 2.3 Coupled Electromagnetic-structural Simulation This coupled simulations can calculate the combined effect of centrifugal and electromagnetic forces on ribs/bridges stress. Usually at low speed and high torque, the electromagnetic force dominates. As the speed increases, the centrifuge force increases and dominates. Fig. 2 shows that when no rib is utilized, the motor can only operate up to around 3500 rpm. On the other hand, if ribs are utilized in the design, the speed range can be extended but the efficiency decreases, as shown in Fig. 3. These coupled simulations will be used to validate the proposed method. 3. Comparison of Proposed Method and Coupled Simulation Some research only used centrifugal force to evaluate the rotor mechanical strength [1-3], but this could be insufficient for some conditions. From this digest, it is found that, if only the centrifugal force is considered, the rotor stress could be underestimated, in particular for small motors. As stated, a modification factor is introduced so that the sole structural simulation can be used without the need of coupled simulation. Fig. 4 shows the comparison of the proposed method and coupled simulation (more motors and results will be shown in the full paper). As can be seen, both methods agree well (2X or 1X indicate the modification factor). It is also found that, for rotor diameter beyond 110 mm, the centrifugal force dominates and the accuracy on rotor stress would be sufficiently good by using only the structural simulation. The smaller the rotor is, the bigger the modification factor is. 4. Experimental Study Some simulation and experiment results are compared in Fig. 5, where both cases agree well. 5. Conclusion The proposed method combines the analytical calculation and structural FEA to evaluate the mechanical strength of the rotors of IPM motors. A modification factor is introduced. The results were validated by coupled electromagnetic-structural simulation using ANSYS. The simulation on motor performance was also verified experimentally. More details will be reported in the full paper.

GV-11. 2D Analytical Subdomain Model of Surface-Mounted PM Machines Accounting for Step-skewed Magnets.

S. Zhang[1] and S. Guo[2]

1. Bangor College, Central South University of Forestry and Technology, Changsha, China; 2. State Grid Hunan Electric Power Research Institute, Changsha, China

Abstract—The subdomain model for analytical calculation of magnetic field is widely developed to predict electromagnetic performance in PM machines. Based on the principle of the mutual flux through the stator windings due to step-skewed PMs identical to that from equivalent non-skewed PMs, a 2D subdomain model of surface-mounted PM machines accounting for step-skewed magnets is proposed. By resolving the analytical expressions of the equivalent PMs subdomain, the 3D problem of step-skewed magnets along axis is simplified to a 2D problem, which saves the computational resources and improves the efficiency. The 2D multislice finite-element analysis confirms accuracy of the analytical method. *Index Terms*—Surface-mounted permanent magnet machines, subdomain model, step-skewed magnets, analytical method. I. Introduction With the performance improvement of permanent magnet materials, permanent magnet motors are widely used in high-performance speed and position control systems. However, the interaction between the permanent magnet and the slotted armature iron core generates torque ripple inevitably, which causes vibration and noise, and then affects the control precision of the system. Due to the low cost and suitable for mass production, magnet skewing is a common method of reducing torque ripple [1]. It is showed that using step-skewed magnet is an effective design approach to improve torque ripple, but requires optimum skew angle and careful design of magnet shapes [2]. In [3], it is also pointed out that step number and magnet-skew angle determines the effect of reducing torque ripple. By optimizing the skewing angle and current phase advance angle together, an improved skewing is proposed to reduce torque ripple over the whole load range [4]. There are mainly two techniques for analyzing skewed PMs, which is finite-element-based method and analytical method. In [5], a number of slices for the finite-element model are employed to represent skewed magnets of the machine, which is called 2D multislice finite-element method. Since the 2D multislice methodology spent a lot of computing time, a geometric equivalent non-skewed PM structure is proposed and performed in 2D finite-element method for surface-mounted PM Machine with skewed magnets [6]. In [7], a 3D analytical model is developed for tubular actuator with skewed PMs, and the 3D finite-element method is used to verity the analytical solution. Compared with the huge computing resource requirements of 2D multislice and 3D finite-element, the analytical method shows the advantages of clear physical concept and fast calculation. In recent years, the subdomain model based on variable separation method [8] has been widely used for calculation of magnetic field distribution in surface-mounted PM Machine [9]-[10], but the influence of skewed PMs are not considered in the analytical model. In this paper, based on the principle of the mutual flux through the stator windings due to step-skewed PMs identical to that from equivalent non-skewed PMs, a 2D subdomain model of surface-mounted PM machines accounting for step-skewed magnets is proposed. The main objective is to express the residual flux density of the equivalent PMs along the circumference, then the resolution of the equivalent PMs sub-domain in 2D polar coordinates makes dimensions reduction feasible. The analytical solution is validated by 2D multislice finite-element analysis. II. Step-skewed Magnets And Equivalent non-skewed PMs Subdomain The schematic model of step-skewed magnets in surface-mounted PM machines is shown in Fig.1. θ_{skew} is the total mechanical angle for PMs skewing, M is the PMs segment number along the axis, L_{ef} is core axial length. The skew angle of each PMs segment α in the circumferential direction can be obtained. In order to consider the effect of step-skewed PMs, an equivalent non-skewed PMs structure is shown in Fig.2, which has the same flux per pole with the step-skewed PMs. Taking the radial magnetization PMs for example, remanent magnetic flux density of each magnet segment is B_r. The equivalent non-skewed PMs have different remanence values per pole along the circumference shown in Fig.2. Regarding the equivalent PMs as a subdomain with new type of remanence magnetization pattern, the analytical solution of PMs subdomain can be resolved in 2D polar coordinates. The result of electromagnetic performance for surface-mounted PM machines accounting for step-skewed magnets and FE validation will be given in the full paper.

This paper propose design strategy of 3-times magnetizer and rotor of ferrite spoke-type permanent magnet synchronous motor (PMSM) for post-assembly magnetization. In spoke-type PMSM, the design of the permanent magnets and the winding of magnetizer have a great effect on the magnetization, demagnetization and the torque of the motor. For this reason, it is very important to design these parameters appropriately[1]-[3]. In addition, transient analysis must be performed in order to perform accurate magnetization analysis. However, in order to derive the final design model, it takes a lot of time to perform transient analysis for each model. Therefore, we proposed a design strategy for shortening design and analysis time. Fig. 1 shows spoke-type PMSM and 3-times magnetizer. The rotor of spoke-type PMSM is 10 poles and 10 of permanent magnets are magnetized by 3-times magnetizer. 3-times magnetizer magnetizes the four permanent magnet per 1 times. Then remaining four magnets are magnetized after the rotor has rotated 144 degrees. Finally, the last two remaining magnets are magnetized after the rotor is rotated 144 degrees. At this time, two of the ten permanent magnets will be magnetized twice. In this paper, the magnetization analysis was performed through finite element analysis and the commercial FE software (Maxwell) was used. Fig. 2 is the FEA results of 3-times magnetizer. Red area is magnetization area (over than 340kA/m), green area is part that is not magnetized (below 340kA/m) and blue area is demagnetization area (below -290kA/m). The magnetic flux from the main pole magnetizes the four permanent magnets. At this time, some leakage magnetic flux generate demagnetization as shown in the blue area. To prevent such demagnetization, magnetic flux from the inter-pole cancels the leakage flux. Therefore, Proper design of the number of turns of the main pole and the inter-pole is necessary for complete magnetization and prevention of the demagnetization.

GV-13. Numerical Design and Validation of SPMSG for Efficiency Improvement of Engine-Generator System of PHEV compatible to Optimal Operating Line.

D. Lee[2], S. Cho[1] and *H. Jung*[1]

1. Advanced Power System R&D Center, Korea Automotive Technology Institute, Cheonan-si, The Republic of Korea; 2. Department of Electrical and Computer Engineering, University of Illinois at Urbana-Champaign, Urbana, IL, United States

I. INTRODUCTION Development of green car like EV(Electric Vehicle), HEV(Hybrid Electric Vehicle) and PHEV(Plug-in Hybrid Electric Vehicle) is dramatically accelerated to deal with the environmental regulation control and fossil fuel depletion dependent on fuel economy and hazardous emissions. EV have disadvantage of high cost, battery weight and deficient total driving distance. Hence, PHEV is getting the spotlight in the eco-friendly vehicle as one of the alternative candidates, which increase the energy storage capacity and extend the pure electric vehicle driving distance. In particular, EGS(Engine-Generator System) is mostly significant to fuel economy and total driving distance of PHEV, which is composed of the electric generator mechanically coupled with engine system. For the sake of PHEV's running fulfillments, EGS is utilized to charge the high voltage battery in accordance with the required electric power. SPMSG characterized with the superiority of high efficiency and torque density takes center stage as an electric generator of EGS in that fuel efficiency of PHEV is directly linked with efficiency characteristics of SPMSG. Continuous rated power and efficiency distribution of SPMSG should be improved for EGS of PHEV [1]. In addition, it is mandatory for EGS of PHEV to employ on OOL(Optimal Operating Line) which comes from the best efficiency points of engine and SPMSG at each operating speed. Hence, OOL of EGS should be obtained to advance the efficiency for the specified operating range of EGS, which can be achieved through the numerical and experimental design validation of SPMSG compatible to the engine characteristics [2]. In this paper, numerically optimal design based on FEM coupled with optimization algorithm has been performed for realizing the maximum efficiency for the specialized SPMSG of EGS compatible to the frequent operating range dependent on OOL. In accordance, optimal design process follows the two-steps; the first step is to obtain the possibly acceptable design result based on analytical method, and the second step is to optimize the design parameters in detail aiming at the maximum efficiency in the continuous rated power region for OOL of engine. Furthermore, the purposely designed SPMSG for EGS of PHEV is experimentally evaluated under static and dynamic condition making use of dynamometer setup. In accordance, validness of the optimized SPMSG is clarified with the measured efficiency map which shows good compatibility to the main operating range and OOL of EGS [2]. II. CHARACTERISTICS OF ENGINE AND SPMSG FOR EGS A. Analysis of Optimal Operating Line for Engine The test of the engine for EGS of PHEV is performed to analyze the OOL. The experiment-layout of engine test with dynamometer is shown in Fig. 1, whereby static performances driven by ECU(Engine Control Unit) are measured following the issued OOL. The major target operating range for design and validation based on the EGS characteristics can be registered In Fig.2 and 3. B. Design Specification of SPMSG for PHEV The most attractive candidate for EGS of PHEV may be SPMSG on account of its higher efficiency and torque density outstandingly near the whole operating range. Particularly, 140kW SPMSG for EGS of PHEV has been applied for the analytical and numerical design on OOL, which is summarized in Table I. III. OPTIMAL DESIGN OF SPMSG USING OPTIMIZATION ALGORITHM COUPLE WITH F.E.M COMPATIBLE TO OOL The optimal design of SPMSG using analytical method and optimization algorithm for EGS of PHEV is performed to maximize the efficiency on OOL. The numerical results for candidates are compared to verify the effectiveness of optimization. As it can be seen in Fig. 4, optimal design of SPMSG, of which the design objective is maximizing the efficiency, can be carried-out using optimization algorithm coupled with F.E.M computing the efficiency with satisfaction for performance and limit conditions. The flux density distribution of the enhanced SPMSG for maximizing the efficiency in the frequent operating area is depicted in Fig. 5. IV. DESIGN VALIDATION OF SPMSG BASED DYNAMOMETER Optimal design results of SPMSG for maximizing efficiency on OOL are compared with the experimental test results at each operating points. Not only the torque characteristics but the efficiency versus main operating points on OOL is compared, which are shown in Fig. 6 - 7, respectively. The experiment-layout of motor test is shown in Fig. 8, whereby static and dynamic characteristics for the purposely designed prototype are measured to verify the efficiency performances. As it can be known in Fig. 9, the measured efficiency of SPMSG with the applied second-step design is distributed from 95.9% to 97.8% on OOL of engine. In addition, the measured efficiency range of EGS with the purposely designed SPMSG is covering level of 35.2% to 39.4% in main operating region of EGS, which shows good-efficiency compatible to OOL. V. CONCLUSION The purposely designed SPMSG in association with analytical method and optimization shows optimal design results compatible to the frequent operating range which is identified for EGS of PHEV. Furthermore, the OOL of EGS is properly obtained through the experimental efficiency maps of engine and SPMSG.

GV-14. Development of enhanced magnetic equivalent circuit (eMEC) by considering dominant fringing fluxes in semi-high-speed Maglev train.

C. Ha[1], J. Jeong[2] and J. Lim[1]
1. Dept. of Magnetic Levitation and Linear Drive, KIMM, Daejeon, The Republic of Korea; 2. Dept. of Electrical Engineering, Chung Nam National University, Daejeon, The Republic of Korea

1. Introduction A magnetic levitation (Maglev) train is one of the innovative candidates to satisfy the requirements of next-generation transport systems. Recently, Maglev trains using linear inductance motor (LIM) have been actively studies in Japan, Korea, and China. The existing target of R&D was focused on development of urban Maglev train for connecting within the city, but recently target has been expanded to development of semi-high-speed Maglev train for the purpose of connecting city to city. The main difference of urban and semi-high-speed Maglev trains is maximum operating speed: around 100km/h (urban) vs around 200km/h (semi-high-speed). In semi-high-speed Maglev train, the guidance system is essential to guarantee stability for curved section and against side winds. When designing levitation and guidance electromagnets in semi-high-speed Maglev train, it is necessary to consider the following matters: 1) Since semi-high-speed Maglev train should use the already developed rail for urban Maglev train, there are many design constraints in designing the guidance system [1]. 2) Owing to the design constraints, the guidance electromagnet have to be placed near the levitation electromagnets. Due to the spatial closeness, magnetic coupling effect is severe [2]. 3) Recent studies have shown that the effect of fringing flux is negligible. Therefore, more accurate model is needed by considering dominant fringing fluxes in semi-high-speed Maglev train. In this paper, we newly proposed enhanced magnetic equivalent circuit (eMEC) model to tackle the issue of 3). The significance of development of eMEC model is as follows: A) When designing levitation and guidance systems of semi-high-speed Maglev trains, it takes a lot of time to design based on FEM analysis and experimental data. But, by adopting eMEC model in the initial design stage, design time can be greatly minimized. B) In order to development of precise controllers for levitation and guidance systems, it is very important to provide an accurate system modeling. The eMEC model can provide a highly accurate closed-form system model between control input (levitation and guidance currents) and control output (levitation and guidance forces), which can greatly shorten development and verification time of the controllers. 2. Development of enhanced magnetic equivalent circuit (eMEC) by considering dominant fringing fluxes in semi-high-speed Maglev train Fig. 1(a) shows FEM analysis of semi-high-speed Maglev train. As shown in Fig. 1(b), by comparing the results of FEM analysis with the previous developed MEC model, there is significant difference: 10.6% and 35.6% at operating point in levitation and guidance systems. The main reason of the difference is that the previous MEC model does not consider fringing fluxes. As shown in Fig. 2(a), the fluxes generated in electromagnets in semi-high-speed Maglev train was quantitatively measured and compared by using FEM analysis. The eMEC model improves accuracy by modeling dominant fringing fluxes as magnetic equivalent circuits as shown in Fig. 2(b). In order to verify the accuracy of proposed eMEC model, results of FEM analysis and experimental data and eMEC model are compared and analyzed as shown in Fig. 2(c). At operating point, the errors between eMEC and FEM and experiments are less than 3%, which means that the accuracy is improved up to 12 times compared with previous MEC model. 3. Conclusion In this paper, we quantitatively analyzed the effect of fringing fluxes in semi-high-speed Maglev train and newly proposed highly accurate eMEC model by modeling dominant fringing fluxes as magnetic equivalent circuits. The proposed eMEC model would contribute shorten the design time of levitation and guidance system in initial design stage and development and verification time of controllers in semi-high-speed Maglev train.

1. Hanyang Univ., Seoul, The Republic of Korea; 2. Busan Institute of Science and Technology University, Busan, The Republic of Korea

As global fuel consumption increases, the requirements for environmental protection are becoming stricter. Therefore, the fuel economy and emission performances of internal combustion engines need to be improved continuously. In addition, the reduction in fuel consumption in cars is a topic of considerable interest for manufacturers, politicians, and environmental activists [1],[2]. The injector is a component of the car's fuel system that plays a significant role in the reduction of fuel consumption. The fuel injector is an electromagnetic device that produces a magnetic field when current is passed through its coil windings. It also refers to a variety of transducer devices that convert electrical energy into kinetic energy [3]. A gasoline direct injector (GDI) has the following requirement: the atomized fuel in the cylinder must be completely burned and saving fuel. Meanwhile, imperfectly injected fuel causes clogging. Therefore, in-depth research regarding the improvement of performance and minimization of response time is required. Therefore, increasing the magnetic force (MF) is the most important design objective. To increase the force density of GDI, extensive control [2],[4],[5] and design methods [2],[6] have been reported, such as using giant magnetostrictive materials and fuzzy control [2], and permanent magnet (PM) ring inserts [6] to obtain a larger magnet flux density and reduce the flux leakage in the magnetic circuit of the GDI. The hybrid GDI with PM increases the total force density by using PMs. However, it is important to note that the irreversible demagnetization in hybrid GDI has been a persistent major concern because it can degrade the machine's performance characteristics substantially. First, the GDI on the side of the cylinder is affected by the great temperature change; second, depending on operating conditions, the peak boost current can reach high values that are three to four times the injector's holding current value, presenting a serious threat of irreversible demagnetization to the PM. Third, caused by the air-gap change and the more sensitive demagnetization reaction for micro-PM, a more subtle analysis is required. This paper proposes the design and analysis of a double-layer magnetic circuit structure hybrid GDI for attaining a high force density, meanwhile hybrid GDI with three different magnet type was inserted to analyze demagnetization characteristics using the 2-D Static and transient finite element method (FEM). Fig.1 shows a general sectional view of the basic GDI. The specifications are described in Table I. Fig.2 shows the hybrid GDI (PM inserted) with its flux paths, and it is shown to be divided into a structure in which both the PM and coil co-supply the magnetic flux. It is referred to as the "double-layer magnetic circuit structure" in this paper. Fig.3 shows the magnetic field distribution of the three types of PMs by 2D static FEM. In Fig.3 (a), as the temperature increases, the magnetic density in the magnet is reduced significantly because of the temperature coefficient. The demagnetization area is depicted by the temperature readings. Green and yellow color is the demagnetization sections at 120 °C. The region in the dotted line is demagnetizing region. Therefore, the design in the GDI system use NdFeB PM is not satisfactory. Fig.3 (b) and Fig.3(c) show the results of the analysis of ferrite PM and SmCo PM, respectively. It is found that the ferrite can maintain the PM characteristics at high temperature; however, at low temperature (-40 °C), a large area of demagnetization occurs. SmCo PM has a good thermal performance; the thermal reaction is small. SmCo PM maintains stable characteristics. For more accurate the effects of temperature, air-gap length change, and peak current are considered. At last, the comparison of the basic and hybrid GDI was discussed. The characteristics of MF, response time, copper loss and cost are investigated.

GV-16. Analytical Model for Axial Flux PM Machines with Halbach Arrays: Taking into Account of Rotor Iron.

B. Guo[1] and y. huang[1]
1. School of Electrical Engineering, Southeast University, Nanjing, China

Abstract: In this paper, a general analytical model is proposed to consider the thickness of backplate of axial flux permanent magnet (AFPM) machine with Halbach arrays. Firstly, the machine is represented in a 3-region model, viz, rotor iron, PM and airgap region, then, the slotless flux density is developed by Maxwell's equations. Second, the Schwarz–Christoffel (SC) mapping technique is introduced to consider the slot effect. Moreover, a simple magnetic equivalent circuit is introduced to calculated the magnetic permeability of rotor iron. The results show that the analytical predictions agree well with the finite element (FE) results, also, the model is verified via the performance of experimental results. The main contribution of this model is that the rotor iron part is taken into consideration, which is more accuracy. I.INTRODUCTION Halbach magnetized permanent magnet arrays are widely used in industrial machines, especially in axial flux permanent magnet (AFPM) machines since the different magnetization direction is easier to be realized because the flat magnets. The machines with Halbach PM arrays have almost sinusoidal induced electromotive force and the torque ripple. This array can cancel the flux on one side and strengthen the flux on the other side. This means that the permanent magnets essentially do not require much or no rotor iron [1]. However, the flux density in the airgap is significant different with and without rotor iron, which means that the thickness of rotor iron can affect the electromagnetic performance and it is necessary to consider the rotor iron when modeling the machines. A significant amount of work has been done concerning the machines with Halbach arrays. Authors in [2], [3] investigate the electromagnetic characteristics of machines with Halbach arrays. Nevertheless, these models are based on the FE method, and the FEM is time consuming, especially for further optimization. Another alternative is analytical method. It is faster than FE method and can obtain acceptable results. Zouaghi investigate the no load features of T-LSMs with 2 segment Halbach magnets by analytical approach [4], while similar research has been done by Jin in [5]. However, these model neglects the slot effect. Most, if not all, there have less research on the analytical model considering both slot effect and rotor iron for machines with Halbach arrays. This paper is organized as follows. In Section II, the parameters of AFPM machine with Halbach array is provided. Section III will introduce the electromagnetic calculations used in this paper. The analytical model and its solution strategy will be presented. Afterward, the effects of thickness of rotor iron is then discussed in Section IV. In section V, the experiment results are presented and compared with the results of model. At the end, conclusions will be presented. II.PROTOTYPE PARAMETERS The prototype construction of AFPMMs is a 5 phase, 2 pole pairs, 10-slot AFPMM, the basic dimensions and key design parameters are listed in full paper. III. Description of Analytical Model Based on the separating variable method, the general magnetic vector potential solution for region PMs, airgap and rotor iron (shown in Fig. 1) can be written as: $A_n(\Theta,z)=(a_n e^{K_n z}+b_n e^{-K_n z})$ $\cos(K_n x)$ where $K_n=n\pi/\tau_p$, $\tau_p=\pi R/p$, p is the pole pairs and R is the radius. By applying the boundary conditions, the coefficients could be solved by Matlab. Using the Schwarz–Christoffel (SC) mapping technique, the flux densities of center airgap are calculated. Afterwards, the magnetic permeability of rotor iron is modelled by using additional magnetic equivalent circuit (MEC). The iteration technique is selected to obtain the final results and the flowchart of the described method is shown in Fig. 2. The iterations are stopped after reaching a predefined threshold. The threshold of relative current change between the last iteration and the previous one is set to 0.1%. IV. RESULTS AND DISCUSSION The results shows the flux densities at the mean radius agree well with the FE results. V. EXPERIMENTAL RESULTS The rotor disk and the stator of the AFPM prototype are shown in full paper. In the test bench, the prototype is coupled with an inductance motor via belt system. The inductance motor is driven by an inverter. VI. CONCLUSION The AFPM machine with Halbach arrays has been emerging in many industrial applications due to their sinusoidal induced electromotive force and the torque ripple. However, it has a critical problem with choosing the thickness of rotor iron when designing the machine. Thus, this paper has a significant contribution in that the model developed in this paper has considered the rotor iron, and the computation time can be reduced remarkably. In addition, it is notable that the method proposed in this paper can be also applied to other types of machines to consider the saturation effect. Consequently, the approach proposed in this paper can be regarded as an effective design tool for AFPM machin. More information could be seen in the full paper.

An enhancement of the spin-orbit effects arising on an interface between a ferromagnet (*FM*) and a heavy metal (*HM*) is possible through the strong breaking of the structural inversion symmetry in the layered films. We have found that the introduction of an ultrathin W interlayer between Co and Ru in Ru/Co/Ru films enables to preserve perpendicular magnetic anisotropy (PMA) and simultaneously induce a large interfacial Dzyaloshinskii-Moriya interaction (iDMI). We find that the Ru/Co/W/Ru films have PMA up to 0.35 nm of the nominal thickness of W (t_W). The study of the spin-wave propagation in the Damon-Eshbach geometry by Brillouin light scattering (BLS) spectroscopy reveals the drastic increase of the iDMI value with the rising t_W. The maximum iDMI of -3.1 erg/cm^2 is observed for t_W=0.24 nm, which is 10 times larger than the latter for the quasi-symmetrical Ru/Co/Ru films [1]. Our polycrystalline Ru/Co/W/Ru films were prepared by magnetron sputtering on the SiO_2 substrates at room temperature. The base pressure in the chamber was 10^{-8} Torr. The working pressure of Ar^+ was 10^{-4} Torr. In order to precise control the thickness of layers, we used low sputtering rates: *V(Ru)*=0.011 nm/s, *V(Co)*=0.018 nm/s, *V(W)*=0.02 nm/s. The Co thickness (t_{Co}) was varied from 0.7 to 1.5 nm. The thickness of the buffer and capping Ru layers (t_{Ru}) was 10 and 2 nm, correspondingly. The W thickness (t_W) was taken in the range from 0 to 0.4 nm. Polarization dependent X-ray spectroscopy measurements at the Co *K*- (7709 eV), W L_3- (10207 eV) and W L_2- (11544 eV) edges on the Ru(10nm)/Co(1nm)/W(*x*)/Ru(2nm) structures were performed at the ESRF ID12 beamline. Four different samples have been measured with *x*=0, 0.21, 0.25 and 0.29, where *x* is the thickness of the layer in nm. The APPLE-II undulator and a Si(111) double crystal monochromator were used to collect the spectra. Circular polarization rate of monochromatic x-rays was in excess of 95% at the W $L_{3,2}$-edges. Magnetic field of 0.27 T generated by an electromagnet was applied in the film plane and nearly parallel to the X-ray beam direction. This filed was sufficient to reach magnetic saturation of the samples at room temperature. In order to detect x-ray absorption spectra from our samples, we had to use an energy resolved detector - Si drift diode with an active area of 10 mm^2. To avoid saturation of the detector with fluorescence of Ru and of Si as well as Compton scattering from SiO_2 substrate a 50 μm Al filter was inserted between sample and the diode. The XMCD spectra were recordered by flipping the direction of applied magnetic field two times at every energy point of the x-ray absorption spectra. To make sure that XMCD signal is free of experimental artefacts, we checked that the sign of XMCD was reverted when it was recorded with opposite x-ray helicity. It should be underlined that the attenuation length for tungsten $L_{3,2}$ edges is about 4 orders of magnitude larger than the total thickness of W in the samples. We plotted normalized x-ray absorption spectra at the *K*-edges of Co in Ru/Co/W/Ru trilayers in comparison with a sample without W. Comparison of our normalized XANES spectra recorded at the *K*-edge of cobalt with published results [2,3] clearly shows that in all studied samples Co has *hcp* structure and practically not affected by the deposition of tungsten. We reproduced normalized XANES and XMCD spectra recorded at the $L_{3,2}$-edges of W in Co/W/Ru trilayers in comparison with those measured on bulk Co_3W alloy [4]. For the XANES spectra the ratio of the tungsten L_3/L_2 was taken equal to 2.19/1. The normalized intensities of XMCD signals is about 1% and evidence that 5*d* states of W carry a magnetic moment for all measured samples. This induced magnetic moment is antiparallel to applied field and therefore to the 3*d* magnetic moment of Co. Due to a rather high level of noise it is very difficult to discuss the orbital magnetic moment and its sign. We can only give its estimate, it is about 10 times weaker than the spin magnetic moment. Integrating the $\langle l_Z \rangle$ and $\langle 2s_Z \rangle$ spectra and taking x-ray absoprtion cross-section per hole from [4], we found $m_L < \pm 0.002$ and $m_S \sim -0.023 \pm 0.004$ for all three studied samples. Similar values were also obtained in [4]: $m_L < \pm 0.004(1)\ \mu_B$ and $m_S \sim -0.023(2)\ \mu_B$ for W on bulk Co_3W alloy. What has attracted our attention is some visible difference in the absorption white-line intensities at W $L_{3,2}$ edges for three samples that can result from variation of the 5*d* DOS above the Fermi level. Specifically, L_3 absorption edge reflects both $5d_{3/2}$ and $5d_{5/2}$ DOS whereas only the $5d_{3/2}$ band is probed at the L_2-edge as given by the dipolar selection rules for corresponding optical transitions: $2p_{3/2} \rightarrow 5d_{3/2}$ and $5d_{5/2}$ at the L_3-edge and $2p_{1/2} \rightarrow 5d_{3/2}$ at the L_2-edge. Surprisingly, Co(1nm)/W(0.21nm) and Co(1nm)/W(0.29nm) show nearly the same structures whereas an increase of the number of W $5d_{3/2}$ empty states for Co(1nm)/W(0.25nm) sample is clearly observed. This is a clear difference, eventhough quite minor, in population of spin-orbit split 5*d* states between these three samples. In summary, we show that there is an induced spin magnetic moments of about -0.02 μ_B per atom for W for all studied samples with a much weaker orbital contribution. The magnetic moment of W is antiferromagnetically coupled with the Cobalt moment in agreement with other studies on 3*d*/W systems [4,5]. Small changes in the population 5*d* spin-orbit split bands for different thicknesses of tungsten were observed.

GW-02. Tunable interfacial Dzyaloshinskii-Moriya interaction in Ta/W/CoFeB/MgO films.

T. Kim[1], I. Cha[1], Y. Kim[1], G. Kim[1], A. Stashkevich[3], Y. Roussigné[3], M. Belmeguenai[3], S.M. Chérif[3], A.S. Samardak[2] and Y.K. Kim[1]
1. Materials Science and Engineering, Korea University, Seoul, The Republic of Korea; 2. School of Natural Sciences, Far Eastern Federal University, Vladivostok, Russian Federation; 3. LSPM (CNRS-UPR 3407), Université Paris 13, Sorbonne Paris Cité, Villetaneuse, France

Introduction Development of next-generation nonvolatile spin orbit torque magnetic random access memory (SOT-MRAM) is attracting attention due to its potential application for low power and high speed Logic-in-Memory. SOT-MRAM incorporates the magnetic tunnel junction (MTJ) as its basic structure and heavy metal layer under MTJ. The interface between heavy metal (HM) with strong spin-orbit coupling and ferromagnet (FM) is a source of spin-orbit effects including the spin Hall effect (SHE) and interfacial Dzyaloshinskii-Moriya interaction (iDMI). Many research groups are investigating on different combinations of HM/FM by varying its thicknesses and materials to achieve higher performance of SHE and iDMI [1-2]. Research interest to iDMI is due to its assistance to fast domain wall movement and magnetization switching as well as stabilization of spin spirals, chiral domain walls and skyrmions [3]. In this study, we have used a W dusting layer of different thicknesses deposited between HM and FM in order to tune the iDMI energy density in a wide range of possible values. Experiment A DC and RF magnetron sputtering system under base pressure of $5x10^{-9}$ Torr was used to deposit all samples. Each sample underwent annealing at $300^{o}C$ for 1 h with a magnetic field of 6 kOe under $1x10^{-6}$ Torr. We used Ta, a strong spin orbit coupling material, as HM, $Co_{40}Fe_{40}B_{20}$ with saturation magnetization 1307 emu/cm^3 as FM, which has large tunneling magnetoresistance with MgO tunnel barrier, and Ta as capping layer. We inserted a dusting W layer between Ta and CoFeB to observe the iDMI transformation depending on the thickness of W (t_W) varied from 0 to 1 nm. The thicknesses of FM and MgO layers were fixed to control the other potential effects on iDMI. The magnetic properties were observed using a vibrating sample magnetometer (VSM) and iDMI was measured using Brillouin light scattering (BLS) spectroscopy of non-reciprocal propagation of spin waves in the Damon–Eshbach geometry, where the sample is in-plane magnetized and the wave vector is perpendicular to the magnetization [3]. The shift between the Stokes and anti-Stokes frequencies of the spin waves at a given wavelength is directly proportional to the iDMI value [4]. Results and discussion The Ta(3)/W(t_W)/$Co_{40}Fe_{40}B_{20}$(0.9)/MgO(1)/Ta(2) films have perpendicular magnetic anisotropy (PMA) after $300^{o}C$ annealing. As the thickness of the W layer increases, coercivity and squareness increase due to the bottom interface transformation. The film without the dusting layer of W exhibits the positive iDMI value 0.07 mJ/m^2. This magnitude starts to rapidly increase with the growing thickness of W layer. At t_W=1 nm we observed the maximum of the iDMI value 0.47 mJ/m^2. Although $Co_{20}Fe_{60}B_{20}$ is known to show stronger iDMI value than $Co_{40}Fe_{40}B_{20}$ does, [5] we found higher DMI value in $Co_{40}Fe_{40}B_{20}$ compared to a previous study that reported iDMI energy density of 0.2 mJ/m^2 in the structure with 2 nm of W, which is an optimum thickness of W exhibiting maximum DMI value, with $Co_{20}Fe_{60}B_{20}$ on top. [6] Our results, however, show that the combination of two different heavy metals can greatly enhance the iDMI value, which implies that further investigation is required.

GW-03. Magnetic proximity effects in Co/Pt/Gd/Pt multilayers.

A. Rogalev[1], F. Wilhelm[1] and N. Jaouen[2]
1. ESRF, Grenoble, France; 2. Synchrotron Soleil, Saint Aubin, France

The rise of spin current physics together with enormous technological advances to engineer layered structures with tailored spin-orbit interactions have placed 4d and 5d transition metals at the heart of the emerging fields of spin-orbitronics, magnonics and caloritronics. In this context, magnetic properties at the interfaces between a ferromagnetic material and non-magnetic metals with large spin-orbit coupling play a central role. Platinum atoms are known to exhibit so-called magnetic proximity effect, *i.e.* they acquire interfacial induced magnetic moments whenever they are in contact with 3d metallic ferromagnets [1]. Very little is known about magnetic proximity effects in Pt at the interface with rare-earth metals. Whether the Pt induced magnetic moments are ubiquitous is still an open question since no interfacial induced magnetic moment has been observed in Pt thin films grown on magnetic insulators, e.g. yttrium iron garnet [2]. To answer this question of crucial importance for understanding mechanisms of spin current generation at interfaces, X-ray magnetic circular dichroism (XMCD) spectroscopy appears to be the method of choice due to its element selectivity and very high sensitivity. In this talk, we present a thorough XMCD study of magnetic proximity effects in exchange coupled Co/Pt/Gd/Pt magnetic multilayers with various thicknesses of Pt layers. In these systems antiferromagnetic coupling between Co and Gd moments, known for bulk intermetallics, persists despite the intercalation of a layer of Pt with a thickness of up to 3 nm [3]. Observation of XMCD signal at the $L_{2,3}$ edges of Pt unambiguously shows that it acquires a magnetic moment at the interfaces and hence mediates magnetic interactions between Co and Gd layers. To unravel the mechanism of the exchange coupling in these multilayers we have recorded element selective magnetization curves by monitoring the intensity of XMCD signals at the Co K-edge, the Gd L_3-edge and Pt L_3-edge as a function of applied magnetic field. These measurements confirmed that independently of the coupling strength varying with the Pt thickness, the Co and Gd magnetization directions are antiparallel at zero magnetic field. Under applied magnetic field two different scenarios are observed. For thick Pt layers (> 1 nm), it is the Gd magnetization that rotates in-plane towards the Co magnetization direction given by an external magnetic field. Gd magnetization is not saturated even under 7 Tesla field that indicates that exchange coupling with Co layer is very strong. For Pt layers thicker than 4 nm, two ferromagnetic layers are decoupled. In the case of thin Pt layers (< 1 nm), Gd magnetization is fixed and Co magnetic moments are rotated by the external magnetic field. By performing XMCD measurements at the Pt $L_{2,3}$-edges at different values of applied magnetic fields, magnetic proximity effects in Pt due to Co and to Gd has been disentangled. Surprisingly the latter is found to favour antiferromagnetic alignment and to be much weaker despite a larger magnetization of the rare-earth layer. To our knowledge these results produce the first direct experimental evidence of magnetic proximity effects at the interfaces of non-magnetic metal and rare-earth metal. Moreover, opposite sign of magnetic coupling at Co/Pt and Gd/Pt interfaces is pointing out a development of a magnetic spring across a non-magnetic spacer layer. This spring can be tuned by a layer thickness, temperature and applied magnetic field.

GW-04. XMCD Investigation of CoFeB/MgO Structure.

Y. Yan[1], X. Lu[1], J. Wang[1], J. Wu[1] and Y. Xu[1]
1. University of York, York, United Kingdom

A major breakthrough in MRAM is the discovery of perpendicular magnetised CoFeB films, sandwiched by MgO and Ta layers, which exhibit not only the perpendicular magnetic anisotropy, but also strong orbital moment and spin-orbital coupling[1]. At the same time, current-induced spin-transfer torque (STT) is very important in high density magnetic media and spintronics devices[2]. Because of the importance of lowering the energy consumption, it is necessary to discover a method to reduce the critical current required to switch the spin direction in STT-MRAM application. The perpendicular magnetic anisotropy (PMA) materials, integrated into a magnetic tunnel junction (MTJ)[3], allow for a small critical current density for current-induced magnetisation switching[4]. These materials are found to have a good balance of thermal stability and low magnetic anisotropy energy. In this part of the project, I have studied the effect of the layered structure and in particularly the role of the element-specific orbital moments on the PMA in Ta/CoFeB/MgO structures. We have investigated perpendicular magnetic anisotropy and the element specific spin and orbital moments in the CoFeB/MgO system by using magnetisation measurement, XMCD measurement and sum rule calculations. The results obtained by VSM measurements confirmed that the PMA can be found in a split layer of 2.2 nm CoFeB, with a MgO layer, and the saturation field along perpendicular direction can rise as high as 7000 Oe, which enhanced 10% compared with sample A, while the and are enhanced by 20%. XMCD measurement revealed that the PMA is correlated with the strong spin-orbital coupling of Co atoms, related to the enhanced orbital to spin moment ratios of Co atoms in CoFeB. More importantly, compared with the samples without PMA (sample C and previous work), the sample with the PMA (sample A and B) shows the orbital moment of Co atoms enhanced from 0.17 in sample C to 0.30 in samples A and B. Meanwhile the orbital moment of Fe atoms has not shown significant change, suggesting the dominant contribution of spin-orbital moment coupling of Co atoms to PMA in CoFeB/MgO structure. According to our findings, these results would be very useful for understanding the origin of PMA in CoFeB/MgO films, which could, in turn, be very important for later researches into new generation spintronics devices like STT- MRAM.

Novel studies and possible technological application of patterned magnetic nanostructures have triggered an intensive research in the field of Spintronic over the last few decades. Magnetic memories [1], microwave filters, magnonic logic devices [2], on-chip data communication [3] are few of the examples where these patterned magnetic structures have shown enormous potentials. Furthermore, Spintronic highly reduces the power consumption and heat expulsion when compared to traditional electronics. By using materials with strong shape anisotropy and easily tunable nature, we can easily achieve the above the mentioned applications. Besides that, it should be easy enough to create a magnonic crystal with well-defined frequency band gap by controlling the propagation direction of spin wave and the anisotropies [4]. Various studies have been performed to understand the static and dynamic properties of such patterned magnonic crystals. Among the various structures studied, the most noticeable ones are nanowires, nanodots, antidots, multilayers and modulated wires. In this study, we consider a slab of a thin film with a periodically modulated surface. Multiple samples with a varying periodicity modulation were fabricated using a top-down approach. Periodic grooves with fix thickness were created by etching a slab of a thin film from the surface. The width of the grooves was varied to creates a spatial variation in the internal magnetic field and boundary conditions whose effects can be studied through the static and dynamic properties of the sample [5]. For a single nanowire with no modulation, a uniform ferromagnetic resonance (FMR) mode with wave vector ($k\neq0$) was observed. However, for modulated structures, multiple non-uniform($k=1$) was observed. As the width of the grooves was decreased, the splitting of FMR mode was distinctly observed, especially at low field and frequency. Angular variation of ferromagnetic resonance provided even more in-depth nature of the resonance modes. Through micromagnetic simulation of experimental structure, modes such as Backward Volume Magnetostatic (BVM) and Damon-Esbach (DV) were also identified. The Coplanar waveguides, with an ideal characteristic impedance of 50ohm, were designed by using CST microwave studio. Then by using the standard photolithography techniques, the ground-signal-ground coplanar waveguides, with the G-S gap of 10um and signal line width of 20 um, was fabricated on top of a silicon substrate. This process was followed by deposition of 5nm Ti, 150nm Cu and 10nm Au, and lift-off technique. Finally, the modulated periodic thin films, with total dimensions of 350um length, 10um width, and 40nm thickness, were prepared on top of the signal line of the CPW using focus ion beam (FIB) technique. The spatial design and the experimental setup is depicted in figure 1. In this study, the width of the groove (a) was varied which increased the distance between each consecutive hill. Other parameters such width of the hills (b) = 400nm, the thickness of the hills (t) = 4nm were kept at constant. Four different samples were created by varying the parameter a: S1 (a = 1500nm), S2 (a=1000nm), S3 (a=500nm) and S4(a=200nm). Standard MOKE technique was used to study the static properties of the sample. The experimental results thus collected are presented in figure 1. In sample S1, each hill is separated by a significant distance (a=1500nm). This allows each hill to act as a single nanowire sample which produces a distinct square shaped MHL response. But as we decrease the distance between the hills (a), we see more interference from the neighboring hills which decreases the overall coercivity and smooths the magnetization switching process. The standard VNA-FMR method was used to study the dynamic properties of the sample at room temperature. To probe the FMR spectra; two-port network analyzer was connected to homemade CPW via coaxial cables. Non-magnetic pico-probes were used to connect planer CPW with the coaxial cables. The external magnetic field was swept from 0.5KOe to -0.5 KOe with field step of 3 Oe. The microwave frequency was swept from 1GHz to 6GHz for each magnetic field step. The transmission scattering parameter (S21) was recorded for each frequency scan and contour plots of frequency, field and S21 are plotted (figure 2). To probe the FMR spectra; two-port network analyzer was connected to homemade CPW via coaxial cables. Non-magnetic pico-probes were used to connect planer CPW with the coaxial cables. The external magnetic field was swept from 0.5KOe to -0.5 KOe with field step of 3 Oe. The microwave frequency was swept from 1GHz to 6GHz for each magnetic field step. The transmission scattering parameter (S21) was recorded for each frequency scan and contour plots of frequency, field and S21 are plotted. To better understand this peculiarity micromagnetic simulations were also performed with Mumax on LONI Queen Bee Supercluster, which consisted of 504 compute nodes each with NVIDIA Tesla K20x GPUs and Intel Xeon 64bit processors.

Center for Spin-Orbitronic Materials, Korea University, Seoul, The Republic of Korea

An interface between *3d* transition metal and *5d(4d)* heavy metal (HM) is a host of intriguing spin-related effects desirable for spin-orbitronic applications [1]. Chiral interaction between two *3d* spins due to a strong spin-orbit coupling (SOC) in an underlying atomic layer of heavy metal is associated with the Dzyaloshinskii-Moriya interaction (DMI) [2]. The and interfacial DMI (iDMI) value is extremely sensitive to the ferromagnetic layer thickness (t_{FM}), where the non-linear dependence of iDMI on t_{FM} implies the degradation of interfaces at small t_{FM} [3]. Recently, *Wells et al.* [4] has demonstrated the effect of interface quality, reflecting both roughness and intermixing of interfaces, on iDMI in symmetrical Pt/Co/Pt trilayers. There is a radically different situation in the inversion symmetry broken systems, where the ideal (which is difficult to achieve in polycrystalline films) or having identical quality of top and bottom interfaces of a ferromagnetic layer are the main source of the enhanced iDMI [5, 6]. One can suppose that if in such systems the quality parameter, defined as the difference between quality of top and bottom interfaces of the magnetic layer, tends to zero, iDMI will be strong. The case of the coherent roughnesses of top and bottom interfaces corresponds to this assumption, which arises from the sensitivity of iDMI to the magnetic layer thickness variation. We report on results of the investigation of the magnetic anisotropy and interfacial DMI in the magnetic layer sandwiched between two *5d* HM (Pt and Ta) (Series 1 - *Pt(2)/CoFeSiB(1.5)/Ta(5)*) or one *5d* HM (Pt) from the bottom and *4d* HM (Ru) from the top (Series - 2 *Pt(2)/CoFeSiB(1.5)/Ru(3)/Ta(5)*), where the layer's thickness is indicated in nm. The two series of samples were deposited by magnetron sputtering on the top of the Pd surface with artificially introduced interface roughness: The substrates with Pd seed layer of different thickness ranging from 0 to 56 ML (or from 0 to 12.6 nm were epitaxially grown on the atomically smooth Si(111)/Cu surface. Roughness of the Pd surface in dependence on the thickness was measured by and AFM. The surface is represented by well-ordered atomic terraces of Si, covered by Cu seed layer with the Pd islands grown on top of it. The island growth leads to the significant increase of the mean-square roughness (R_q) as well as the amplitude of roughnesses of the Pd surface. But the period of roughnesses remains constant within the value distribution: p=70±10 nm. In order to analyze the interface quality (roughness, intermixing, thickness variation) we used the X-ray reflectivity (XRR) measurement technique. The study was performed on a SmartLab (RIGAKU) X-ray diffractometer at CuKα radiation wavelength (1.54Å). The simulations of XRR spectra were performed with GlobalFit software. The main trend is the increase of the interface roughness for all layers with the rising t_{Pd}. Noteworthy, the initial R_q for CoFeSiB is higher than for rest layers. It can relate to the amorphous nature of the magnetic layer. With increase of t_{Pd} up to 10.2 nm roughness of CoFeSiB layer approaches to R_q of the underneath Pd and Pt layers, which corresponds to the roughness coherency. The experimental data revealed that Ta capping layer smooths the surface roughness. We observed the correlation between the interface quality factor ($\Delta\sigma/\sigma$) and iDMI for both series. The direct measurement of DMI was performed by Brillouin light scattering (BLS) spectroscopy based on DMI-driven asymmetric dispersion shift of long-wavelength thermal spin waves in the Damon-Eshbach surface mode. At the small Pd roughness the magnitude of $\Delta\sigma/\sigma$ has maximum that means the highest incoherency between top and bottom interfaces of CoFeSiB layer leading to the relatively small iDMI. The flowing tendency of $\Delta\sigma/\sigma$ with rising t_{Pd} reflects the growing coherence of interface roughnesses causing in significant increase of iDMI about twice for series 1 and 2. We demonstrate the direct dependence between the quality of CoFeSiB interfaces, the iDMI value and magnetic anisotropy. The coherent roughnesses of top and bottom interfaces can enhance the iDMI value up to 2.5 times with the maximum obtained value D_{eff} = -0.9 mJ/m^2 (or surface DMI is Ds = -1.05 pJ/m), which is largest known iDMI for CoFeB-based systems. For samples with high iDMI we observed the isolated skyrmions (or skyrmion bubbles) formation with the size about 200-300 nm. GW-07. Lattice distortion and thermal stability of $[Fe_2CoSi/Pt]_n$ multilayers with high perpendicular magnetic anisotropy.

Y. Liu[1], Y. Zheng[1], L. Ren[1], H. Yang[1] and K. Teo[1]
1. Electrical and Computer Engineering, National University of Singapore, Singapore

Multilayers with perpendicular magnetic anisotropy have attracted extensive attention due to their promising applications on magnetic random access memory (MRAM). Higher perpendicular magnetic anisotropy (PMA) can increase the thermal stability and reduce the critical switching current [1, 2]. Due to the orbital hybridization of Co or Fe and Pt or Pd atoms, the multilayers exhibit PMA such as $[Co/Pt]_n$ [3], $[Co/Pd]_n$ [4], $[CoFeB/Pt]_n$ [5], $[Co_2FeAl(Si)/Pt]_n$ [6-8]and $[Co_2MnSi]_n$ [9]. However, the PMA of Pt/Fe-based Heusler multilayers hasn't been reported. Besides, the analysis of the ferromagnetic layer is lacking. Our group used Fe-based Heusler in the multilayers. Because the Fe_2CoSi has smaller lattice mismatch with Pt than that of Co_2FeAl. Hence it is reasonable to expect a higher PMA in $[Fe_2CoSi/Pt]_n$ multilayers. In this work, we observed high PMA in $[Fe_2CoSi/Pt]_n$ structure. The thermal stability and lattice distortion of Fe_2CoSi is also discussed. The $[Fe_2CoSi$ (FCS)/$Pt]_n$ multilayers are deposited on amorphous oxidized Si with Pt buffer by ultra-high vacuum magnetron sputtering system at room temperature. The thickness of Pt, FeCoSi and the number of period are optimized and the highest K_u of 2.64 Merg/cc is achieved in the stack Ta(3)/Pt(10)/$[FCS(0.6)/Pt(2)]_2$/Pt(3). Optimal t_{Pt} of multilayers is found as 2 nm. Furthermore, PMA is only observed when t_{FCS} = 0.6 nm or 0.8 nm and the films gradually tune to in-plane anisotropy with FCS thickness larger than 0.8 nm. We confirmed that PMA originates from the orbital hybridization of Co and Pt according to nonexistence of PMA in $[Fe_2CrSi/Pt]$ multilayers. Since $L2_1$ or $B2$ phase is very crucial for Heusler alloys to exhibit good magnetization and also distortion would affect the magnetic anisotropy energy, so the phase information and lattice distortion is studied using X-ray diffraction (XRD) and Transmission electron microscope (TEM). We found that Fe_2CoSi is in $B2$ phase with Pt thickness of 2 nm, as shown in Fig.1(a). The analysis of TEM result shown in Fig.2 suggests that the interface of Pt/Fe_2CoSi is smooth. Besides, the analysis of FFT suggests that the unit of Fe_2CoSi is laterally compressed in only one direction and the vertical lattice parameter increases accordingly. The vertical tensile strain and the small lattice mismatch can account for the high PMA of $[Fe_2CoSi/Pt]_n$ structure. Finally, the thermal stability is studied. Our results show that the optimized stack can maintain PMA after annealing process at 350C for 30 mins. Our work paves the way for application of Fe-based Heusler alloys in MRAM.

Together with the emergence of new concepts, the progresses of spintronics are intimately linked to the progresses in materials, heterostructures and interfaces elaboration and control. Among the wide range of available deposition techniques, only a few are used in the field of spintronics. Molecular beam epitaxy has been essential to the study of important phenomenon (including of course Giant MagnetoResistance), but sputter deposition is omnipresent and mainly used as well in academic as in industrial context. On the other hand, Atomic Layer Deposition (ALD) is now unavoidable in the semiconductor industry as it is a key enabler for the smallest technology nodes (down to 7nm) and 3D devices. It is also widespread in many other fields (like OLED encapsulation, photovoltaic, fuel cells, packaging…). Being self-limited, the ALD growth offers an excellent and unique control of film thickness, assuring conformal deposition on wide surfaces and 3D shapes. Despite these potential advantages, the use of ALD for thin magnetic film and spintronic applications has remain very limited (1,2). We report here on the ALD growth of cobalt films. Metallic cobalt is obtained from the bis(cyclopentadiényl)cobalt(II) precursor which is reduced with ammonia. The film is protected from oxidation by an alumina film deposited in-situ by ALD. Structural, electric and magnetic properties of the film have been characterized (figure 1). Whereas ALD deposition is known to involve some contamination issues, our films appear to be essentially composed of metallic cobalt as shown by XPS (figure 1.a). This metallic behavior is confirmed by the temperature dependence of the resistance. The magnetization is close from bulk values as assessed by magnetometry measurements (figure 1.b) and ferromagnetic resonance (figure 1.c). The growth temperature dependence of all the parameters will be discussed in order to shed light on the growth processes. Furthermore, the ALD grown cobalt films exhibit significant anisotropic magnetoresistance (figure 1.d), up to 2%. Consequently the Atomic Layer Deposition can be considered as a pertinent technique for magnetic thin film depositions. Different perspectives of new 3D devices grown by ALD will be discussed.

Specific features of cobalt are observed without visible contamination. b) Room temperature hysteresis curve of an ALD grown cobalt film. c) Ferromagnetic resonnace frequency of an ALD grown cobalt film. The field evolution of the resonnance frequency is well reproduced by the Kittel law using bulk value of cobalt magnetization. d) Evolution of the resistance as a function of the angle of applied magnetic field. The periodicity is typical of anisotropic magnetoresistance.

GW-09. Large Perpendicular Magnetic Anisotropy in Fe-Al/MgA-l_2O_4(001) epitaxial heterostructures.

T. Scheike[1], H. Sukegawa[1], X. Xu[1], K. Hono[1,2] and S. Mitani[1,2]
1. National Institute for Materials Science (NIMS), Tsukuba, Japan; 2. University of Tsukuba, Tsukuba, Japan

Magnetic tunnel junctions (MTJs) with large perpendicular magnetic anisotropy (PMA) at ferromagnet (FM)/oxide barrier interfaces play a key role in state-of-the-art magnetic random access memory (MRAM). With demand of increasing the MRAM capacity, MTJs need to be constantly downscaled which leads to increased thermal instability of FM layers. Therefore, many attempts were examined to compensate the thermal instability by further strengthening of the PMA at FM/oxide barrier interfaces. Recently, relatively large PMA at Co_2FeAl/MgO[1] and $Co_2FeAl/MgAl_2O_4$ heterostructures were reported.[2] For these cases, the Al is found to diffuse from Co_2FeAl into MgO or $MgAl_2O_4$, resulting in promotion of the Fe-O orbital hybridization to enhance the interfacial PMA.[3] Additionally, the use of $MgAl_2O_4$ leads to lattice-matched interfaces with these FM materials, being effective in improving the PMA by reducing the interfacial strain. In bcc Fe-Co alloys, Fe-rich composition tends to show larger PMA than Co-rich ones due to stronger hybridization of interfacial Fe-orbitals with O-orbitals.[4] Considering this, we replace Co in Co_2FeAl with Fe, i.e. Fe_3Al. Here, we report growth of off-stoichiometric $Fe_{80}Al_{20}$ ultrathin films in combination with an $MgAl_2O_4$ barrier. Large effective PMA energy density K_{eff} up to 1.1 MJ/m^3 with a large interfacial anisotropy energy density K_i of 2.8 mJ/m^3 was demonstrated in a 0.8 nm thick Fe-Al/$MgAl_2O_4$(001) sample. The following structures were deposited on an MgO(001) single crystal substrate using a magnetron sputtering system with a base pressure of 4×10^{-7} Pa: MgO//Cr (40)/$Fe_{80}Al_{20}$ (t_{FeAl})/Mg (0.2)/$Mg_{40}Al_{60}$ (0.7) /oxidation /Ru (2) (thickness in nm). The MgO substrate and Cr buffer were annealed at 750°C for 1 h. The Fe-Al was deposited by co-sputtering of Fe and Al. The Fe-Al composition was confirmed by inductively coupled plasma analysis. Post-oxidation of the barrier (Mg + Mg-Al) was performed using an oxygen plasma process. Samples were annealed *ex-situ* at a temperature T_{ann} for 30 min. Magnetization loop measurements were performed with a vibrating sample magnetometer (VSM). Microstructure analysis was done using a high resolution annular dark-field scanning transmission electron microscope (HAADF-STEM). Elemental distribution and crystal ordering was investigated by energy dispersive X-ray spectroscopy (EDS). In Fig. 1, the effective anisotropy K_{eff} vs. T_{ann} is plotted for t_{FeAl} = 0.8, 1.0, 1.2, and 1.4 nm. K_{eff} is defined as $M_sH_k/2$, M_s is the saturation magnetization and H_k the anisotropy field. The largest PMA is observed in a 0.8 nm thick film with K_{eff} = 1.1 MJ/m^3 (T_{ann} = 450°C) similar to electron beam-evaporated Fe/MgO heterostructures.[5,6] Above 450°C PMA disappears indicating strong diffusion of Cr into the magnetic layer. Additionally, strong temperature dependence of K_i was found. K_i reaches around 2.8 mJ/m^3 at 450°C. The strong temperature dependence also suggests Cr diffusion into Fe-Al. STEM imaging confirmed the bcc structure of the metallic layer and a cation-disordered $MgAl_2O_4$ barrier.[7] The Cr/Fe-Al and Fe-Al/$MgAl_2O_4$ interfaces are smooth and lattice-matched, see Fig. 2. The high temperature annealing treatment promotes a high crystalline arrangement at the Fe-Al/$MgAl_2O_4$ interface. Additionally, Al is also found to diffuse almost completely into the barrier as confirmed by EDS observation resulting in an almost pure Fe/$MgAl_2O_4$ interface. This leads to a strong Fe-O hybridization. In $Co_2FeAl/MgAl_2O_4$ heterostructures such a diffusion process is also observed.[3] Hence, the here presented structure leads to more effective Fe-O hybridization increasing the PMA drastically. In conlusion, large interfacial PMA with K_{eff} = 1.1 MJ/m^3 after annealed at T_{ann} = 450°C was obtained in a 0.8 nm $Fe_{80}Al_{20}/MgAl_2O_4$ heterostructure. The large PMA is attributed to the highly arranged Fe-Al/$MgAl_2O_4$ interface creating strong Fe-O hybridization after high temperature annealing. This work was partly supported by the ImPACT Program of Council for Science, Technology and Innovation, Japan, and JSPS KAKENHI Grant Numbers 16H06332 and 16H03852.

GW-10. In-depth structural analysis of MgO/Co(bcc) by XPS and XPD.

K. Shamout[1], P. Roese[1], P. Espeter[1], U. Berges[1] and C. Westphal[1]
1. Experimentelle Physik I, Technical University Dortmund, Dortmund, Germany

Fe(bcc) and Co(bcc) were one of the first electrodes that were combined with MgO in order to create magnetic tunnel junctions [1]. These systems lead to even more complex electrodes like FeCo, FeCoB, or even Heusler-alloys [2]. Bcc structures, in general, have widely been used in MgO-based MTJs to make use of their spin-polarization at the Fermi level. To increase the efficiency of these MTJs, ultra-thin MgO films are necessary [3]. Yet, MgO film thinner than 3 monoatomic layer are amorphous making MTJs impossible. Therefore, the optimal thickness for a MgO film is 3-4 monoatomic layers (ML). Different *ab-initio* and first principle calculations usually predict higher tunnel magnetoresistances (TMR) than the measured ones [4-6]. It has been shown that most of this discrepancy is due to the surface roughness since different MgO thicknesses arise creating large defects [3]. By smoothening the surface higher TMR in MgO-based MTJs have been achieved. Still, the calculations do not match the experiment. With this work, we show that the MgO and the Co structures differ strongly at the interface for ultra-thin MgO layers. With these crucial structural information, new calculations can be carried out and order to provide a better understanding of the physics of the MgO-based MTJs. In previous calculctions, it was assumed that the Co(bcc) electrode is in a bulk-type structure, i.e. with lattice constants of $a_{Co} = 0.285$ nm. Further, MgO unit cell is assumed to be compressed to a lattice constant of $\sqrt{2}\times a_{Co}$ [7-9]. In this work, we investigated the structures of MgO and Co(bcc) at the MgO/Co(bcc) interface with X-ray photoelectron spectroscopy (XPS) and diffraction (XPD). THe highly surface sensitive XPS provides chemical information and with XPD the local enviroment of the atoms is determined. Therefore, the lattice sides can be resolved in a Sub-Angstrom range. The experiment was perfomred with an incoming photon energy of hf = 260 eV. We recorded the Co 3p and Mg 2p XPD patterns over a polar- and azimuth-angle range of $24° \leq \theta \leq 70°$ and $0° \leq \phi \leq 180°$ with increments of $\Delta\theta = 2°$ and $\Delta\phi = 1.8°$. We produce Co(bcc) electrodes on a Ga-rich GaAs substrate. Then, 4 ML of MgO is evaporated corresponding to two MgO unit cells. We calculated XPD patterns for the Co 3p and Mg 2p orbitals and obtained impressive R-factors of $R_{Co} = 0.08$ and $R_{Mg} = 0.04$. The resulting structure is displayed in Fig. 1 (left). It is clear, that the resulting structure from the XPD measurement differs heavily from the assumptions in different theoretical calculations [8]. The Co(bcc) lattice constant does not change in [100] or [010] direction, but it is strained in [001] direction at the interface. Further, we observe a shift in every second layer as indicated in Fig. 1. No bonding between MgO and Co(bcc) occurs. For 4 ML of MgO, the XPD calculations yield a stronlgy distorted unit cell. Therein, we observe a weaker compression in [100] and [010] direction than the predictions and a slight strain in [001] direction.

Research Center for Spectrochemistry, The University of Tokyo, Bunkyo, Japan; 4. Department of Physics, The University of Tokyo, Bunkyo, Japan

Interface perpendicular magnetic anisotropy (PMA) is one of the most important issues to develop perpendicular magnetic tunnel junctions (p-MTJs), particularly in p-MTJs using CoFeB alloys that do not show PMA in a bulk form [1]. Besides the continuous efforts to improve the PMA characteristics in CoFeB/MgO heterostructures, the mechanism of PMA has been intensively studied. First-principles calculations show that the hybridization of Fe-3d_z^2 and O-2p_z states plays a crucial role in the occurrence of the interface PMA [2], where O atoms are positioned just above Fe atoms at the interface. Such an interface atomic configuration is likely essential, which is supported by the fact that PMA energies are dramatically increased by post-annealing in most of Fe-based alloy/MgO heterostructures [3-6]. On the other hand, interface PMA can also be observed even for the annealing-free CoFeB/MgO heterostructures, depending on the underlayer materials [3,7]. In this study, we investigated PMA in annealing-free La/CoFeB/MgO heterostructures, since the PMA in annealing-free heterostructures was obtained depending on underlayer materials with a small electronegativity such as Ta or Zr. Note that La also exhibits a typical small electronegativity material that is likely to cause interatomic charge transfer, as well as to be easily oxidized. CoFeB (t_{CFB})/MgO (2nm) bilayer structures with a 2-nm-thick La underlayer were prepared by rf sputtering on a W-buffered thermally oxidized Si substrates. The whole stacking structures are Si/SiO_2-subs.//W-buffer(3nm)/La(2nm)/CoFeB(1nm)/MgO(2nm)/W-cap(1nm) which are grown at room temperature. The thickness of CoFeB layer, t_{CFB}, was varied ranging from 0.8 nm to 1.4 nm. No annealing process was performed in the sample preparation procedures. Magnetic properties were examined by a vibrating sample magnetometer, and x-ray magnetic circular dichroism (XMCD) was measured for the element-specific characterization. Figure 1 shows the areal PMA energy density $K_{eff}t_{CFB}$ as a function of t_{CFB}. Around t_{CFB} = 1.0 nm, definite PMA is obtained for the annealing-free La/CoFeB/MgO heterostructures. The PMA energy density reaches $K_{eff}t_{CFB}$ = 0.2 mJ/m^2 (K_{eff} = 0.2 MJ/m^3). In the XMCD measurements, it was found that the normal component of the orbital magnetic moment in Fe is slightly larger than the in-plane one, being qualitatively the same as the results in a previous XMCD study for a single-crystalline Fe/MgO heterostructure [8]. This suggests that the anisotropy of the orbital magnetic moment brings about the interface PMA even in the annealing-free and therefore presumably amorphous CoFeB layer. To further investigate the correlation between PMA and the sample structures, a comparative study was also performed. Table 1 shows the stacked structures (t_{CFB} = 1.0 nm) used for this purpose. Namely, symmetric and asymmetric heterostructures were prepared using La and/or MgO layers as under- and over-layers. While the asymmetric structures tend to show PMA rather than the symmetric structures, only the La/CoFeB/MgO shows PMA clearly. This means that each interface does not contribute to the occurrence of PMA independently. It is inferred that there is a certain interplay of the roles of under- and over-layers. One possible mechanism would be that the La underlayer works as an excess oxygen absorber to the well-oriented MgO overlayer. However, such a simple idea would not explain the entire results obtained in this study. Internal electric field generated at the La/CoFeB interfaces locally due to the large difference in electronegatibity might influence the observed PMA. In summary, we investigated the PMA in annealing-free La/CoFeB/MgO heterostructures and the role of La insertion as an underlayer. We confirmed the orbital moment anisotropy in Fe, which might be originated from absorbing the excess oxygen in MgO or internal electronic fields due to the differences of electronegativities.

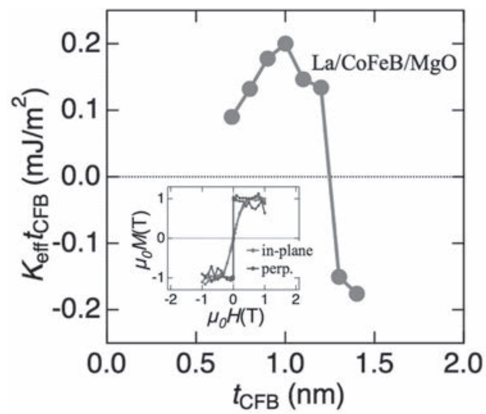

Fig. 1. Areal PMA energy $K_{eff}t_{CFB}$ as a function of the CoFeB thickness t_{CFB} in La/CoFeB/MgO heterostructures. Inset shows the VSM data in t_{CFB}=1nm.

	K_{eff} (MJ/m^3)	M_s (T)
(1) La/CoFeB/MgO	0.2 [PMA]	1.0
(2) MgO/CoFeB/La	-0.034 [Isotropic]	0.85
(3) La/CoFeB/La	-0.014 [Isotropic]	0.685
(4) MgO/CoFeB/MgO	-0.26 [IMA]	1.31

Table 1. PMA energy K_{eff} and saturation magnetization M_s for four different stacks consisting of La(2nm), CoFeB(1nm), and MgO(2nm) layers. The square brackets represent the estimated magnetic anisotropy, where PMA and IMA stand for perpendicular and in-plane magnetic anisotropy, respectively.

GW-12. Structural and magnetic properties of $CoMnO_3$-(0001) orbital ferrimagnet epitaxial thin films.

H. Koizumi[1], S. Sharmin[1] and H. Yanagihara[1]
1. University of Tsukuba, Tsukuba, Japan

Introduction $CoMnO_3$ has an ilmenite structure, in which Co^{2+} and Mn^{4+} layers are alternatively stacked along the c-axis. [1] Both Co^{2+} (d^7) and Mn^{4+} (d^3) possess $S_z = 3/2$, and are antiferromagnetically coupled through the super-exchange interaction with Neel temperature of 391K. Therefore, the spin angular momentums of Co and Mn cancel each other. However, the orbital angular momentum of Co^{2+} in crystal field is 0.72 μ_B. Since the net magnetic moment thus originates only from orbital angular momentum, this compound has been termed an "orbital ferri-magnet". The magnetic properties of $CoMnO_3$ is of interest from the viewpoint of both fundamental magnetism and applications including novel devices for spintronics. The magnetic anisotropy energy of $CoMnO_3$ is large with negative sign, as understood within the framework of the single ion model of Co^{2+} originally proposed by Slonchewski. [2] However, magnetic and other physical properties of $CoMnO_3$ are not as yet well understood. In this study, we report on the growth technique of epitaxial thin films of $CoMnO_3$(0001) on α-Al_2O_3(0001) and its magnetic properties. Experimental $CoMnO_3$ films were grown by an RF-magnetron sputtering technique with oxygen as a reactive gas. The alloy target had the desired composition of $Co_{0.5}Mn_{0.5}$. In order to optimize growth conditions, we varied oxygen flow rates, process temperature, and the film thickness. The surface condition was measured by reflection high energy electron diffraction (RHEED) technique. The film thickness was determined by X-ray reflectivity (XRR) measurement. The lattice constants of the Co-Mn oxide films were determined by X-ray diffraction (XRD). Magnetic properties such as in-plane MH-loops, and magnetic anisotropy constants were measured by a vibrating sample magnetometer (VSM) and magneto-torque meter with the Physical Properties Measurement System (PPMS : Quantum Design). The film composition was determined by inductively coupled plasma mass-spectroscopy (ICP-mass). The valences of both Co and Mn ions were evaluated by an X-ray absorption near edge structure (XANES) experiment and the distance to neighboring atoms was measured by an extended X-ray absorption fine structure (EXAFS) experiment. We also performed X-ray magnetic circular dichroism (XMCD) experiment to estimate spin and orbital angular momentum. Results and discussion The RHEED images indicate that $CoMnO_3$ is epitaxially grown on the α-Al_2O_3 (0001) substrate, and the XRD results suggest that the crystal structure of the film is consistent with the ilmenite structure. The composition ratio of the film is Co:Mn = 45.7% : 54.3% as determined by ICP-mass. Figure 1 shows the in-plane MH-loops of 70-nm-thick $CoMnO_3$ (0001) film on Al_2O_3 (0001). The room temperature saturation magnetization is smaller than the previously reported value of $M_s = 0.61$ [μ_B / f.u.]. [1] This can be explained by the imperfection of the site order of Co and Mn or the off-stoichiometry of Co:Mn = 4.6 : 5.4. Figure 2 shows a magneto-torque curve of the 70-nm-thick $CoMnO_3$ (0001) film at H = 90 kOe. The torque curve indicates that the film has a large negative perpendicular magnetic anisotropy K_u = -3 Merg / cm^3 and it does not saturate even at H = 90 kOe along the hard magnetization direction. The results of XANES for the film exhibiting relatively large magnetization indicate that the valency for both transition metal ions are Co^{2+} and Mn^{4+}. XMCD shows that the spin directions of Co^{2+} and Mn^{4+} are opposite to each other, reflecting the AF coupling. In addition, the orbital angular momentums were negligibly small for Mn but significantly large for Co, which is consistent with the picture of orbital ferrimagnetism of $CoMnO_3$.

GW-13. Interlayer exchange coupling of FeCoB/(Ta,Mo)/FeCoB.

T.J. McKinnon[1], P. Omelchenko[1], B. Heinrich[1] and E. Girt[1]
1. Physics, SFU, North Vancouver, BC, Canada

In this work, we present a detailed ferromagnetic resonance (FMR) study of two FeCoB layers coupled across a nonmagnetic spacer layer. The structures of studied samples are FM1/X(d)/FM2 where FM1 is a magnetic layer composed of Fe/FeCoB, FM2 is a magnetic layer composed of FeCoB/NiFe, X is Ta or Mo, d is the thickness of the X layer in nm, and d is varied from 0.375 nm to 4 nm. These structures were deposited on top of an underlayer of Ta/FeCoB(0.5)/MgO, where FeCoB is thin enough to be non magnetic, and MgO is (100) oriented. This underlayer was chosen because MgO grows well oriented in the (100) direction when grown on top of amorphous FeCoB, which is the orientation chosen for typical memory device applications. The FeCoB within FM1 is strongly coupled to higher Ms Fe, and the FeCoB in FM2 is strongly coupled to lower Ms NiFe allowing one to separate the FMR resonance positions which is required to determine the strength of interlayer exchange coupling (J). We analytically solved a system of coupled LLG equations, representing the coupled magnetic layers, and used it to fit the FMR data measured at 8 to 32 GHz frequencies in order to determine J, uniaxial anisotropy Ku, gilbert damping alpha, and g factor of each layer as a function of the spacer layer thickness and annealing temperature. We did this for both Ta and Mo as spacer layer materials. For samples with Ta as the spacer layer, the dependence of the coupling strength on Ta thickness is the same for as-deposited samples and those annealed at 200 C: the coupling drops to 0 above approximately 0.5 nm and ferromagnetic coupling increases rapidly below 0.45 nm. For samples annealed at 300 C ferromagnetic coupling increases rapidly below approximately 0.6 nm. This temperature dependence can be seen in Fig. 1. Damping of FM1 in the same samples remains approximately constant with an average of 0.0066 for all samples within the range of Ta thickness from 0.4 nm to 4 nm. It was also found to be unaffected by annealing temperature. Damping for FM2 was found to be below 0.009 for all samples. It was also found to decrease with an increase in annealing temperature, and to decrease with Ta thickness less than 0.5 nm. Ms for FM1 and FM2 was measured using a superconducting quantum interference device (SQUID), and was found to be unaffected by spacer layer thickness or annealing temperature. Ku for both FM1 and FM2 was found to not depend on the thickness of the Ta spacer layer. However, Ku for FM1 was found to increase slightly when annealed at 200 C, then decrease when annealed at 300 C. The decrease in Ku was found to be caused by a complete loss of surface anisotropy at the Fe/MgO interface. Ku for FM2 was found to be unaffected by annealing temperature. For not-annealed samples with Mo as the spacer layer, the ferromagnetic coupling increases rapidly for Mo thickness less than 0.35 nm. Antiferromagnetic coupling is observed for Mo thickness ranging from 0.35 nm to 0.6 nm and a weak ferromagnetic coupling for thickness greater than 0.6nm. Fig. 2 shows the dependence of J on spacer layer thickness for both Mo and Ta for the not-annealed samples.

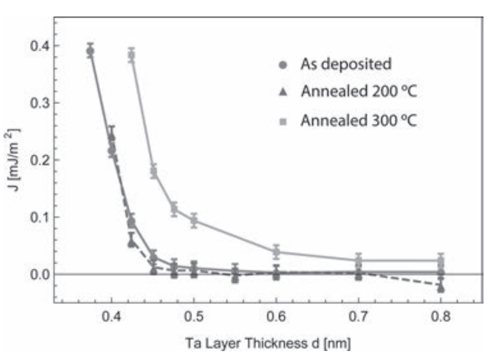

Fig. 1. Coupling constant as a function of Ta layer thickness for samples as deposited, samples annealed at 200 C, and samples annealed at 300 C.

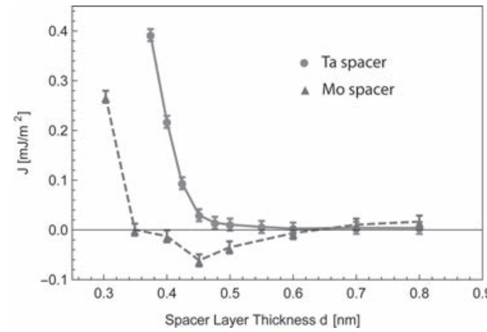

Fig. 2. Coupling constant as a function of spacer layer thickness for not-annealed samples with Ta and Mo spacer layer materials.

GW-14. Influence of inclined perpendicular anisotropy on the current-induced magnetization reversal.

M. Stebliy[1], A. Kolesnikov[1], A. Davydenko[1], A. Ognev[1] and L. Chebotkevich[1]
1. Far Eastern Federal University, Vladivostok, Russian Federation

Investigation of energy-efficient method of local control of the magnetization is one of the crucial points of spintronics development. One of the promising areas is the so-called spin-orbit torque effect (SOT) [1]. This effect can lead to the magnetization orientation switching in structures with perpendicular magnetic anisotropy (PMA) in the case of broken inverse symmetry, with respect to the current flow direction. To induce the asymmetry an external magnetic field can be used [1]. Previously some local methods were studied, it was shown that can be used: exchange-coupled layers [2]; additional antiferromagnetic layer [3]; thickness change of the ferromagnetic or coating layer [4,5]; inclined of magnetic anisotropy axis [6]. In this work, the influence of the angle of anisotropy inclination on the magnetization switching efficiency is presented. The Hall bars Ru(8 nm)/Co(0.9 nm)/Ru(1.5 nm) were obtained by magnetron sputtering. To induce an incline of perpendicular magnetic anisotropy axis, the method of oblique deposition of the ferromagnetic layer Co was used. During the Co deposition the angle between the samples normal and the sputtering source was 17° and 40°. During the formation of Ru layers, the sample was in rotation. An investigation of magnetization reversal in sample by a perpendicular field with presence of an inplane field [6] allows to determine the angle of inclination of the anisotropy axis relative to the normal of the film. For the case of the extreme positions of the magnetron source, the incline of the anisotropy was 2° and 3.5°, respectively. It has been experimentally establish that the magnetization switching occurs in the absence of an external field in the case of the conduction current orientation perpendicular to the plane of inclination of the anisotropy axis, Fig.1a. Whereas in the case of using an external magnetic field the magnetization should be inclined along the direction of the current. To estimate the influence of incline of the anisotropy, the sample was saturated by an external perpendicular field to the state +M, and then the field turned off. A series of current pulses of increasing amplitude was applied to the sample, while the value of the anomalous Hall effect (AHE), which is proportional to the perpendicular component of the magnetization, was recorded. At small values of the coercive force ~ 15 Oe, the action of the Oersted field leads to demagnetization of the sample. In the absence of inclined anisotropy, the demagnetization effect should be the same when the direction of the current is changed, but in the considered case, the value of the magnetization depends on the direction of the current, Fig.1b. The level difference ΔM characterizes the value of the effective field H_z induced by the SOT effect. By varying the current between the maximum values hysteresis loop can be obtained. It was established experimentally that increasing the inclination angle of anisotropy lead to increasing of the ΔM value, Fig.2a. The experimental data were compared with the results of the micromagnetic simulation performed in the MuMax^3 software [7]. The investigated model included an inhomogeneous distribution of the current density, as well as the Oersted field, which were calculated separately. In the simulation were used standard magnetic parameters for Co, energy of magnetic anisotropy was 8.4e5 J/m^3 with the different orientation of the anisotropy axis. The maximum density of the spin current was 2e10 A/m^2, with the direction of flow (0, 0, 1) and the polarization orientation (0, -1, 0). Obtained results are in qualitative agreement with the experimental data, Fig.2b. By using micromagnetic simulation, it was found that the value of the magnetization reversal ΔM is determined not only by the incline angle of anisotropy, but also by the competition between the effective field H_z and Oersted field. Switching efficiency can be increasing by increasing the spin current density, it can be achieved by using a material with a large spin Hall angle. This approach was made experimentally by the addition of the W coating layer. In the structure Ru(8)/Co(0.9)/Ru(1.5)/W(2) with a anisotropy axis inclined of 3.5° the switching ΔM = 70% was obtained in the absence of an external magnetic field. Support by the Grant program of the Russian President (MK-2643.2017.2) and RFBR (grants 17-52-50060, 18-02-00205), are acknowledged.

GW-15. Magnetization studies of obliquely sputtered CoFeB for TMR sensors.

S. Willing[2,1], K. Schlage[1], T. Guryeva[1] and R. Roehlsberger[1,3]
1. Deutsches Elektronen-Synchrotron (DESY), Hamburg, Germany;
2. PIER Helmholtz Graduate School, Hamburg, Germany; 3. Hamburg University, Hamburg, Germany

In this contribution we clarify to which extend magnetic anisotropy can be tuned via oblique-incidence deposition in ultra-thin CoFeB layers for tunneling magnetoresistance (TMR) application. Already for years, CoFeB has been one of the most used magnetic materials in the fields of magnetic memory devices and sensors that employ the TMR effect. The core of such a sensor consists of a trilayer stack, usually two CoFeB electrodes separated by an insulating barrier like MgO. Depending on the relative orientation of magnetization in the CoFeB layers, the probability of electrons tunneling through the barrier varies which can be seen as a change in electrical resistance. In order to obtain the predicted giant TMR effects, the (001)-textured MgO must act as a structural template. In a so-called solid-state epitaxy process during thermal annealing, the CoFeB crystallizes with the same (001)-orientation. As a result, the highly spin-polarized bands with Δ_1-symmetry couple across the barrier acting as a spin-filter. Thus, the crystallization process and resulting structure of the magnetic electrodes is of major importance. Furthermore, some form of magnetic asymmetry between the barriers is required for the TMR. This assures that the two magnetic layers behave differently under an external magnetic field and the relative orientation of their magnetizations (or so called magnetic easy axes) changes. It can be achieved, for example, by inducing additional anisotropy in one of them through application of a magnetic field during growth, through pre-stressed substrates, creation of an exchange-bias structure, or, most easily and most flexible, through oblique-incidence deposition (OID) [1]. By taking advantage of the two angular degrees of freedom during sputter deposition, the orientation of the magnetic easy axis (via azimuthal angle) and the layer's coercivity (via polar angle) can be freely tailored to modify each single layer's properties [2]. The available range of possible coercive field values varies with the layer thickness. This restriction is due to the fact that OID is closely related to the thin film's morphology, texture and surface profile that changes during growth. While there have been many studies on the magnetic and structural properties of CoFeB and the role in TMR sensors before, they either investigated the structure of conventional non-OID TMR stacks, e.g. [3], or were based on films far beyond the relevant thin film regime [4]. We have investigated the magnetic behavior of obliquely deposited CoFeB as single layers in the relevant thicknesses regime and in complete TMR stacks via the Magneto-optical Kerr effect (MOKE). The magnetic properties of CoFeB could well be tuned by the polar deposition angle (Fig. 1) and a strong dependency on film thickness and layer structure (amorphous vs. crystalline) was seen. We have found that an application of OID to CoFeB with its required thermal annealing process is not only possible but also yields unforeseen magnetic behavior which is relevant from a technical as well as scientific point of view: Above a quite low threshold thickness (~1-3 nm depending on the polar deposition angle), the magnetization in the film plane is rotated by 90° with respect to the OID-induced easy axis, however, upon annealing, the expected direction is presumed (Fig. 2). This is a behavior that no other material (like Fe, Co, $Ni_{80}Fe_{20}$) has exhibited in our studies. Beyond simple CoFeB layers, we have successfully tested the applicability of OID in custom-made TMR trilayers. By altering the polar angle during deposition of two CoFeB electrodes, they inherited different coercive fields yielding a distinct double-switching behavior along the easy axis. It is worth mentioning that the wavy surface profiles of the CoFeB layers, which are typical for the OID deposition process, seem not to render the sensitive thin MgO barrier ineffective. It has been shown before [1] that even in more complex multilayer and superlattice (ferromagnetic hybrid) structures OID can be employed to precisely tailor the magnetic properties of individual layers. With the findings of this work we thus conclude that OID opens new possibilities to realize customized TMR structures, not only for the first time but in a simple and convenient fashion.

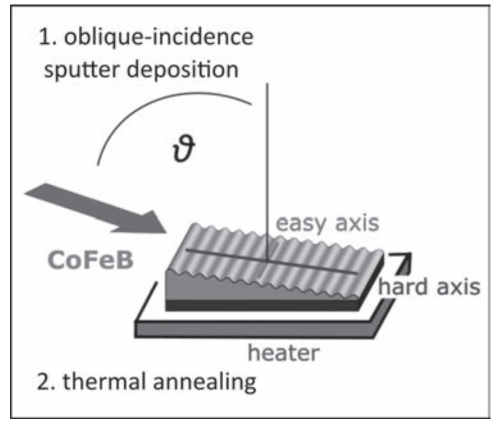

Fig. 1. Sample preparation. CoFeB is deposited under a polar angle θ resulting in an ultra-thin magnetic film with a thickness gradient and defined magnetization axes. The orientation of these axes and the magnetic switching field are determined by both, the deposition angle θ and a subsequent thermal annealing process. To avoid oxidation the CoFeB layers are capped with Ta (not shown).

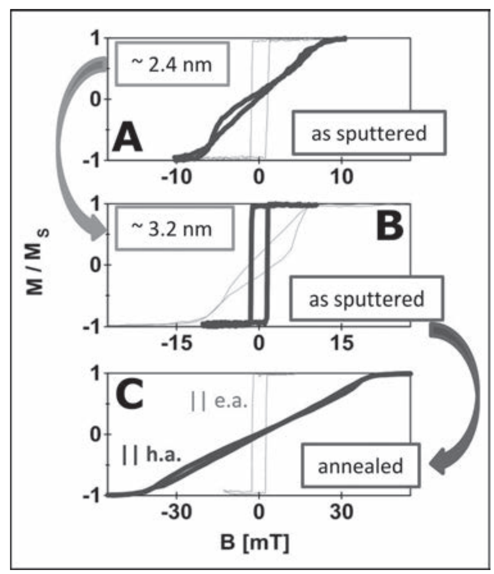

Fig. 2. The magnetic behavior of the CoFeB layers was investigated via MOKE measurements with external magnetic field along the two axes shown in Fig. 1 (magnetic field parallel to sputter direction in blue, perpendicular to sputter direction in red). (A) In ultra-thin layers the magnetization is aligned along the easy axis yielding a sharp switching (red) and a diagonal along the hard axis (blue). This is the expected behavior in OID layers. (B) Above a low threshold thickness, the magnetization is unexpectedly rotated by 90° in plane compared to that of conventional OID magnetic layers. The MOKE curve with field along the hard axis now displays the switching behavior instead of a diagonal. (C) After the annealing and crystallization process the magnetization presumes the expected direction along the easy axis that is intended via the OID process.

GW-16. Magneto-optical properties of Pt/TbCo heterostructure films.

1. Introduction Magnetic film with a heavy metal layer shows strong interfacial interaction of spin-orbit. Spin-orbit interaction (SOI) is one of the key technologies for spintronics and its applications. It is important to reveal the SOI [1]. On the other hand, it is known that magneto-optical Kerr effect is a useful method to detect interfacial information, especially using interference [2] [3]. There are many reports about magneto-optical Kerr effect in a rear earth transition metal (RE-TM) film with a noble metal layer such as Pt, Pd, etc [4][5]. However, there are few reports about discussion on the SOI. In this paper, we measured magneto-optical Kerr spectrums of Pt/TbCo heterostructure films, and discuss about contribution of the SOI. 2. Experimental Figure 1(a) shows sample structures. We prepared three samples on a thermally oxidized silicon (SiO_x) substrate (0.3mm); A: TbCo(6nm)/Pt(3nm) B: Pt(3nm)/TbCo(6nm)/Pt(3nm) C: Pt(3nm)/TbCo(6nm)/SiO_2(5nm). SiOx thickness was 100 nm to enhance Kerr effect using interference. SiO_2 was used as a non-heavy metal layer as well as a protective layer for the TbCo. Each layer was deposited with a sputter method. Magneto-optical Kerr spectrum was measured with a wavelength of 300-700 nm using a Xenon light source and a PEM (photo-elastic modulator) [7]. Optical index was measured by an ellipsometer (JASCO-M150). 3. Results & Discussions Figure 1(b) shows Kerr hysteresis loops for each sample with a wavelength of 700 nm. The samples show perpendicular magnetic anisotropy of rare-earth rich composition. Their coercivity are 5 KOe for the sample A, around 3 KOe for the sample B, C. Kerr rotation angle of the sample C is larger than that of the sample A, B. Figure 2 shows magneto-optical Kerr spectrum of the samples. (a) TbCo(6nm)/Pt(3nm) (b) Pt(3nm)/TbCo(6nm)/Pt(3nm) (c) Pt(3nm)/ TbCo(6nm)/SiO2(5nm). The dots show measured ones and the lines show simulated ones. The Kerr rotation angle (θ_K) and the ellipticity (η_K) changed with wavelengths. θ_K was maximum value with a wavelength of around 400 nm where a sign of η_K changed. A peak position of θ_K shifted slightly to shorter wavelengths in the sample B with a symmetric structure. The magneto-optical Kerr spectrums may include contribution of both interference and interfacial effect. To isolate them, we simulated the spectrums using the effective refractive index method [6]. Optical constants of the TbCo for a right and a left hand circular polarization light were calculated from θ_K, η_K and optical index n, k with a 100 nm TbCo film. The simulated spectrums change by interference between a Si substrate and a SiO_2/TbCo, Pt/TbCo or a TbCo/Pt interface, and almost same manner as the measurement results. In the sample B with a symmetric structure, the spectrums are well consistent with the measurement ones. Reasons for the peak shift of θ_K in shorter wavelengths seem to be optical interference. In the sample A and C with an asymmetric structure, there are some differences between the simulated θ_K, η_K and measurement ones. We could not see any enhanced θ_K or η_K in shorter wavelength [4] [5]. It may be caused by interfacial effects of the spin orbit interaction. 4. Conclusions We demonstrated magneto-optical spectrums of Pt/TbCo heterostrucure films. The films with the asymmetric structures showed the enhanced magneto-optical effect. The reason for an enhanced magneto-optical effect may be interfacial effects of the spin orbit interaction. HA-01. Interface as key unit in molecular spintronic devices.

V.A. Dediu[1]
1. DSCTM, CNR-ISMN, BOLOGNA, Italy

Information and communication technology (ICT) is calling for solutions enabling lower power consumption, further miniaturization and multi-functionality requiring the development of new device concepts and new materials. A fertile approach to meet such demands is the introduction of the spin degree of freedom into electronics devices, an approach commonly known as spintronics. This already lead to a revolution in the information storage (GMR read heads) in the last decades. Nowadays, the challenge is to bring spintronics also into devices dedicated to logics, communications and storage within the same material technology [1]. Organic semiconductors emerged as an extraordinary spintronic material about ten years ago, when a few papers appeared with straightforward and encouraging claims on spintronics phenomena [2]. From then on Organic Spintronics has evolved into a prolific discipline populated by a large number of experimentalists and theoreticians. Research in molecular spintronics began with the aim of using molecules as spin transport media, thanks to their intrinsically weak spin relaxation mechanisms. Initial experiments focused on reaching spin transport in molecular films and on replicating previous device concepts taken from inorganic spintronics, such as spin valves and magnetic tunnel junctions. However, it soon became apparent that molecules were playing another role beyond that of mere spin transport materials. For example, in experiments with vertical spin valves, many groups were reporting consistently negative magnetoresistance. These results were striking, as they contradicted the well-established spin polarization sign of the ferromagnetic electrodes and the present knowledge at that time regarding spin transport. A few years later, a coherent picture arose invoking the role of molecular layers in tuning the spin polarization of ferromagnetic materials at the interface, and 'spinterface' was officially born. Along this line I will especially concentrate on interfaces, representing the most important and the most hidden part of any spintronic device. Revealing their secrets is scientifically hard and experimentally costly, requiring sophisticated spectroscopic methods and massive calculations. For an interface consisting of a hard metallic electrode touching a soft organic layer, the situation obviously becomes even more complicated. I will overview the main achievements of the community in the investigation of very complex and very rich interface properties [3] and will describe the possibilities to develop and fabricate multifunctional devices which operation is fully dominated by the interface.

HA-02. Activating the molecular spinterface.

M. Cinchetti[1]
1. Experimentelle Physik VI, Technical University Dortmund, Dortmund, Germany

The miniaturization trend in the semiconductor industry has led to the understanding that interfacial properties are crucial for device behaviour. Spintronics has not been alien to this trend, and phenomena such as preferential spin tunnelling, the spin-to- charge conversion due to the Rashba–Edelstein effect and the spin–momentum locking at the surface of topological insulators have arisen mainly from emergent interfacial properties, rather than the bulk of the constituent materials. In this talk I will describe inorganic/molecular interfaces by looking closely at both sides of the interface: the “organic” side and the “metallic” side (see Figure). When describing hybrid interfaces from the organic side, focus is put on how the molecular orbitals of the free molecule develop as a function of the strength of hybridization with the inorganic substrate. On the metal side, on the other hand, focus is put on the modification of the spin properties of the inorganic substrate as a consequence of the hybridization with the molecule. Within this framework, I will discuss recent developments in the field and underline how molecular materials have arisen as an ideal platform for creating interfacial spin effects [1]. As an example, I will show that the extreme multi-functionality of organic molecules can be used to functionalize the spin properties of surfaces with a spin-texture induced by strong spin-orbit coupling. I will present our results on the following two-dimensional electronic systems: the surface states of the topological insulator Bi_2Se_3 [2], and the Rashba-split surface states of a Pb-Ag surface alloy [3]. Topological insulators present spin-momentum locked helical surface states induced by the large spin-orbit interaction. These states are protected by time-reversal symmetry and result in a surface chiral spin-texture preventing back-scattering between states of opposite spin and momentum. In Rashba systems, on the other hand, the spin texture results from the lifting of the spin degeneracy of a two-dimensional electron gas by the large spin-orbit coupling. Possible applications of spin-textured materials are anticipated in the area of spintronics, e.g. for the creation of dissipationless spin currents. With this motivation, lately much effort has been devoted to the control and the manipulation of spin-textured surface states. In our recent work [2], we could show that the spin-texture of the Bi_2Se_3 surface can be influenced by choosing molecules with tailored hybridization strength. In particular, we have presented a rational design approach to customize the spin texture of surface states of a topological insulator. This approach relies on the extreme multifunctionality of organic molecules that are used to functionalize the surface of the prototypical topological insulator (TI) Bi_2Se_3. For the rational design we have used theoretical calculations to guide the choice and chemical synthesis of appropriate molecules that customize the spin texture of Bi2Se3. The theoretical predictions have been then verified in angular-resolved photoemission experiments. We could show that, by tuning the strength of moleculeTI interaction, the surface of the TI can be passivated, the Dirac point can energetically be shifted at will, and Rashba-split quantum-well interface states can be created. These tailored interface properties - passivation, spin-texture tuning, and creation of hybrid interface states- lay a solid foundation for interface-assisted molecular spintronics in spin-textured materials. In the other work [3], on the other hand, we have studied the influence of specific chemical bonds (as formed by the organic molecules CuPc and PTCDA) on a Pb-Ag Rashba surface alloy. We find that delocalized van der Waals or weak chemical π-type bonds are not strong enough to alter the alloy, while localized σ-type bonds lead to a vertical displacement of the Pb surface atoms and to changes in the alloy’s surface band structure [4]. These results provide an exciting platform for tuning the Rashba-type spin texture of surface alloys using organic molecules. In the light of the presentes results, I will discuss the key role that molecular interfaces may play in the development of a new generation of spin-based technologies, thanks to their unique capability of being actively tuned to reach as-yet unexplored functionalities.

HA-03. Under-barrier spin-phonon relaxation in molecular magnets.

A. Lunghi[1], F. Totti[2], R. Sessoli[2] and *S. Stefano*[1]

Single molecule magnets (SMMs) are molecules comprising only a handful of magnetic ions, which show some of the properties of bulk magnets and at the same time those of low-dimensional systems. These, for instance, include magnetic hysteresis together with quantum tunneling of the magnetization. A typical way to characterize the magnetism of SMMs is through relaxation experiments, where an ensemble of SMMs is polarized along the direction of an external field and then the relaxation of the magnetization is monitored in time. Surprisingly, many experiments measure a relaxation time considerably faster then what expected from the measured zero-field splitting (e.g. extracted from spin resonance), and such discrepancy usually increases with the strength of the anisotropy barrier. This surprising result collides with the most common SMMs design rules, which consist in engineering the ligand field of the magnetic ions so to increase the magnetic anisotropy or to increase the molecule total spin. Here we demonstrate that spin-phonon coupling can account for such discrepancy and in particular that phonon dissipation is key to explain the under-barrier relaxation. Our calculations combine advanced post Hartree-Fock electronic structure theory with a master equation approach to the spin-dynamics. In particular we construct the spin-phonon Hamiltonian by first calculating the phonon spectrum via a finite difference method and then by mapping the spin-phonon matrix elements onto a giant spin Hamiltonian. This constructs a master equation, which now includes both diagonal and non-diagonal terms in the spin-state occupations. At this level also spin-spin interaction is taken into account and the many-body problem is solved by exact diagonalization over a truncated spin-Fock space. Crucially phonon dissipation is included in the model and it is treated through an appropriate temperature-dependent stochastic model [1]. The central result of our work is the demonstration that, in general, in the presence of spin-phonon coupling the relevant energy scale for spin relaxation is given by the lower-lying phonon modes interacting with the spin system. These provide a channel for the relaxation at energies lower than that needed to overcome the anisotropy barrier, hence producing a fast spin-decay mechanism. Importantly, such mechanism becomes dominant over the standard over-the-barrier relaxation process only for molecules presenting large zero-field split, a fact that calls for a redefinition of the design criteria for highly stable SMMs. Our methodology is put to the test at the quantitative level for a class of Fe(II) molecules [2] presenting long spin lifetimes. In this case we find that the relaxation time has a complex temperature behaviour, where different relaxation mechanisms dominate over different energy ranges (see Fig. 1) [1]. Furthermore we have been able to identify the phonon modes most relevant for the spin relaxation [3]. These typically involve vibrations of the first coordination shell around the transition metal center, vibrations that affect strongly the spin-orbit interaction. Our work suggests several designing strategies for reducing the spin relaxation and thus for engineering long-living SMMs. For instance, although complicated to exploit in practice, a possible strategy may be that of modulating the spin excited state energy in order to obtain a non-resonant condition with the phonon spectrum.

Sessoli, Intra-molecular origin of the spin-phonon coupling in slow-relaxing molecular magnets, Chem. Sci. 8, 6051 (2017)

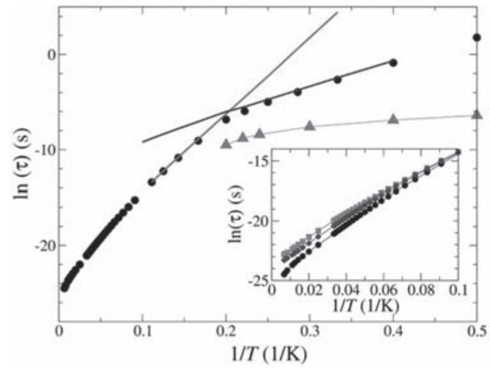

Fig. 1. Calculated temperature dependence of the relaxation time. Black dots are for simulations where all the relaxation processes are considered. The green triangles and the green line represent the experimental results of Ref. [2]. Arrhenius's fits performed for the T < 5 K and for 5 K < T < 10 K cases return effective barriers of 19.7 cm^{-1} and 55.7 cm^{-1}, respectively. These are consistent with an under-barrier phonon-activated relaxation mechanism.

HA-04. Portraying the spin dynamics of molecular nanomagnets by four-dimensional inelastic neutron scattering.

S. Carretta[1]
1. University of Parma, Parma, Italy

Molecular nanomagnets (MNMs) are molecules containing a core of interacting magnetic ions embedded in shells of organic ligands, which provide a magnetic separation between different cores. MNMs are at the forefront of current research in magnetism and have been used as test beds for addressing several quantum phenomena [1]. Interestingly, on the one hand MNMs show magnetic hysteresis as ordinary magnets do and, on the other hand, they are small enough to show clear quantum effects. Hence, they are promising systems to encode quantum bits for quantum information processing [2] or for storing classical information in single molecules [3]. However, a deep understanding of the spin dynamics of MNMs is mandatory to design molecules fulfilling all the requirements for these demanding applications. Recently we have shown that the quantum spin dynamics of MNMs can be fully unravelled by the so-called four-dimensional Inelastic Neutron Scattering (4DINS) [4]. In particular, the dependence of the transition intensity on the three components of the neutron wavevector transfer Q enables us to probe and extract two-spin dynamical correlation functions. In this contribution, I discuss very recent applications of the 4DINS approach to solve two important problems in molecular magnetism. Addressing fundamental and applicative issues in polycentric molecules can be hampered by the difficulty to determine the interactions within the core. Mn12 is an outstanding example of this: although it is the forefather and most studied of all molecular nanomagnets, a sound determination even of the leading magnetic exchange interactions was still lacking. In the first part of this contribution, I show that we have now exploited 4DINS to solve this problem. We have investigated the dynamics of Mn12 at low temperature where only the ground |S=1 0,M=+-10> doublet is populated (S being the molecular total spin and M its z component) and detected several transitions to excited M=+-9 states belonging to the lowest S=10 and S=9 multiplets. The dependence of the intensity of each transition on the three components of Q is characterized by a pattern of maxima and minima (e.g., see Figure 1), which directly reflects how the individual Mn spins move when the excitation is triggered [5]. These precession patterns are fingerprints of the magnetic Hamiltonian and we thus pinpoint the exchange interactions of Mn12 for the first time [5]. These results open novel perspectives in understanding spin clusters and motivate the synthesis of new polycentric MNMs, where the interactions are optimized for addressing specific fundamental issues or applications. In the last years, we have shown that Cr7Ni antiferromagnetic rings are very promising systems to encode qubits [2]. Indeed, at low temperature they behave as spin-1/2 and can be manipulated in times much shorter than the measured decoherence time. In addition, these molecular rings can be magnetically linked to each other either directly or through magnetic ions and dimers. Entanglement is a crucial resource for quantum information processing and its detection and quantification is of paramount importance in many areas of current research. However, entanglement between molecular qubits had only been experimentally studied rather indirectly. In the second part of this contribution, I show that 4DINS can be exploited to investigate entanglement in weakly coupled molecular qubits and to directly quantify it [6]. As a benchmark to test our idea, we have investigated the (Cr7Ni)2 prototype dimer of molecular qubits. The key point is that entanglement between the Cr7Ni qubits is connected with dynamical correlations between spins belonging to different rings that can be selectively addressed by 4DINS. Indeed, such correlations between distant spins lead to short-Q modulations in neutron scattering intensity. We have applied a sizeable external magnetic field in order to induce a factorized dimer ground state, which we have exploited as a reference state to investigate entanglement in the excited states. We performed low-temperature (T=1.2 K) measurements and detected two transitions. The observed Q dependences of the intensities clearly display short-Q modulations (see e.g. Figure 2) that constitute a sort of "portrayal" of entanglement in the excited states of the dimer. The analysis of the two measured patterns of maxima and minima show that the excited states involved in the transitions are maximally entangled states [6]. This approach can be applied also to dimers of more complex molecular qubits, thus opening remarkable perspectives in the understanding of entanglement in complex spin systems.

The application of quantum physics to the information theory turns out to be full of promises. The first step is to realize the basic block that encodes the quantum information, the qubit. Among all existing qubits, spin based devices are very attractive since they reveal electrical read-out and coherent manipulation. Beyond this, the more isolated a system is, the longer its quantum behavior remains, making of the nuclear spin a serious candidate for exhibiting long coherence time and consequently high numbers of quantum operation. In this context I worked on a molecular magnet spin transistor. This setup enabled us to read-out electrically both the electronic and the nuclear spin states and to coherently manipulate the nuclear spin of the Terbium ion [1,2]. I will present the study of the dynamic of a single 3/2 nuclear spin under the influence of a microwave pulse. After the energies difference measurement between these states I will show the coherent manipulation of the three nuclear spin transitions up to 10MHz using only a microwave electric field with coherence time higher than 1ms. More than demonstrating the qubit dynamic, these measures demonstrate that a nuclear spin embedded in a molecular magnet transistor is a four quantum states system that can be fully controlled. Theoretical proposal demonstrated that quantum information processing could be implemented using a 3/2 spin such as quantum gates [3] and algorithm [4]. I will then present the implementation of the Grover algorithm [5] using a single molecular magnet.

HA-06. Electron spin resonance of single atoms in scanning tunneling microscopy.

A.J. Heinrich[1], Y. Bae[1] and P. Willke[1]
1. Center for Quantum Nanoscience, Institute for Basic Science, Seoul, The Republic of Korea

The scanning tunneling microscope is an amazing tool because of its atomic-scale spatial resolution. This can be combined with the use of low temperatures, culminating in precise atom manipulation and spectroscopy with microvolt energy resolution. In this talk we will apply these techniques to the investigation of the quantum spin properties of magnetic atoms sitting on thin insulating films. We will start our exploration with the understanding of the quantum spin states (also called the magnetic states) of these adsorbates. To measure these states, we combined scanning tunneling with x-ray absorption spectroscopy and found amazing agreement of those vastly different techniques (Science 2014, PRL 2015). Next, we will investigate the lifetimes of excited states. Surprisingly, we find lifetimes that vary from nanoseconds to hours, a truly amazing consequence of the quantum states of different adsorbates. Finally, we will explore the superposition of quantum states which is inherent to spin resonance techniques. We recently demonstrated the use of electron spin resonance on single Fe atoms on MgO (Science 2015). This technique combines the power of STM of atomic-scale spectroscopy with the unprecedented energy resolution of spin resonance techniques, which is about 10,000 times better than normal spectroscopy.

HB-01. Microstructure and magnetic properties of anisotropic polycrystalline $Sm(Fe_{0.8}Co_{0.2})_{12}$ thin films with $ThMn_{12}$ structure.

D. Ogawa[1,2], Y. Takahashi[1,2], S. Hirosawa[1,2] and K. Hono[1,2]
1. Elements Strategy Initiative Center for Magnetic Materials (ESICMM), Tsukuba, Japan; 2. National Institute for Materials Science (NIMS), Tsukuba, Japan

I. INTRODUCTION The $ThMn_{12}$-type hard magnetic compounds composed of rare earth elements and 3d ferromagnetic transition metals such as Fe have been known as possible candidates for the development of permanent magnet materials. In order to stabilize the $ThMn_{12}$ phase, the substitution of Fe with non-magnetic element M such as Ti, V, Mo and Si is required [1, 2], which results in the reduction of saturation magnetization $\mu_0 M_S$. Kuno *et al*. reported that high $\mu_0 M_S$ of 1.63 T in strip cast alloy by doping Zr in Sm site, and controlling the content of non-magnetic element M with the $(Sm_{0.8}Zr_{0.2})(Fe_{0.75}Co_{0.25})Ti_{0.5}$ composition [3]. Recently, Hirayama *et al*. showed excellent intrinsic hard magnetic properties with saturation magnetization $\mu_0 M_S$ of 1.78 T, anisotropy field $\mu_0 H_A$ of 12 T and Curie temperature T_C of 859 K for epitaxial $Sm(Fe_{0.8}Co_{0.2})_{12}$ films prepared by sputtering process, which are superior to those of $Nd_2Fe_{14}B$ [4]. Owing to these promising intrinsic properties, the $Sm(Fe_{0.8}Co_{0.2})_{12}$ compound can be a candidate for high performance permanent magnet applications. One drawback of $ThMn_{12}$ compound based magnets is their too low coericvity [5, 6]; however, considering the value of the anisotropy field, there is still room for improving coercivity. The purpose of the present investigation is to explore the possibilities for obtaining high coercivity in $Sm(Fe_{0.8}Co_{0.2})_{12}$ based alloy using strongly textured polycrystalline thin films. II. EXPERIMENTAL PROCEDURE $Sm(Fe_{0.8}Co_{0.2})_{12}$ thin films were prepared by an UHV magnetron co-sputtering system. The stacking structure of the films were thermal oxidized Si (SiO_2) substrate / NiTa (20 nm) / MgO (10 nm) / V (10 nm) / $Sm(Fe_{0.8}Co_{0.2})_{12}$ (46 nm) / V (10 nm). NiTa and MgO [7] was used to obtain textured V underlayer for growing $Sm(Fe_{0.8}Co_{0.2})_{12}$ anisotropic polycrystalline films. When the V and $Sm(Fe_{0.8}Co_{0.2})_{12}$ layers were deposited, the substate was heated at 400°C. The $Sm(Fe_{0.8}Co_{0.2})_{12}$ layer was deposited by co-sputtering Sm, Fe, and Co targets. We also tried grain boundary diffusion process into the $Sm(Fe_{0.8}Co_{0.2})_{12}$ layer, which is known as an effective methods to increase coercivity of fine grained magnets. We deposited five kinds of overlayers such as Cu, Zn, $Sm_{70}Cu_{30}$, Sm/Cu, La/Cu onto the $Sm(Fe_{0.8}Co_{0.2})_{12}$ layer and post-annealed at 300 ~ 600°C. In this presentation, we will mainly report the results of Cu overlayer, because it was so far the most effective to increase the coercivity. III. RESULTS AND DISCUSSION X-ray diffraction measurement showed that *c*-axis textured $ThMn_{12}$ polycrsytaline layer was grown on a V underlayer. Fig.1 (a) shows cross-sectional TEM image of a $Sm(Fe_{0.8}Co_{0.2})_{12}$ thin film before grain boundary diffusion process. Perpendicular texture of columnar-shaped $Sm(Fe_{0.8}Co_{0.2})_{12}$ grains are grown on a V underlayer with the grain size of several dozen nm. The shape of the grains are considerably changed after deposition of Cu (3 nm) overlayer and post annealing at 400°C as shown in Fig.1 (b). Fig.2 shows magnetization curves for the films before and after the diffusion process, i.e., deposition of Cu (3 nm) and post annealing at 400°C. Both curves show perpendicular magnetic anisotropy, which corresponds to the *c*-axis orientation observed from the XRD pattern. The demagnetizing field were corrected by using demagnetizing factor $N = 0.45$ in both samples. The coercivity of the $Sm(Fe_{0.8}Co_{0.2})_{12}$ films increased from 0.5 T to 0.8 T by depositing Cu and post-annealing at 400°C. We carried out EDS analysis of the Cu diffused $Sm(Fe_{0.8}Co_{0.2})_{12}$ film with compared to the sample before the diffusion process. In the sample before diffusion process, Sm, Fe, and Co elements are distributed uniformly. On the other hand, in the sample after Cu diffusion, the distribution of the Sm element become non-uniform, following the distribution of Cu elements. Moreover, Cu seems to be diffused into not only grain boundary, but also $Sm(Fe_{0.8}Co_{0.2})_{12}$ grains partially, and the formation of other phases were suggested which should be influence on coercivity. In summary, a polycrystalline $Sm(Fe_{0.8}Co_{0.2})_{12}$ perpendicular anisotropy film shows the coercivity of 0.5 T, giving rise to the $(BH)_{max}$ value of 386 kJ/m³. The coercivity can be further enhanced to 0.8 T by the diffusion of Cu; however, this does not lead to the continuous formation of grain intergranular phase. A search for a grain boundary phase that is more effective in intergrain exchange coupling is necessary to develop high coercivity $Sm(Fe_{0.8}Co_{0.2})_{12}$-based permanent magnet material.

There is an increase demand for a magnet which has comparable intrinsic hard magnetic properties with those of $Nd_2Fe_{14}B$. The intrinsic magnetic properties of the $ThMn_{12}$-type phases in $Sm(Fe_{1-x}Co_x)_{11}Ti$ alloys with $0 \le x \le 0.3$ and $Sm_{1-y}Zr_y(Fe_{0.8}Co_{0.2})_{11.5}Ti_{0.5}$ alloys with $0 \le y \le 0.3$ are potential candidate as a permanent magnet, as is shown in Fig. 1. Increasing Co substitution for Fe, from $x = 0.1$ to 0.3 increases the saturation magnetization ($\mu_0 M_s$) of the 1:12 phase from 1.34 T to 1.50 T, while the largest magnetic anisotropy field ($\mu_0 H_A$) of 10.9 T was achieved for $x = 0.2$ with $\mu_0 M_s = 1.47$ T and Curie temperature (T_c) 800 K. The saturation magnetization is increased by reducing Ti content where the phase stability is obtained by Zr substitutions for Sm. Increase of Zr in $Sm_{1-y}Zr_y(Fe_{0.8}Co_{0.2})_{11.5}Ti_{0.5}$ from $y = 0.1$ to 0.3 decreases $\mu_0 M_s$ from 1.57 to 1.53 T. Although, the largest T_c of 830 K was found for the ThM_{12}-type phase in the $(Sm_{0.8}Zr_{0.2})(Fe_{0.8}Co_{0.2})_{11.5}Ti_{0.5}$ alloy, $\mu_0 M_s$ and $\mu_0 H_A$ of which were determined to be 1.55 T and 8.4 T at 300 K, respectively. The $ThMn_{12}$-type phase in the $(Sm_{0.8}Zr_{0.2})(Fe_{0.8}Co_{0.2})_{11.5}Ti_{0.5}$ alloy has comparable intrinsic hard magnetic properties with those of $Nd_2Fe_{14}B$ and may exhibit maximum energy product with the optimized microstructure.

After the discovery of R-Fe-B (R:rare-earth) compounds with excellent magnetic properties, the research and development on permanent magnets has been focused almost exclusively on these alloys. In the last decade [1], because of the exponentially increasing demand for these magnets, increasing cost and supply risks involving the R-metals, there has been a renewed interest in the $ThMn_{12}$-type (1:12) compounds. These compounds contain a 7.7 at.% of R (compared with 11.8 at.% in $R_2Fe_{14}B$) and have a tetragonal structure which is a required condition for uniaxial magnetocrystalline anisotropy. The binary compounds RFe_{12} in bulk do not exist but by adding a third element such as Ti, V, Mo, Cr, W or Si, it can be stabilized into the 1:12 structure [1,2]. However, the addition of this element decreases the saturation magnetization (M_s) and the Curie temperature (T_C); due to this, it is important to keep its amount as low as possible. So far the 1:12 structure for the $SmFe_{12-x}V_x$ alloys has been obtained for high concentrations ($x \geq 1.5$) and it is very difficult to synthetize as a single-phase material. In order to obtain high H_c, it is necessary to avoid the formation of the soft-magnetic α-Fe phase in the alloy. One of the challenges is then in obtaining a single-phase 1:12 alloy with the minimum concentration of V. Previous results have reported the stabilization of 1:12 for x=2 for samples annealed at 850-1050 °C for 1-14 days [3–5] and for x=1.5 annealed at 900-1000 °C for 7 days [6]. Sugimoto *et al.* obtained the phase relation of Sm-Fe-V [7] and reported that 1:12 phase was only stable for $x \geq 1.4$. In this work, we present the results obtained on $SmFe_{12-x}V_x$ alloys for $x \leq 2$. We have studied the stability of the 1:12 phase over a range of V-content lower than that of the previous reports, and obtained a nearly pure 1:12 phase. The extension of the stability range to x = 1 has increased the M_s and T_C. Ingots of $SmFe_{12-x}V_x$ (x=1-2) alloys were prepared by arc-melting the pure metals. The samples were re-melted several times in order to achieve homogenization. An additional amount of Sm (20 wt. %) was added for compensation of evaporation loss. After arc-melting, the ingots were annealed in Ar athmosphere for 1-3 days at temperatures in the range 900-1100 °C and then quenched in water. The crystal structures of the samples were determined by using x-ray diffraction (XRD). The annealed ingots were ground in a mortar and the fine powders were subsequently mixed with an epoxy and aligned in a magnetic field of 2 T. The anisotropy field (H_A) and M_s measurements were performed on aligned samples using a vibrating sample magnetometer with a maximum applied field of 12 T. The T_C values were determined by thermogravimetry. Microstructure studies were carried out by using a scanning electron microscope (SEM). Figure 1 shows the XRD patterns of non-oriented and oriented $SmFe_{11}V_1$ powders. The pattern presented in the fig 1(top) is indexed with a single phase of the tetragonal $ThMn_{12}$ type structure (space group 14/mmm). No other secondary phase (α-Fe) peaks were detected. This shows that the stability range of Sm-Fe-V alloys is broader than that of suggested by previous studies on these compounds. The SEM microstructure analyses confirm the results obtained by XRD. In the as-cast sample (Fig. 2 top), an Fe-V phase (in black) is present along with a Sm-rich phase (in white) and a minor phase (in grey), identified to be the 1:12 phase. After annealing, the only phase that is present is the 1:12 (Fig. 2 bottom). Structural analysis reveals an increase in the lattice parameters (a = 8.54217 Å and c = 4.78228 Å for x=1 and a = 8.53681 Å and c = 4.77221 Å for x=2) with the decrease of the V-content. The fig. 1(bottom) shows XRD pattern of the oriented powders of $SmFe_{11}V$, the prominent reflection from (002) planes suggests the uniaxial nature of this sample, which is expected. The magnetization measured at room temperature as a function of applied field parallel and perpendicular to the orientation axis are shown in the inset of Fig. 1. The H_A value is estimated from the value of the applied field at which the two curves intersect. The H_A value for $SmFe_{11}V$ was estimated to be around 11 T and the M_s to be 118 Am^2/kg, both values larger than those of $SmFe_{10}V_2$. The T_C also shows an increase from 599 K to 634 K with the reduction of V content from x = 2 to 1. The authors acknowledge Iñaki Orue assistance with the high field measurements. This work has been supported by the European Union's Horizon 2020 research and innovation programme, grant agreement No 686056 (NOVAMAG).

Introduction Sm_2Co_{17}-type sintered permanent magnets have attracted a great attention for good high-temperature magnetic properties, extremely low temperature coefficient, excellent oxidation resistance [1-3]. The researches on Sm_2Co_{17}-type permanent magnets have mainly focused on the improvement of the magnetic properties [4, 5]. Only a few researchers have investigated mechanical properties: bending strength, impact toughness, and so on [6-9], which are important parameters from the view point of application. Recently, we have found that sintering process has much impact not only on magnetic properties but also on mechanical features of Sm_2Co_{17}-type sintered magnets. In this work, sintering process, i.e., solidification behavior, and its effect on the magnetic and mechanical properties of the $Sm(Co_{bal}Fe_{0.227}Cu_{0.07}Zr_{0.023})_{7.6}$ has been investigated. It is beneficial to understand the mechanism of sintering and how to improve the magnetic and mechanical properties for Sm_2Co_{17}-type sintered magnets. Experimental The alloy ingot with the nominal composition of $Sm(Co_{bal}Fe_{0.227}Cu_{0.07}Zr_{0.023})_{7.6}$ was prepared by vacuum induction melting. Heat treatments during the preparing procedures consisted of four steps, including sintering at a temperature (1463, 1468, 1473, 1478, 1483, 1488K) for 1h, and then homogenizing treated at 1448K for 4h, followed by isothermal aging at 1103K for 20h and finally step-cooling to 673K, followed by quenching to room temperature. Six groups of corresponding specimens were obtained and labeled as A, B, C, D, E and F, respectively. Bending strength of the specimens was measured by a 3-point bend test with a span of 14.5mm. The size of the bending specimens was 5mm×6mm×18mm. Compressive toughness of the Ø10mm × 10mm specimens was measured with a rate of indenter decline, 1mm/min. A scanning electron microscopy (SEM) was employed to observe the micro-fractures of the experimental magnets, and the phase compositions were determined by an energy dispersive x-ray (EDX) analysis system. Results and Discussion It is found that with the sintering temperature increasing from 1463K to 1488K, the bending strength (BS) increases from 108MPa to 140MPa. The specimens show similar BS values, about 120MPa with the sintering temperature increasing from 1468K to 1478K. The compressive toughness (CT) first increases from 142MPa to 488MPa quickly, and then increases to 563MPa slowly. The micro-fractures of bending specimens were observed using a SEM, as shown in Fig. 1. As a whole, the typical SEM images are quite different from each other. There are a lot of voids, whose average size is about 5μm in specimen A, which results in low BS (108MPa) and CT (142MPa). It is interesting that the size of voids becomes bigger, 13μm with the sintering temperature increasing to 1473K, improving the CT (488MPa) remarkably. Then the voids disappear and the BS and CT values increase with the sintering temperature increasing. It is impressive that some particles are found in the voids. EDX analysis shows that it is SmCoFe phase with lean Cu and Zr. With the sintering temperature increasing, the SmCoFe phase transforms to be Sm-rich phase. For specimens E and F, sintered at relatively high temperature, the EDX analysis shows there exists CoZrFe phase, giving rise to improvement of the mechanical properties. Moreover, in order to further make clear the solidification behavior and its effect on the mechanical properties of the specimens, typical SEM-BEI images of six groups of as-sintered magnets are shown in Fig. 2. The results show that there are small size voids in specimens A-C, whose average size is 0.2, 0.3 and 0.5μm and the voids average size increases from 8μm to 10μm with the sintering temperature increasing to 1488K. Moreover, the phase constitution of the as-sintered specimens changes a lot during sintering. The EDX analysis shows that the 2:17H and 1:5H phases, separate gradually and the voids tend to form in 1:5H phase with the sintering temperature increasing from 1463K to 1488K. After solid solution and aging process, the phase structures of all the specimens become homogeneous. But the voids grow up for specimens B and C and disappear for specimens D, E and F. Conclusions The bending strength and compressive toughness of Sm_2Co_{17}-type sintered magnets have been investigated systematically. With the sintering temperature increasing from 1463K to 1488K, the BS increases from 108MPa to 140MPa. The compressive toughness first increases from 142MPa to 488MPa quickly, and then increases to 563MPa slowly. There are small size voids (5μm) in specimen A, and the voids average size increases to 13μm and then disappears with the sintering temperature increasing. Moreover, it is found some CoZrFe phases are helpful to improve the mechanical properties. It is found that average voids size increases from 0.2μm to 10μm and the 2:17H and 1:5H phases separate with the sintering temperature increasing from 1463K to 1488K. Permanent magnets based on abundant and cheap rare earth (RE) elements are surfacing as promising candidates to fulfill the large gap between hard ferrites and Nd-Fe-B magnets. La-Ce alloy extracted from the natural ore has great potential to replace a large portion of Nd-Pr alloy that has been overused due to the rapid growth of Nd-Fe-B industry. Here we performed a comprehensive study on microstructure and magnetic properties of the $[(La_{0.352}Ce_{0.648})_x(Nd_{0.796}Pr_{0.204})_{1-x}]_{2.14}Fe_{14}B$ ($0.6 \leq x \leq 1.0$, in at.%) casted strips to evaluate the potential replacement of La-Ce for Nd-Pr. Through the entire substitution range, the matrix 2:14:1 phase keeps stable at 1273 K, suggesting that they are suitable for high temperature sintering. Transmission electron microscopy characterizations show that spinodal decomposition-like phase separation occurs for the 2:14:1 phase grains at certain La-Ce contents due to the different solubilities of La/Ce/Nd/Pr elements, i.e. manily to the low soluted concentration of La element. Such inhomogeneous distribution of La/Ce/Nd/Pr elements within the 2:14:1 phase results in the deviation of Curie temperature from the estimation based on the rule of mixture. The dependence of saturation magnetization on La-Ce amount is also found beyond the estimation due to the presence of α-Fe phase. These findings suggest that $La_{0.352}Ce_{0.648}$ alloy can fully replace Nd-Pr alloy to achieve the stable 2:14:1 phase suitable for high temperature sintering and highlight the further work to suppress the formation of magnetically soft α-Fe phase.

HB-06. YCo_5 and $CeCo_5$ thin films with perpendicular magnetic anisotropy grown by molecular beam epitaxy.

S. Sharma[1], E. Hildebrandt[1], M. Major[1], P. Komissinskiy[1], I.A. Radulov[1] and L. Alff[1]
1. Institute of Materials Science, Technische Universität Darmstadt, Darmstadt, Germany

The interest in thin films with perpendicular magnetic anisotropy (PMA) is growing because of their potential applications in ultra-high density magnetic storage and nano-scale spintronic devices. One approach to achieve PMA is the *c*-axis (easy axis) textured growth of materials which possess strong intrinsic magnetocrystalline anisotropy that is large enough to overcome the shape anisotropy of thin films. The family of Co based rare-earth (*RE*) intermetallic compounds of the form, *RE*Co_5 are known for their extremely large uniaxial magnetocrystalline anisotropy. In this work, we have investigated the magnetic performance of epitaxial thin films of two lesser critical rare-earth material systems, YCo_5 and $CeCo_5$ [1-2]. Both YCo_5 and $CeCo_5$ possess a very strong uniaxial magnetocrystalline anisotropy with first anisotropy constant, K_1 of 5.78 MJ/m^3 and 6.4 MJ/m^3, respectively as bulk phases [3]. The YCo_5 and $CeCo_5$ thin films were deposited directly onto *c*-cut Al_2O_3 substrates without the use of additional underlayers using an MBE setup. The films were grown by co-evaporation of elemental *RE* and Co by electron beam at a pressure of 10^{-8} mbar. MBE allows to tune the composition of the *RE*-Co system by *in situ* controlling the evaporation rates of *RE* and Co. The manipulation of individual atomic beams of *RE* and Co, as well as their ratio allows establishing a thin film phase diagram for Y-Co and Ce-Co systems as shown in Fig. 1(a) and (b), respectively. With increasing *RE* to Co rate ratio (or decreasing Co rate), first, the soft magnetic, *RE*$_2Co_{17}$ phase is formed followed by the highly anisotropic, *RE*Co_5 phase. The *RE*$_2Co_{17}$ films are soft magnetic with the easy-axis of magnetization in the film plane. On the other hand, the *RE*Co_5 films are hard magnetic showing perpendicular anisotropy. The magnetization, *M*, was measured as a function of applied field, *H*, in two directions, perpendicular and parallel to the film plane using a SQUID magnetometer. Fig.1(c) and (d) show the hysteresis curves for YCo_5 and $CeCo_5$ thin films (30 nm), respectively. It can be seen that perpendicular to the film plane, the saturation magnetization, remanent magnetization, and coercivity are higher than along the film plane. This shows that the easy-axis of magnetization is aligned perpendicular to the film plane, i.e. it is parallel to the structural *c*-axis. Angular dependent magnetic torque measurements were used to determine the value of the first anisotropy constant, K_1 and the anisotropy field. The magnetic parameters measured for YCo_5 and $CeCo_5$ thin films are summarized in Table 1. These magnetic parameters and the perpendicular anisotropy obtained without additional underlayers make the material systems interesting for application in magnetic recording devices.

Permanent magnets are used in various applications ranging from space to home appliances. Fundamental constituents of these magnets are rare-earth elements (such as Nd, Dy, etc.), whose cost is increasing rapidly. Magnet manufactures are strongly demanding for a low cost material (ie. rare-earth free), which can replace rare-earth magnets. Unfortunately, options are limited. Most promising candidate is chemically ordered $L1_0$ FeNi phase present in Fe-meteorite. Based on its saturation magnetization (M_s~1270 emu cm^{-3}) and uniaxial magneto-crystalline anisotropy (K_u ~1.3 x 10^7 erg cm^{-3}), hard magnetic performance comparable to high grade rare-earth magnet is expected. However, artificial production of $L1_0$ FeNi phase is extremely difficult due to low order-disorder transition temperature (~320 ^{0}C). Recently, we have demonstrated the possibility of $L1_0$ FeNi phase formation through annealing of an amorphous $Fe_{42}Ni_{41.3}Si_8B_4P_4Cu_{0.7}$ alloy[1-3]. Precipitated $L1_0$ FeNi grains require a magnetic field of at least ~ 3.7 kOe to switch their magnetization[3]. High magnetization switching field is consistent with the large magnetocrystalline anisotropy of the chemically ordered $L1_0$ FeNi phase. The ordered phase like $L1_0$ is associated with the presence of a superlattice reflection in X-ray as well as in electron diffraction, and we have confirmed them experimentally. Electron diffraction detected four-fold 110 superlattice reflections.[2] Simulation of electron diffraction pattern suggested that the chemical ordering parameter (S) for the developed $L1_0$-FeNi phase 0.8. Generally S is determined from the intensity ratio of superlattice to fundamental diffraction peaks in X-ray diffraction ie. (001)/(002). However, the experimentally measured ratio is found to be higher than the calculated for fully ordered $L1_0$ FeNi ie. the estimated $S > 1$. This surprising result leads to speculations such as presence of a texture, another phase with diffraction peak position same as (001) of $L1_0$ FeNi etc. Although, TEM and magnetic measurements confirmed the formation of $L1_0$ FeNi phase without any doubt, it is extremely important to clarify the results of X-ray measurements and provide stronger alternatives for the confirmation of $L1_0$ FeNi phase. Detection of superlattice diffraction peak with a standard laboratory X-ray machine is difficult because the scattering factors for Fe and Ni are very similar. The situation changes drastically if the X-ray energy is close to the absorption edge of Fe or Ni. At the absorption edge, anomalous scattering factor plays an important role and intensity of superlattice diffraction peaks such as (001) increases significantly. However, the intensity of fundamental peaks such as (002) decreases significantly. Since the sudden changes in diffracted intensity is element specific, the anomalous X-ray diffraction (AXRD) measurement is a powerful technique for identification of phase and its state (ordered or disordered). The AXRD measurements on $Fe_{42}Ni_{41.3}Si_8B_4P_4Cu_{0.7}$ alloy ribbons annealed at 400 ^{o}C for 288 hours were carried out at SPring 8 under the beam line of BL13XU. This sample showed high magnetization switching field of ~ 3.7 kOe. The details of magnetic properties are reported in ref. 3. Energy of X-ray was varied from 7.0 to 7.2 keV for Fe- absorption edge, and 8.25 to 8.4 keV for Ni-absorption edge. The diffraction data was collected around (001) superlattice and (002) fundamental diffraction peaks of $L1_0$ FeNi. Diffraction curves obtained at each energy was fitted to Gaussian type and peak area was estimated at each X-ray energy. A drastic change in integrated intensity with the energy of X-ray was observed for both the (001) super lattice and (002) fundamental diffraction peaks at Fe and Ni- absorption edges (Fig. 1). This suggested that the (001) and (002) diffraction peaks originate from phase which is made from Fe and Ni. As expected for the (002) fundamental peak, the X-ray intensity decreases strongly at both the absorption edges (Fig. 1 c & d). However, for (001) superlattice, the intensity increases at Ni-absorption edge (Fig. 1b) and decreases for the Fe-absorption edge (Fig. 1a). Increase in intensity at Ni-absorption edge clearly confirms the presence of a chemically ordered $L1_0$ FeNi phase, but the results obtained at Fe-edge are surprising. A detailed analysis of data suggested the presence of a Fe related phase which coincides with the (001) diffraction peak of $L1_0$ FeNi. The information obtained from AXRD analysis is very significant for determining S by laboratory X-ray (slow scan with a rotating anode type). The S estimated from X-ray for $L1_0$ FeNi precipitated in FeNiSiBPCu alloy is 0.76 and it is close to the S locally determined by TEM analysis.[2] Details of the measurements and analysis of the results will be presented during the conference.

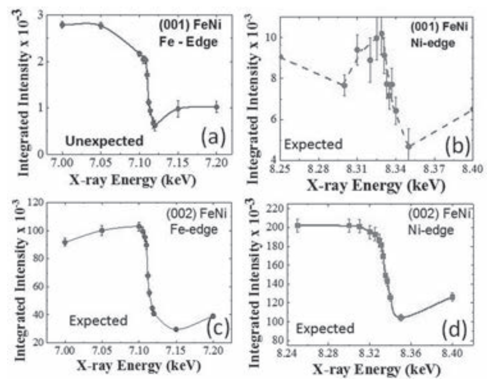

Fig. 1. Variations in X-ray intensity with energy around (001) superlattice and (002) fundamental diffractions peaks of $L1_0$ FeNi. Increase in intensity of (001) peak at Ni-absorption edge confirms the ordered state of FeNi. Unexpected decrease at Fe-edge for (001) is due to the presence of an overlapping phase, which is made from Fe and B.

Introduction: Recently, $L1_0$ MnGa has attracted much attention because of a high magnetic anisotropy constant K_u, attractive for rare-earth free permanent magnets and spintronics applications [1,2]. In the phase diagram of Mn-Ga alloys, the $L1_0$ phase is stable over a range of about 55~63 Mn at% at an ambient temperature [3]. In the case of thin films, much work on magnetic properties has been made for the Mn composition range over 55 at% (or Mn/Ga >1), but few studies have been found in literature for Mn <55 at%. The present work is to investigate the effect of Al addition on magnetic properties in $L1_0$ MnGa thin films. Effort has been made to fabricate highly ordered $L1_0$ single crystalline films and to study their magnetic properties in conjunction with structure. Experimental: Multilayers of (MnGa), Mn and Al with various thicknesses were fabricated onto MgO(100) substrate held at about 600 °C during deposition in a multi-target UHV confocal sputtering system. The film-composition thus fabricated was determined by energy dispersive X-Ray spectroscopy (EDS). In the present work, three samples of $Mn_{53-x}Al_xGa_{47}$ with x=0, 3 and 6 were chosen to study, namely $Mn_{53}Ga_{47}$, $Mn_{50}Al_3Ga_{47}$ and $Mn_{47}Al_6Ga_{47}$. The nominal film thickness for all the samples was 50~60 nm. Structural analyses were performed by XRD and TEM. Magnetic properties were measured by a vibrating sample magnetometer and a torque magnetometer over a temperature range from 5 to 400 K in fields up to 90 kOe. Results and Discussions: Figure 1(a) is the XRD pattern result for the samples with x=0, 3 and 6. All the samples possess the c-axis orientation along the film normal. The (001) super-lattice peak is clearly seen for x=0 and 3, but decreases its intensity with x or the decrease of Mn concentration. The order parameter S estimated based on the intensity ratio between *I(001)/I(002)* is found to be 0.9, 0.7 and 0.4 for x = 0, 3 and 6, respectively. Fig.1(b) and (c) of the TEM images for x = 0 shows the trapezium shape islands with a height of about 50nm and a width of about 100nm. The nano-diffraction pattern indicates that the trapezium islands are of epitaxially grown $L1_0$ phase with the c-axis along the substrate normal (S=0.9). The sample for x=3 (S=0.7) does not consist of islands of such a well-defined shape, but rather rounded one. Most of the grains are of $L1_0$ phase, but consist of sub-grains of unknown phases. The sample for x=6 (S=0.4) is also formed of islands, the majority of which is not of $L1_0$ phase but unknown phase. The result that the highly ordered $L1_0$ MnAlGa islands with less than Mn 50at% are found strongly suggests that an addition of Al into MnGa is useful to expand the composition range of the $L1_0$ phase. Fig. 1 (d) shows the element mappings observed by EDS. Little evidence of the multilayered structure is found and all the elements of Mn, Ga and Al are uniformly distributed within an island. Both the out-of-plane and in-plane M-H curves were measured as a function of temperature from 5 to 400K. All the samples exhibit the remanence close to one, and possess the easy axis for magnetization along the film normal. The M_s at 5K are found to be about 380, 480 and 90 (emu/cm^3) for x=0,3 and 6, respectively. The K_u at 5K are $1.1x10^7$, $6x10^6$ and $2x10^5$ (erg/cm^3) for x=0, 3 and 6, respectively. The out-of-plane coercivity H_c at 5K are 18, 4 and 11 (kOe) for x=0, 3 and 6, respectively. Fig.2 shows the normalized temperature dependences of M_s and K_u for x=0, 3 and 6, together with the data reported [4]. The solid lines are the fitting curves in the form of $M_s(T)/M_s(5K) = (1- T/T_c)^\alpha$, where T_c is a Curie point and α is a parameter [1]. The behavior of the temperature dependence of M_s is consistent with the results shown in the inserted figure [4], where a sharp decrease occurs near T_c. It is seen that the sample (x=6) exhibits a faster decrease in magnetization with T, compared to x=0 and 3. Using a method of least squares, it is found that the T_c value for x=6 is about 550K with α =0.27. The uniaxial magnetic anisotropy constant K_u decreases with T, much faster than that for M_s. (The dotted lines are only for the eye-guidance.) The log-log plot for M_s and K_u shows that the power dependence of K_u on M_s varies, depending on a temperature range. Nevertheless, it is found that K_u is approximately proportional to M_s^n, where n≈2.3~2.7, and 2.3 for x=0 and 3, respectively for the entire range of T from 5 to 400K. This result suggests that the two ion model is likely responsible for the magnetic anisotropy mechanism of $L1_0$ MnGa.[5,6] *In summary,* the epitaxially grown single crystalline films of $L1_0$ $Mn_{53-x}Al_xGa_{47}$ (x=0~6) are found to be of island structure. The temperature dependence of saturation magnetization indicates that the Curie point is about 550K for x=6. The two ion model likely accounts for the magnetic anisotropy mechanism of the $L1_0$MnGa. The present work was supported in part by NSF-CMMI (#1229049) and TDK Corporation.

HB-09. Synthesis of Phase-Pure τ-MnAlC Using Mechanical Alloying and a Single-Step Annealing Route.

V. Øygarden[1], J. Rial[2], A. Bollero[2] and *S. Deledda*[1]
1. Institute for Energy Technology, Kjeller, Norway; 2. Permanent Magnets and Applications, IMDEA Nanoscience, Madrid, Spain

Permanent magnets (PMs) play an important role in the continuous technological development of the modern world [1]. Rare-earth (RE) magnets, such as $Nd_2Fe_{14}B$ with an energy density $(BH)_{max}$ up to 59.1 MGOe (470 kJ m^{-3}), are used for applications where high magnetic energy-density values are needed. For applications where lower energy-density suffice, ferrites such as $(Sr,Ba)Fe_{12}O_{19}$, dominate the market with an energy density $(BH)_{max}$ up to 5.0 MGOe (40 kJ m^{-3}). The rising cost and exposed supply-chain of rare-earth magnets have spawned a global search for rare-earth free alternatives that are able to plug the gap between the rare-earth based and ferrite-based permanent magnets that currently dominate the market. τ-MnAl has long been investigated as a promising candidate due to its high potential energy density, low weight, and readily available resources, but development has been slowed down by challenging synthesis conditions and issues with phase purity [2]. The τ-phase can be synthesized via a two-step route involving at least two annealing steps. Firstly the ε-phase is isolated by rapid quenching from high temperature, followed by one or more annealing step(s) at intermediate temperatures to form the τ-phase. The latter annealing step is problematic because it often results in a multiphase material [3]. To avoid this, the τ-phase can also be formed directly during the quenching of the ε-phase. The one-step route, named so because only one heat treatment is needed, is beneficial regarding phase-purity because the full transformation from ε- to τ occurs during the cooling, and no subsequent heat treatments are needed thereby avoiding any potential decomposition of the metastable τ-phase. In this contribution, mechanical alloying was used to optimize the microstructure prior to annealing. Excess Mn is needed as ε-MnAl is only stable for Mn-rich compositions (Mn > 54 at%). To enhance the formation of the τ-phase, a small amount of carbon was added as an interstitial element [4] giving the composition $Mn_{0.54}Al_{0.46}C_{0.02}$ (MnAlC). Appropriate milling conditions gave a highly active starting material for enhanced formation of τ-MnAlC. The X-ray diffraction (XRD) pattern of the as-milled powder is shown in Fig. 1a. The XRD-data were indexed to the β-Mn(Al) phase with lattice parameter a = 6.441(5) Å, significantly larger than elemental β-Mn (a = 6.316 Å), suggesting the larger Al was mechanically alloyed into the β-Mn lattice. The average crystallite size was estimated to be ~16 nm. β-Mn(Al) transformed to ε-MnAlC upon heating to 1050 °C, whilst the conversion of ε-MnAlC to τ-MnAlC was achieved during quenching. The phase purity of the τ-phase was shown to be highly dependent on the quenching rate. XRD patterns of τ-MnAlC powders produced with varying quenching rates from 1050 °C are presented in Fig. 1b-d. The impact of the quenching rate on phase formation in the MnAlC-system can be illustrated schematically in a continuous cooling transformation diagram, or CCT-diagram, see Fig. 2. The diagram illustrates the phase changes that occur when starting with the ε-phase and cooling with different rates from 1050 °C. For slower quenching in air (~3.5 C/min, see curve *III.*) the cooling time is sufficiently slow for the ε to τ phase-transition to complete, whilst simultaneously fast enough to avoid further phase decomposition. Powder synchrotron x-ray (SR-XRD) and neutron diffraction data (PND) were used to demonstrate the phase-purity, as well as the magnetic structure and the magnetic moments of the Mn-site. Rietveld fit of the SR-XRD and PND data gave a = 2.7635(1) Å and c = 3.6114(2) Å, while the magnetic moment of the Mn-site was refined to 2.43(5) μ_B, in line with previous reports. A coercivity of μ_0H_c = 0.15 T was found for the as-synthesized τ-phase. The possibility of further improving the coercivity by cryomilling in liquid N_2 was explored. In summary, this study presents a simplified, up-scalable and reliable synthesis-route to produce phase-pure τ-MnAlC, using mechanical alloying combined with a single annealing step. The resulting synthesis-route is a streamlined and repeatable route to phase-pure τ-MnAlC, avoiding needs for more complicated synthesis techniques such as drop synthesis, melt spinning and induction melting. The importance of the cooling rate of the annealing step is highlighted and discussed in detail. We also provide a description of the magnetic structure and properties of the phase-pure τ-MnAlC, which showed promising magnetization and energy product.

HB-10. Tuning permanent magnet properties in MnAl nanocrystalline powder processed by ultrafast-milling with different milling media.

J. Rial[1], P. Svec[2], *E. Palmero*[1], J. Camarero[1], P. Švec Sr[2] and A. Bollero[1]
1. Division of Permanent Magnets and Applications, IMDEA Nanoscience, Madrid, Spain; 2. Institute of Physics, Slovak Academy of Sciences, Bratislava, Slovakia

Permanent magnets (PMs) are used in a multitude of energy-related technological applications [1] and cannot be substituted without an increased cost and/or a detrimental performance of the devices. These PMs contain critical raw materials [heavy and light rare-earths (REs)] as fundamental constituents with additional environmental issues related to their extraction and processing. MnAl has been considered a strong alternative to RE-PMs in recent years. This material shows an attractive combination of characteristics for technological applications provided development of the ferromagnetic τ-MnAl phase and an appropriate microstructure [1,2]. The τ-MnAl phase is metastable and forms from the non-magnetic ε-phase. However, decomposition of the ε-phase normally results in the formation of the γ_2- and β-Mn phases, which are the equilibrium phases at room temperature. Most of the studies found in literature and related to MnAl are focused in achieving a maximized content of the τ-MnAl phase, i.e. enhanced magnetization, with a subsequent decrease in coercivity, which limits its potential use in PM applications. Moreover, ball milling processing techniques used for controlling the phases formation in MnAl powder require typically tens of hours, thus making them unviable for practical applications. We have developed a novel rapid-milling method that requires milling times below 5 min to achieve high coercivity values, which has been proven effective with a variety of RE-free PMs [3-5]. It has been recently demonstrated [5] that application of this ultrafast-milling procedure to gas-atomized $Mn_{54}Al_{46}$ particles for only 30 s results in a refined nanostructure, and allows introducing defects that eases the formation of the metastable ferromagnetic τ-MnAl phase from the starting stable and non-magnetic ε-phase. The use of such a short milling times avoids the high temperatures (several hundred degrees) typically achieved in milling experiments that might ease undesired grain growth effects, relaxation processes and phase transformations. Annealing of the powder milled for 30 s results in a high coercivity of 4.2 kOe, superior to 4.1 kOe achieved for gas-atomized MnAl powders after milling for a much longer time of 26 h [6]. The present study correlates the evolution of phase transformation and microstructural changes with the magnetic properties, induced during ultrafast-milling and annealing. This has been managed by using milling media with very different densities (tungsten carbide and steel with ρ= 14.7 and 7.8 g/cm^3, respectively), which are proven to influence very differently morphology, microstructure and magnetic properties in MnAl due to the different energy impact attained during ball milling. X-ray diffraction (XRD) pattern of the starting gas-atomized material (particle size below 30 μm) showed only intensity peaks corresponding to ε- and γ_2-phases, with no presence of the τ-phase. XRD patterns measured during *in-situ* annealing of the as-milled powders (270 s) in the temperature range of 30 to 500 °C (ramp: 1 K/min), show that the temperature needed for ε- to τ-MnAl transformation decreases in about 50 °C by using the higher density tungsten carbide media. Figure 1 shows the hysteresis loops measured for the MnAl powder milled for 270 s with tungsten carbide and steel, after annealing at 400 °C. The choice of tungsten carbide in the milling process results in MnAl powder with a very high coercivity of about 5 kOe by milling for only 270 s, but this comes at the expense of a decreased magnetization. A better combination of magnetic properties is obtained by using steel material as milling media, with a significant coercivity of 3 kOe and above a 50% increase in magnetization after same processing parameters used with tungsten carbide. It will be shown that this is the result of the development of the τ-phase and the low annihilation of defects induced during milling that, in combination with the formation of the stable β-phase, act as pinning centers during magnetization reversal. High-resolution transmision electron microscopy TEM analysis was carried out with a FEI Titan microscope to confirm the coexistence of the τ- and β- phases in the resulting powders. Figure 2 shows structural configuration images for the τ- and β-phases coexisting in the high-coercive MnAl powder milled for 270 s with tungsten carbide.

Mn-based alloys have been emerged as potential replacement to high-cost rare-earth and novel metal based permanent magnets. Among these, tetragonally ordered $Mn_{3-x}Ga$ ($0 \le x \le 1$) alloys are more promising due to high Curie temperature (600 K ≤ Tc ≤ 800 K), tunable retentivity and coercivity and high uniaxial magneto-crystalline anisotropy (UMCA; ~ M erg/cc) [1-5]. But, synthesis of single tetragonal phase of $Mn_{3-x}Ga$ alloys is a challenging task subjected to the existence of manifold (near-stoichiometric and structural) stable phases due to their complex phase diagram [6]. On top of this, the permanent magnets characteristic energy product, BH_{max} value relies on the extrinsic parameters, coercivity (H_c) and remanence (M_r), which are determined by the exchange interactions between hard magnetic grains [8], i.e. controlled by microstructure of the sample, largely dependent on the synthesis technique. Till now, only arc-melting (AMT) technique has been implemented which is limited on the large scale production [1-5]. However, interestingly the hot-compressing of the arc-melted samples resulted in higher coercivity than in as-synthesized alloys [9]. This implies that the single step Spark Plasma Sintering (SPS) technique may be a better alternative which already has numerous industrial advantages. In SPS, in addition to synthesis temperature, the quasi-static compressive stress in SPS technique can optimize the distribution of magnetic grains over the critical magnetic domain wall size uniformly within the material [10]. In this work, we firstly synthesized the alloys with Spark Plasma Sintering technique and XRD results confirm the single phase DO_{22}-Mn_3Ga, while DO_{22}- Mn_2Ga alloy with minimal 15 % volume fraction of a Mn_9Ga_5-phase, which is unavoidable during synthesis due to more negative formation energy, as obtained from density functional theory calculations. The dc magnetization results show T_c ~ 780 K for Mn_3Ga and 710 K for Mn_2Ga (Fig.1), in consistent with earlier studies with AMT. The MH results shows hard magnetic behavior with negligible temperature dependence of $M_s \sim 1.87\ \mu_B$ (10 K) to $1.72\ \mu_B$ (300 K) and H_c ~ 2.65 kOe for Mn_3Ga, while $M_s \sim 1.0\ \mu_B$ and H_c ~ 4.95 kOe (10 K) to $M_s \sim 0.82\ \mu_B$ and H_c ~ 4.35 kOe (300 K) for Mn_2Ga alloy (inset of Fig.1). The comparison of experimental H_c with Stoner-Wohlfarth model yields microstructural parameter, $\alpha \sim 0.6$ (Mn_3Ga) and ~ 0.5 (Mn_2Ga) and confirms nucleation mechanism [8]. The maximum energy product (BH_{max}, MGOe) from MH loops and UMCA (K_u, Merg/cc) from Approach-to-saturation analysis of MH isotherms and maximum energy product (BH_{max}, MGOe) from hysteresis loops are obtained as 0.61 MGOe, 10.81 Merg/cc (Mn_3Ga, 10 K) and 0.34 MGOe, 6.51 Merg/cc (Mn_2Ga, 10 K), respectively (Fig.2). The above K_u and BH_{max} values for Mn_3Ga are slightly lower, while for Mn_2Ga are higher than obtained with arc melted samples reported till date.

HB-12. Tailoring Magnetic Properties of Al-substituted M-Type Strontium Hexaferrites.

Y. Dai[1], Z. Lan[1], K. Sun[1], Z. Yu[1], R. Guo[1] and X. Jiang[1]
1. University of Electronic Science and Technology of China, Chengdu, China

M-type Strontium Hexaferrites have gained considerable attention for their applications in the permanent magnets, microwave devices and magnetic recording media due to the large uniaxial magnetocrystalline anisotropy, excellent remanent magnetization, and corrosion resistivity and low price [1]. Any further enhancement to the magnetic properties of M-type Sr-hexaferrite is of relevance for technological innovation. Aiming at this target, many works have been done to investigate the influence of main compositions, fabricating methods, and sintering processes on the magnetic properties. Y. Yang et al [2] reported Al substituted M-type Ca-Sr-hexaferrites ($Ca_{0.6}Sr_{0.1}La_{0.3}Fe_{12-x}Al_xO_{19}$, x=0~1.4), and the results indicated that the saturation magnetization (M_s) linearly decreases while the coercivity (H_c) increases with the increase of Al contents. F. Rhein et al [3] prepared $SrFe_{12-x}Al_xO_{19}$ powders via mechanochemical activation, and afterwards the powders were milled and annealed at 1000°C in NaCl to produce ultrafine nano-particles. It is concluded that the furthermore milling and annealing treatment allow to improve both the coercivity H_c and saturation magnetization M_s of Al substituted Sr-hexaferrites (x=0, 1) as compared to the conventional ceramic process. Z. Chen et al [4] studied $Sr_{0.61-x}La_{0.39}Ca_xFe_{11.7}Co_{0.3}O_{19}$ ferrites with various calcium concentrations (x=0, 0.1, 0.2, 0.3) through microwave calcining. The largest saturation magnetization of 68emu/g and coercivity of 5320Oe were observed for a composition of $Sr_{0.41}La_{0.39}Ca_{0.2}Fe_{11.7}Co_{0.3}O_{19}$ calcined at 1140°C for 30min. In this work, the M-type hexaferrite $Sr_{0.7}La_{0.3}Fe_{12-x}Al_xO_{19}$ (x=1~1.4) have been synthesized by the standard solid-state method. The influence of Al^{3+} substitutions on the microstructure and magnetic properties of M-type Sr hexaferrites have been investigated in detail. In order to probe into the effect of Al^{3+} substitutions on the magnetocrystalline anisotropy, the law of approach to saturation was utilized to calculate the magnetocrystalline anisotropy constant K_1, which could be written as Eq. (1)~(3) [5]: $M=M_s(1-e/H-f/H^2-\ldots)+\chi_p H$ (1) $f=H_a^2/15$ (2) $H_a=2K_1/\mu_0 M_s$ (3) where e and f represent the resistance of technical magnetization, M_s the saturation magnetization, H the applied magnetic field, χ_p the paramagnetic susceptibility. H_a can be derived accordingly. The X-ray diffraction patterns of the hexaferrite $Sr_{0.7}La_{0.3}Fe_{12-x}Al_xO_{19}$ with x=0~1.4 are shown in Fig.1. It can be observed that the XRD patterns of all the samples are single magnetoplumbite phase patterns. The result indicates that Al^{3+} ions are all indexed to the standard powder diffraction pattern of M-type hexaferrite. Fig.2 illustrates the magnetic hysteresis loops of the as-sintered samples. Note that the coercivity H_c of Al substituted hexaferrites increase significantly with increasing Al substitutions. Concomitantly, the relatively high remanence ratio (M_r/M_s) of 80% is observed in Al substituted hexaferrites.

HC-01. Resonance Spin Transfer Torque Magnetoresistive Memory.

J. Zhu[1] and A. Shadman[1]
1. Data Storage Systems Center, Carnegie Mellon University, Pittsburgh, PA, United States

INTRODUTION Spin transfer torque magnetoresistive random access memory (STT-MRAM) has shown a great promise to be a main stream novel nonvolatile memory technology. Reduction of state switching current still remains to be a continued research focus for scaling down the size of the addressing transistors. One of the switching characteristics attributing to the relatively high power consumption is the asymmetry of switching current threshold: switching from parallel (P) to antiparallel (AP) state requires more than twice as much current as switching from antiparallel to parallel state. In this paper, we present a design that can significant reduce the switching current threshold for switching from P to AP state to substantially reduce or eliminate the switching asymmetry. By incorporating an antiferromagnetic/ferromagnetic stack to provide a rotating spin transfer torque that matches with the ferromagnetic resonance frequency of the free layer, switching threshold can be significantly reduced. DSIGNE AND SIMULATION RESULTS Figure 1(a) shows the actual design: The upper portion of the memory including the free layer is a conventional STT-MRAM design with stray-field compensated reference layer structure. The lower portion of the memory is a structure for generating a rotating spin transfer torque through the other interface of the free layer, which comprises, starting from the bottom, a perpendicularly magnetized spin polarization layer, an antiferromagnetic layer (AF) with negative uniaxial anisotropy of easy plane, a non-magnetic interlayer, a ferromagnetic layer exchange biased with the antiferromagnetic layer, and a non-magnetic interlayer separating the ferromagnetic layer and the free layer. The bottom spin polarization layer yields polarized spin current in the antiferromagnetic layer, resulting in the canting of the antiferromagnetic coupled spins as illustrated in Fig. 1(c). The spin canting gives rise to the exchange fields on the two sets of antiparallel coupled spins, consequently resulting in spin precession around the perpendicular direction within the film plane with precessional chirality governed by the left-hand rule [1][2]. The precessional frequency is partially determined by the ratio between the numbers of injected spins and the localized spins in the AF layer as well as the AF-biased ferromagnetic laye. The magnetization rotation of the AF-biased ferromagnetic layer generates a rotating spin transfer torque to the free layer magnetization. As the free layer magnetization experience the antidamping spin transfer torque generated from the tunnel barrier side, the magnetzation will precess at the ferromagnetic resonance freqency. By adding a rotating spin transfer torque that matches the chirality of the magnetization precession and the ferromagnetic resonance frequency, Switching current threshold should be signifiantly reduced. By selecting the thickness and the material of both the antiferromagnetic layer and the ferromagnetic layer, the freqency of the rotating STT can be adequated selected at the operating current. Figure 2(a) shows the calculated switching time, defined as the minimum current pulse duration need, as a function of the frequency of the rotating spin transfer torque for different current injection for fixed free layer parameters with the ferromagnetic resonance (FMR) frequency $\gamma H_k/2\pi \approx 22$ GHz. An effective H_k of 8 kOe is assumed for a circular device of 20nm diameter. At smaller current values, which are significantly below the threshold by the usual one-side spin transfer torque only, the switching time dramatically reduces as the freqnecy of the rotating spin transfer torque approaches to the FMR frequency from the left side (smaller freqency). The effect of resonance is evident. Figure 2(b) shows the calculated switching time with an artificially fixed rotating spin transfer torque at a frequency of 21GHz for P-to-AP switching. The reduction of switching current threshold with the rotating spin transfer is significant and the reduced switching current threshold becomes the same as the AP-to-P switching, hence, essentially eliminating the switching asymmetry. It is important to note the designs shown in Fig. 1(a) and 1(b) only help the P-to-AP switching while the switching from AP-to-P is virtually unaffected. For the results shown here, we artificially fixed parameters of the rotating spin transfer torque, such as its frequency, or its amplitude, mainly for the purpose of illustrating and understanding the physics behind the phenomena and the operation mechanism.

New free layer (FL) materials and designs have recently drawn a lot of interest as the devices of spin-transfer-torque magnetic random access memory (STT-MRAM) keep scaling down. The so-called dual-MgO FL consisting of two CoFeB/MgO interfaces is under development. However, the perpendicular magnetic anisotropy (PMA) from two CoFeB/MgO interfaces is insufficient to provide the required thermal stability (Δ) for long data retention time for devices with critical diameter (CD) below 20nm. In our earlier work, a new FL design, the hybrid FL, was proposed. This hybrid free layer (HFL) design consists of a single layer of CoFeB coupled via a spacer to a [Co/Ni] multilayer [1]. Here, we report on the electrical and magnetic properties of the hybrid free layers in top-pinned magnetic tunnel junction (TP-MTJ) devices with various electrical CD (e-CD). We show that HFL's can provide larger coercivity (H_c) and retention (Δ) than dual-MgO. Besides, the relation of Δ and e-CD in both cases fits well with the energy barrier model based on domain wall mediated reversal (DWMR) when the CD is larger than ~30 nm. The switching characteristics of the HFL in comparison to the dual MgO free layer will be discussed. Fig.1 (a) and (b) show the schematic of the TP-MTJ stack with a HFL and an optimized dual-MgO FL, respectively. Both types of FL's have equal thickness. The corresponding resistance-field (R-H) loops after device fabrication are also shown. The switching of the free layer and reference layer (RL) is indicated, respectively. The tunnel magnetoresistance (TMR) is ~100% and the sharp steps in the R-H loops confirm PMA in both the FL and RL. From R-H loops, H_c of the HFL and dual-MgO FL can be derived. Fig.2 (a) shows the coercive field H_c of the FL obtained from the R-H loops as a function of e-CD. In both cases, H_c increases slightly with the decreasing e-CD down to around 40nm. H_c then drops for devices with 20 nm e-CD, and it is attributed to the patterning damage leading to PMA loss, which becomes more important at small CD. Note that the coercive field H_c of the HFL is for all CD's larger than those of dual-MgO FL. To derive Δ of both free layers, the field sweep method is applied [2]. R-H loops of selected devices were scanned for 100 cycles. The cumulative switching probability as a function of switching field is fitted by existing magnetization reversal models, which provides intrinsic Δ after offset correction [3]. For small devices, the macrospin model is used for fitting and Δ derivation [4]. Results are plotted in Fig.2 (b). Indeed, the Δ values from both types follow quadratic relation with CD in small e-CD range (<40nm) based on the macrospin model. However, the Δ values of larger devices from macrospin model fitting deviate a lot from the expected quadratic relation between Δ and CD (not shown). It is thus natural to expect that Δ in large devices is determined by a DWMR model, whose principle is illustrated briefly in the insert in Fig.2 (b) [4.5]. The Δ values increase linearly with CD larger than 40nm in agreement with the DWMR model, where the intrinsic Δ is purely determined by the domain wall energy when the domain wall sits along the center of the device, i.e. $\Delta=\sigma_{dw}l_{dw}t/k_BT=\sigma_{dw}Dt/k_BT$. Here D is the diameter or CD of the device and t is the FL thickness. Note that also in the DWMR regime, the Δ values for the dual-MgO FL are lower than for the HFL. That indicates that the domain wall formation in HFL requires more energy than in dual-MgO, which is attributed to its higher PMA. On the other hand, one may argue that the critical dimension (d_c) of the transition between macrospin and domain wall formation of HFL is smaller than that of dual MgO FL due to smaller A_{ex} and larger K_U^{eff}. Because d_c can be estimated as $d_c \propto (A_{ex}/K_U^{\mathrm{eff}})^{½}$, where A_{ex} is the exchange stiffness and K_U^{eff} is the FL effective anisotropy. The transition from macrospin to domain wall reversal occurs earlier for the HFL than for its dual-MgO counterpart. However, one should note that, even in the macrospin regime, HFL devices perform better due to higher H_c and Δ. In conclusion, the HFL can provide large H_c and Δ in devices down to the macrospin regime. Due to its Δ tunability via [Co/Ni] bilayer increase, it can clearly outperform dual MgO FL's. Experimental results of Δ with respect to e-CD can be fitted by a domain wall based energy barrier model down to 30nm e-CD. At smaller e-CD, macrospin switching occurs. Electrical switching, however, could not be realized before dielectric breakdown in HFL devices and needs further research. Previous study showed that the interlayer exchange coupling (IEC) through the spacer layer in the HFL strongly impacts the switching current [6]. Therefore, HFL optimized for low current switching could be achieved with new spacer materials.

HC-03. X nm Magnetic Tunnel Junctions with Perpendicular Anisotropy.

K. Watanabe[1], B. Jinnai[2], S. Fukami[1,2], H. Sato[1,2] and H. Ohno[1,2]
1. RIEC, Tohoku University, Sendai, Japan; 2. CSIS, Tohoku University, Sendai, Japan

Since the discovery of a perpendicular-easy-axis CoFeB/MgO system [1] and subsequent development of double-MgO interface structures allowing double thermal stability factor [2], magnetic tunnel junctions (MTJs) have been successfully miniaturized down to 20-nm scale towards the application of them to large-scale magnetoresistive random access memory. However, there has been no technological solution to satisfy the requirements on thermal stability and switching current simultaneously at 1X and X nm generations. Here we show a new methodology utilizing a shape anisotropy to address this issue. The sign of shape anisotropy changes to positive direction at ultrafine scale by adopting relatively thick recording layer of MTJ, allowing high thermal stability. Making the thickness comparable to or greater than the diameter, we obtain perpendicular MTJs with sufficiently high thermal stability even down to X-nm scale. Moreover, because the shape-anisotropy approach does not require any special material systems, we employ a conventional MgO/FeB/MgO structure with low magnetic damping (~ 0.004), allowing spin-transfer-torque (STT)-induced switching even in X-nm MTJs having high thermal stability. The concept of *shape-anisotropy* MTJ is described as follows: In the conventional *interfacial-anisotropy* regime, the thickness of the recording layer is designed to be thin enough so that the interfacial perpendicular anisotropy energy overcomes the negative shape anisotropy, or the demagnetization, energy and achieve high enough thermal stability factor. On the contrary, the *shape-anisotropy* regime focused in this work achieves the perpendicular easy axis by increasing the thickness so that the sign of shape anisotropy changes to positive. Another feature of the *shape-anisotropy* approach is that one can employ various material systems because it is material-independent, allowing a use of low-damping materials to achieve low switching current. An analytical calculation reveals that the *shape-anisotropy* approach provides MTJs with sufficiently high thermal stability factor Δ (= E/k_BT; E is the energy barrier, k_B the Boltzmann constant, and T the absolute temperature) of more than 80 that yet can be switched by spin-transfer torque even at around 10 nm, whereas the *interfacial-anisotropy* approach cannot achieve it. Based on the analytical calculation, we fabricate MTJs with the perpendicular shape anisotropy. Similar MTJ stack structure to a previous report [3] is used except for the thickness of recording layer; Si/SiO_2-sub./ Ta(5)/ Ru(10)/ Ta(15)/ Pt(5)/ $[Co(0.4)/ Pt(0.4)]_{x6}$ /Co(0.4) /Ru(0.4) /Co(0.4) / $[Pt(0.4)/ Co(0.4)]_{x2}$ /Ta(0.2)/ CoFeB(1.0)/ MgO/ FeB(15)/ MgO/ Ru(5) (in nm). Films are deposited by dc/rf magnetron sputtering, processed into nanoscale MTJs with various nominal diameters, and annealed at 300°C for 1 hour. All the measurements are performed at room temperature. Diameter D of MTJ is electrically determined from the resistance and resistance-area product. Square hysteresis loops for MTJ resistance R versus out-of-plane magnetic field H are observed below a certain diameter D (~20 nm), indicating perpendicular easy axis owing to the shape anisotropy. Coercive field H_C increases as D decreases, due to the increasing shape anisotropy energy density. Switching probability measurement is carried out using pulsed magnetic field to evaluate effective anisotropy field H_K^{eff} and Δ [4]. H_K^{eff} increases as D decreases, in line with the trend of H_C. Importantly, as shown in Fig. 1, sufficiently high Δ of more than 80 is obtained even for X-nm MTJs unlike the previous works with the *interfacial-anisotropy* MTJs and the values are consistent with our analytical calculation. For the smallest MTJ we measure (D = 3.8 nm), D is obtained to be 73. We next examine the STT-switching using pulsed currents with 10-ms duration. Bidirectional switching at zero magnetic fields is observed for a number of MTJs with various sizes down to 8.8 nm MTJ. Switching current density J_{SW} is found to increase as D decreases, as expected from a theory that predicts increase in J_{SW} with D^{-2}. Also, the obtained values of J_{SW} roughly agree with the theoretical expectation, for instance, for 10.4-nm MTJ, switching is obtained at 3.2×10^7 A/cm^2, corresponding to J_{C0} [5] of 3.9×10^7 A/cm^2 whereas our calculation based on the STT switching model predicts $J_{C0} = 4.4 \times 10^7$ A/cm^2. In summary, we revisit the shape anisotropy of nanoscale MTJ and achieve high thermal stability and STT switching simultaneously at ultrafine scale for the first time. The present results provide a new insight for the miniaturization of MTJs for STT-MRAMs and open up the next era of nano-magnetics/spintronics [6]. In information and communication technology (ICT) equipment indispensable for modern society, semiconductor memories occupy the main position of storage memories, working memories, and e-memories in logic blocks. In current semiconductor memories, rapid increase in the power consumption is most serious issue, as the more energy-saving is strongly required for ICT technology. From above view point, STT-MRAM and its application such as NV-Logic are aggressively studied in the world and many excellent results were published. However, almost results of STT-MRAM were fabricated by ion beam etch (IBE) process. Therefore, for higher density STT-MRAM's mass-production under wide patterning process margin and high TAT, plasma based reactive ion etch (RIE) process technology for MTJs is needed. In this invited paper, it is reviewed our previas results regarding STT-MRAM and NV-Logic fabricated by RIE process as shown in Fig. 1. It is shown that STT-MRAM and NV-MCU etc. were successfully worked under extremely low power consumption. Moreover, it is reviewed our previas results of RIE process technology itself. We presented process and device results from a developed chemistry set which significantly reduces the etch damage compared with conventional chemistry. An etched MTJ stack profile is included in Fig. 2. The damage caused by RIE on the magnetic properties of the CoFeB free layer in a MTJ with a perpendicular easy axis (p-MTJ), and on the TMR ratio of CoFeB–MgO p-MTJs was characterized to identify its root cause. Fig. 3 includes TMR data from a selection of different chemistry sets. Our developed chemistry is based on learning that it is N and H radicals that are the primary source of damage. With our developed process, high TMR ratio was achieved with very slight degradation. We report our chemistry, its underlying concept, resultant MTJ profiles, device electrical and magnetic properties. Finally, we summarize the MTJ damage mechanism useful for bringing MTJ fabrication etch technology to maturity. *Acknowledgements:* This work was partly supported in part by CIES's Industrial Affiliation on STT -MRAM Program and ACCEL & OPERA Program under JST.

The development of the magnetic tunnel junctions with perpendicular easy axis using interfacial anisotropy [1–4] (p-MTJs) has been intensively advanced toward realization of high performance spin-transfer-torque magnetoresistive random access memories (STT-MRAMs). The p-MTJs used in the STT-MRAMs are required to withstand 400°C annealing to be compatible with CMOS back-end-of-line-process. Although we have demonstrated the thermal tolerance against 400°C annealing for the free layer in the CoFeB/MgO-based p-MTJs [5], we also found variation of properties in synthetic ferrimagnetic (SyF) reference layer. We revealed that the variation was caused by the diffusion of Fe in the CoFeB reference layer toward the bottom Co/Pt pinned layer after annealing [6]. We simultaneously observed degradation of perpendicular anisotropy of the Co/Pt multi layer. Perpendicular anisotropy of Co/Pt is influenced by the Co/Pt thickness ratio, buffer layer material, and roughness [7]. In this study, we focus on modification of the buffer layer and reveal that degradation can be suppressed by employing a surface modification treatment (SMT) of the Pt buffer layer. MTJ stacks from the substrate side, Ta /Pt buffer layer/with or without SMT/ $[Co/Pt]_4$/Co /Ru/ $[Co/Pt]_2$/Co /Ta /CoFeB /MgO barrier/free layer/top electrode, were deposited on a 300-mmΦ thermally oxidized Si wafer using a DC/RF magnetron sputtering system at room temperature (Fig.1(a)). In the SMT process, the Pt buffer layer was exposed to an ion plasma. The upper layers on the Pt buffer layer were deposited without breaking the vacuum. After deposition, samples were annealed at 350 °C for 2 h or 400 °C for 1 h in vacuum without applying magnetic field. The out-of-plane magnetic moment per unit area versus magnetic field (m-H) curves of the blanket films were measured by a vibrating sample magnetometer, and the film structures were investigated by energy dispersive x-ray spectroscopy (EDX) and high-resolution X-ray diffraction (HRXRD) using Cu Ka radiation. As shown in Figs. 1(b) and 1(c), perpendicular anisotropy of the SyF reference layer without SMT degraded after 400 °C annealing, while that of the SyF reference layer with SMT hardly changed. Interestingly, after annealing at 400 °C, magnetic moment variation in the top and bottom parts of the reference layer is observed in the stack without SMT due to Fe diffusion from the CoFeB reference layer toward the bottom Co/Pt layer, as we previously reported [6]. In contrast, the magnetic moments of the top and bottom parts of the reference layer in the stack with SMT are almost the same. This indicates that Fe diffusion in the reference layer is suppressed by the SMT of the Pt buffer layer. In order to verify this hypothesis, we performed cross-sectional EDX line analysis (Fig. 2). In the stack without SMT, Fe element in the CoFeB reference layer is observed in the other layers such as the top and bottom Co/Pt multilayers after annealing at 400 °C (Fig. 2(a)), which indicates that Fe diffused toward the bottom Co/Pt layer. In contrast, in the stack with SMT, Fe element is observed only in the CoFeB layer in the as-deposited state and after annealing at 400 °C (Fig. 2(b)). These results are consistent with the variation of magnetic properties shown in Figs. 1(b) and 1(c). In order to clarify the reason for the suppression of perpendicular anisotropy degradation of the Co/Pt multilayer after 400 °C annealing by SMT, we evaluated the crystal structure of the Co/Pt multilayer using HRXRD. X-ray diffraction analysis revealed that the ions penetrated the Pt buffer layer, expanding the Pt lattice constant and enhancing Co/Pt grain growth, which well oriented to the fcc (111) closed-packed plane parallel to the substrate surface. This caused larger perpendicular anisotropy in the Co/Pt multilayer and higher thermal tolerance. In addition, this may suppress Fe diffusion from the CoFeB reference layer toward the bottom Co/Pt layer. HC-06. Role of Curie temperature on thermal stability limits of perpendicular STT-MRAM.

L. Tillie[1,2], R.C. Sousa[2], J. Chatterjee[2], N. Lamard[2], J. Guelfucci[2], E. Nowak[1], B. Dieny[2] and I.L. Prejbeanu[2]

Perpendicular STT-MRAM (P-STT MRAM) are seen as one of the most promising next-generation non-volatile memory thanks to their high speed[1], high endurance[2], low voltage operation[3] and high data retention at room temperature. However, using thin film changes significantly some physical parameters for the magnetic storage layer compared to bulk. One of these parameters is the Curie temperature, value at which the magnetic material loses its magnetization resulting in losing data retention. Studying this parameter remains critical in order to answer to the industrial prerequisites in temperature and the soldering reflow criterion at 260°C. In this paper, magnetic stack with different capping materials and annealing temperatures are being study in order to extract their coercive field, Curie temperature and thermal stability factor. For this study, single-MTJ stacks with a bottom SAF with different capping materials have been patterned from 20 nm up to 150 nm diameter devices. The single-MTJ films have also been deposited with two wedges: one in the vertical direction for the storage layer and one in the horizontal direction for the oxide barrier resulting in different thicknesses on the same wafer. The deposited stacks are as follow (in Å): Ta 30/ Ru 150/ W 30/ Ta 10/ Pt 50/ [Co 5/ Pt 2.5/]$_6$/ Co 5/ Ru 9/ [Co 5/ Pt 2.5/]$_3$/ Co 5/ Ta 3/ $Fe_{72}Co_8B_{20}$ 11.4/ MgO *wedge*/ $Fe_{72}Co_8B_{20}$ *wedge*/ *Cap* / Ta 10/ Pt 20 where *Cap* is either nothing or W 20. The Ta-capped stack has been annealed at 350°C for 30min while W-capped wafers have been annealed at 425°C and 450°C. Due to setup limitations in temperature, the Curie temperature had to be extracted through the coercive field Hc decrease in temperature using the Neel-Brown equation [4]: Hc (T) = Hc (T = 0 K)*(1-√ (T / Tb)) (1) Where Tb is the blocking temperature, value at which the data retention of the system is of the order of the measurement time meaning that the blocking and Curie temperature are equal when the measurement time tends to 0s. In our case, the measurement time is ~70µs, making the blocking temperature close to the Curie temperature. Using this method, the blocking temperature for the single-MTJ stacks have been measured and plotted in Fig.1a as a function of the storage layer thickness. For these wafers, the storage layer's magnetization is perpendicular in the thickness range of 13 Å to 18 Å. In this range, the blocking temperature shows a linear behavior versus the thickness. The measured values are significantly lower than the bulk values (~770°C for Fe and 1115°C for Co [5]) but relatively of the same value for the same storage layer's thickness of the different stacks. However, The W-capped stack with a 425°C annealing (W425) shows higher blocking temperature values due to its higher values of thickness. This shows that the capping material does not have a significant impact on the Curie temperature of the storage layer but its magnetic surface anisotropy allows different range of storage layer thickness and so, different Curie temperature values. In Fig.1b, the coercive field extracted at room temperature shows a non-linear behavior on the perpendicular-thickness range. As shown, W425's coercive field first increases up to 550 Oe at 15.2Å and then decreases beyond this thickness value until the magnetization goes in-plane. The constant increase of the Curie temperature with thickness and the decrease of the coercive field beyond 15.2Å show a trade-off between the working temperature limit and the magnetic immunity of the memory device for large thicknesses. Fig.2 shows the thermal stability extracted electrically using the method used in our group [6] from 40°C up to 190°C for the W425 devices with a storage layer of 13.4Å and 14.3Å. For both thicknesses, all the devices lose their data retention around the same temperature value (170°C and 200°C), independently of their diameter while the thermal stability factor inceases with diameter at room temperature. The 0.9Å increase in the storage layer thickness also shows an increase of ~10% in the thermal stability factor at room temperature allowing the 20nm diameter devices to appear for the 14.3Å storage layer thickness. In conclusion, we measured the coercive field in temperature of single-MTJ with different capping materials and annealing temperatures showing that the Curie temperature is linear with the storage layer thickness between 13 Å and 18Å and does not depend directly on the capping material. However, W as capping material allows a larger storage layer thickness and higher coercive field than Ta. A 450°C annealing temperature for W-capped stacks improves magnetic surface anisotropy and coercive field compared to 425°C. We also saw that the coercive field is increasing and then decreasing with the storage layer's thickness, inducing a trade-off between high working temperature and magnetic immunity when increasing the thickness. At last, thermal stability measurements showed that the device diameter does not influence on the Curie temperature and that a thicker storage layer increases data retention.

HC-07. Back hopping in spin-transfer-torque devices, possible origin and counter measures.

C. Abert[1], H. Sepehri-Amin[2], F. Bruckner[1], C. Vogler[1], M. Hayashi[2] and D. Suess[1]
1. Physics of Functional Materials, University of Vienna, Vienna, Austria; 2. National Institute for Materials Science (NIMS), Tsukuba, Japan

Spin-transfer torque magnetoresistive random-access memory (STT MRAM) is considered a very promising future data storage technology as it combines the high speed of conventional DRAM with a very low power consumption due to its persistent nature. These devices consist of two magnetic layers separated either by a tunnel barrier or a nonmagnetic conducting layer. The information is stored in the magnetization direction of one of the magnetic layers (free layer). In order to write data, an electric current is applied perpendicular to the layer structure. In this case, the second layer acts as a spin polarizator and the spin-polarized electrons exert a torque on the free-layer magnetization which enables the selective switching of the free layer depending on the sign of current. The polarizing layer is often referred to as pinned layer as it is constructed to be very hard magnetic in order to be insensitive to the polarized electrons coming from the free layer. In order to switch the free-layer magnetization, a critical current has to be exceeded. A further increase of the write current is expected to further stabilize the free layer so that the write process should be robust with respect to the exact writing current and duration as long as both are high enough. However, experiments exhibit a stochastic switching of the free layer under certain conditions [1]. This back-hopping effect was observed in various devices including in-plane and perpendicularly magnetized MRAM stacks as well as devices with tunnel junctions and conducting spacer layers. Various explanations for this undesirable effect have been proposed [2]. In this work we investigate the destabilization of the magnetic pinned layer as a possible origin of the back-hopping effect by means of micromagnetic simulations. For the description of the spin torque we use the spin-diffusion model introduced by Zhang, Levy and Fert [3]. In contrast to the popular macro-spin model by Slonczewski, this models properly accounts for geometry and material parameters as well as the bidirectional interaction of the free layer with the pinned layer. Hence, this approach allows us to study the critical currents for both, desired free-layer switching as well as back hopping due to pinned-layer switching, depending on various system parameters. Moreover we perform thermally activated simulations using Langevin dynamics in order to confirm the stochastic nature of the free-layer switching as well as the giant-magnetoresistance (GMR) signal of the stack as found experimentaly, see Fig. 1. A trivial measure to suppress back hopping due to pinned-layer destabilization is the increase of the pinned-layer anisotropy. However, the reduction of lateral MRAM size in order to increase the storage density introduces significant restrictions on the maximum anisotropy of the pinned layer. Our parameter studies indicate that also the saturation magnetization Ms and the polarization β have significant impact on the critical currents of the system. Namely, it is found that the choice of a free-layer material with low polarization β and saturation magnetization Ms, and a pinned-layer material with high β and Ms lead to a low free-layer critical current and a high pinned-layer critical current and thus reduce the likelihood of back hopping, see Fig. 2.

HC-08. Spin Transfer Torque efficiency enhancement utilizing precessional spin current (PSC) structure for STT-MRAM application.

M. Pinarbasi[1], B. Kardasz[1], G. Wolf[1], J. Vasquez[1], S. Watts[1], T. Boone[1], J. Hernandez[1], K. Bozdag[1], D. Guarisco[1], M. Schabes[1], P. Manandhar[1], E. Dobisz[1], P. Shrivastava[1], Y. Chin[1], E. Ryan[1] and G. Jagtiani[1]
1. Spin Transfer Technologies Inc., Fremont, CA, United States

In this work we report a significant enhancement of the spin transfer torque efficiency in a novel type of Spin Transfer Torque Magnetic Random Access Memory (STT-MRAM) that utilizes a precessional spin current (PSC) structure. STT-MRAM is considered the upcoming new memory class with the potential to fulfill the needs of modern memory applications [1, 2]. STT-MRAM distinguishes itself as an advantageous technology due to its non-volatility, high speed and high endurance. However, in conventional STT-MRAM based on perpendicular magnetic tunnel junctions (pMTJ) the retention of a memory bit is fundamentally coupled to the write current [3], such that higher retention requires higher write current, thereby increasing the energy consumption and reducing the endurance. Even in the case of high speed cache memories where a high retention is not necessarily required, it is important to consider that low retention can also result in a higher probability of data disturbance during the read operation. The spin transfer torque efficiency - the ratio of the thermal energy barrier over the critical write current - is a key pMTJ parameter. The PSC structure comprises a spacer/coupling and magnetic layers deposited on top of the free layer of the pMTJ. Here we describe a pair of pMTJ structures where one features the PSC structure, while the other one, is a pMTJ only structure, which serves as control. All structures were fabricated by depositing the MTJ stacks onto CMOS wafers and formed into multiple 4kbit memory test chips with the Spin Transfer Technologies BEOL process. Fig. 1 shows the average spin torque efficiency extracted from pulsed switching experiments for three different diameters of the MTJ pillar, 40, 50, and 60nm. Both the pMTJ only (blue dots) and PSC stacks (red triangles) show an increasing STT-efficiency as the size of the pillar decreases, a well-described trend [4]. However, the PSC structure shows an enhanced STT-efficiency over the comparison pMTJ structure, and the enhancement gets even larger as the size of the pillar decreases. The STT-efficiency enhancement is largely attributed to an increase in the energy barrier up to 30%, while the switching current remains the same as in the pMTJ structures. Moreover we observed that the STT-efficiency enhancement is robust over a wide range of temperatures relevant for modern memory applications. Fig. 2 shows the energy barrier for the pMTJ only (blue dots) and PSC (red triangles) for temperatures of 30°C, 85°C and 125°C for 40nm pillar size. The energy barrier of the PSC structure is significantly larger than the comparison pMTJ even at elevated temperatures, with both PSC and comparison pMTJ showing a similar trend as a function of temperature. Conventional thermal retention experiments at high temperature show much lower error rates for the PSC structures compared to the pMTJ reference, confirming the higher energy barrier in the PSC obtained from the current switching experiments. This achievement shows that the PSC structure brings important advantages to MRAM technology. It allows to achieve higher data retention while keeping the write current the same. The effect tends to get better as the size of the pillar is decreased. Furthermore the effect can also be utilized to increase the read current for better signal to noise ratio as the device size gets smaller and faster read times, by directly reducing the read disturb error rate.

HC-09. Polar Coding for Spin-Torque Transfer Magnetic Random Access Memory (STT-MRAM).

Z. Mei[1], K. Cai[1] and B. Dai[2]
1. Singapore University of Technology and Design, Singapore, Singapore; 2. Beihang University, Beijing, China

I. INTRODUCTION Spin-torque transfer magnetic random access memory (STT-MRAM) has emerged as a promising non-volatile memory (NVM) technology with various potential applications such as working as the embedded NVM or replacing the stand alone DRAM [1]. However, STT-MRAM suffers from process variations and thermal fluctuations, leading to both the write errors and read errors [2]. Hence it is critical to construct effective error correction codes (ECCs) to improve the system reliability. A single-error-correcting (71, 64) Hamming code is adopted by Everspin's 16Mb MRAM [3]. Extended Hamming codes with hybrid decoding are further proposed for STT-MRAM for the purpose of replacing DRAM [2]. Multiple-error-correcting BCH codes as well as low-density parity-check (LDPC) codes have also been investigated for STT-MRAM [4], for applications with relaxed requirement of the read latency. In this work, we propose, for the first time, the design and optimization of polar codes [5] for the STT-MRAM channel. Compared with LDPC codes with short code lengths, polar codes can achieve better error performance with lower decoding complexity. Moreover, polar codes allow easy adjustment of the code rates with a single encoder/decoder, which is a significant advantage over the Hamming codes and BCH codes. Such rate-compatible property can mitigate the raw bit error rate (BER) diversity of STT-MRAM cells caused by process variations. II. POLAR CODING FOR STT-MRAM For the two typical code construction methods of polar codes, the heuristic method [6] can achieve the capacity of the binary erasure channel (BEC), while the density evolution (DE) method [7] is proposed for the binary memoryless symmetric channel. In this work, we first show that polar codes constructed by using the heuristic method cannot achieve satisfactory performance since the STT-MRAM channel is significantly different from the BEC channel. Moreover, as the STT-MRAM channel is asymmetric by nature [2], we further propose a novel approach to 'symmetrize' the channel, based on which we can construct effective polar codes by using the DE method. Next, we propose rate-adaptive polar coding scheme in conjunction with adaptive decoding to further combat the channel raw BER diversity. During encoding, by adding/deleting certain number of information bit-channels based on the reliabilities of the polarized bit-channels, the code rate of polar code can be easily adjusted with a single encoder. Various decoding algorithms of polar codes are also investigated, such as the original successive cancellation (SC) algorithm, the SC-Flip algorithm, and the cyclic redundancy check (CRC)-aided SC-list (CA-SCL) algorithm. We further present and demonstrate that the adaptive SCL (AD-SCL) algorithm can achieve the best trade-off between the performance and complexity for the STT-MRAM channel. III. SIMULATIONS AND COMPLEXITY ANALYSIS Based on the STT-MRAM channel model proposed by [2], the simulations assume a write error rate of 10^{-4}, and vary the mean normalized resistance spread $\sigma_0/\mu_0=\sigma_1/\mu_1$ of the low and high resistances of STT-MRAM, to account for the influence of different process variations on the read decision error. A 3-bit capacity-maximizing quantizer [2] is used in all simulations of polar codes and the LDPC code. In Fig. 1, the central bunch of curves shows the block error rates (BLERs) of different ECCs with a similar code rate of R≈0.86. The capacity of the rate 0.86 code for the STT-MRAM channel is also included as a reference. Observe that the (256, 220) polar code with different decoders all perform significantly better than the (255, 223, 4) BCH code with hard-decision decoding. In particular, with the SC decoder, polar code constructed using DE after 'symmetrizing' the channel outperforms that constructed using the heuristic method by 0.5% in terms of the resistance spread σ_0/μ_0, at BLER=10^{-4}. Hence polar codes are constructed by DE in all the other simulations. We further observe that among various decoding algorithms, the AD-SCL with maximum list size L_{max}=256 (Curve 8) achieves the best performance, and the BLER is similar to the CA-SCL decoder with list size of 16 (Curve 7) at low error rate regions. It also outperforms the (336, 285) LDPC code [4] with the reliability-based min-sum (RB-MS) decoder by 1.2% of σ_0/μ_0. Moreover, with the best performance AD-SCL decoder, the BLERs of a rate 0.95 and rate 0.77 polar codes (Curves 9 and 10) are also illustrated in Fig. 1. They enable the system to work with different levels of resistance spread (i.e. process variations) as compared to the rate 0.86 case (Curve 8), with a single encoder/decoder. This demonstrates the advantage of the proposed rate-adaptive polar coding scheme to tackle the raw BER diversity of STT-MRAM. We also analyzed the computational complexities of the BCH code, LDPC code, and polar code with different decoders. The various complexities normalized to that of the SC decoder are presented in Fig. 2, for the case of R≈0.86. Observe that at small σ_0/μ_0 regions where the BLER is low, the complexity of the AD-SCL decoder converges to that of the SC decoder, which is lower than the complexities of both the BCH decoder and LDPC decoder. This indicates that the AD-SCL decoder of polar codes achieves the best compromise between performance and complexity for the STT-MRAM channel. CoFeB/MgO-based magnetic tunnel junctions (MTJs) with a perpendicular easy axis are critical building block in spintronics-based non-volatile memories.[1,2] The CoFeB/MgO-based MTJs at junction diameter of less than 20 nm is now being developed.[3,4] In such a small dimensions, magnetic properties could alter during device-processing;[5-7] the magnetic-field-angle dependence of coercivity combined with micromagnetic simulation suggested that effective magnetic anisotropy field H_K^{eff} of the free-layer with the size of ~ 20 nm decreases at the vicinity of the device edge, depending on the device-processing condition.[5] H_K^{eff} and damping constant a are the two important material parameters as those determine intrinsic critical current and thermal stability factor, which are the two major metrics characterizing the MTJs. Homodyne-detected ferromagnetic resonance (FMR) is powerful tool to probe H_K^{eff} and a of the free layer in the nanoscale MTJs.[8-11] In this study, we investigate the dependence of the effective magnetic anisotropy field and damping constant on the free-layer size in the nanoscale CoFeB/MgO MTJs down to the free-layer size of 15 nm using the homodyne-detected FMR. A stack with the structure, from the substrate side, Ta(5 nm)/ PtMn(20 nm)/ Co(2.6 nm)/ Ru(0.9 nm)/ CoFeB(2.4 nm)/ MgO(1.1 nm)/ CoFeB(1.8 nm)/ Ta(5 nm)/ Ru(5 nm) is deposited on a sapphire substrate by dc/rf magnetron sputtering. Numbers in parentheses are nominal thicknesses in nm. The stack is processed into circular MTJs on a coplanar waveguide by electron beam lithography, reactive ion etching, and Ar ion milling. We fabricate the two types of MTJs with various free-layer sizes D; one has the reference layer much larger than the free-layer size (step structure), and the other has almost the same reference layer size as that of the free-layer (standard structure). The process conditions for the two types MTJs are the same as those employed in the previous study.[5] The free-layer size is varied from 15 to 150 nm. After fabricating the MTJs, the MTJs are annealed at 300°C in vacuum for 2 hours under an in-plane magnetic field of 1.2 T. The 1.8-nm-thick CoFeB layer is the free layer with a perpendicular easy axis. The synthetic ferrimagnetic structure is adopted to the reference layer with an in-plane easy direction. This non-collinear magnetization configuration allows us to detect the FMR spectra of the free layer under the perpendicular magnetic field H_{perp}.[11] We measure the homodyne-detected FMR spectra by sweeping the H_{perp} at several rf frequencies f_{rf} using the same setup used in Ref. 11. The amplitude of the rf signal is fixed to be -25 dBm, which is modulated at 273 Hz for lock-in detection. The typical FMR spectrum for both structures with D = 80 nm and f_{rf} = 6 GHz is shown in Fig. 1. In the spectrum, resonance peak observed at m_0H_{perp} = 125 – 150 mT corresponds to uniform ferromagnetic resonance mode (Kittel mode) and the other peaks observed at a lower m_0H_{perp}, which are not focused in this study, correspond to spin-wave resonance mode.[12,13] The spectrum can be fitted by superposition of the symmetric and antisymmetric Lorentz function, from which we obtain resonance field H_R and linewidth DH. H_K^{eff} is determined from the intercept on horizontal axis of a linear fit to f_{rf} versus resonance field and a is determined from slope of a liner fit to DH versus f_{rf}. Fig. 2 shows the free-layer size dependence of H_K^{eff} for both structures. In case of the step structure, H_K^{eff} monotonically increases with decreasing D, which can be explained by decrease (increase) of demagnetization factor along out-of-plane (in-plane) direction. On the other hand, in case of the standard structure, H_K^{eff} does not increase in a monotonic manner and the increasing rate of H_K^{eff} with respect to D is smaller than the step structure. The dependence of H_K^{eff} on D for the step structure can be well reproduced as blue curve shown in Fig. 2 where we take into account variation of demagnetization factor with respect to D assuming that anisotropy field H_K and spontaneous magnetization M_S (1.39 T determined by magnetization measurement) is intact during the device-processing. On the other hand, to reproduce the results for the standard structure, we need to consider a decrease of H_K^{eff} at the vicinity of the device edge as shown in inset of Fig. 2. In Fig. 2, the calculation result using edge width w of 4 nm and the reduction rate for H_K^{eff} at the edge h of 0.1 is shown as orange curve, which is in good agreement with the experimental results. The results indicate that the anisotropy field of the free layer depends on the device-processing condition. In contrast to the free-layer size dependence of H_K^{eff}, the damping constant shows almost constant value down to D = 15 nm regardless of the structures, indicating that the damping constant is not sensitive to the device-processing condition. HD-01. Enhanced spin relaxation and spin-to-charge conversion at the surface of Cu thin film decollated with molecules.

S. Takizawa[1], K. Kondou[2], H. Isshiki[1], K. Shimose[3], T. Kawabe[3], S. Miwa[3] and Y. Otani[1,2]

The interconversion between spin and charge currents is a key ingredient in spintronics. Recently direct and inverse Edelstein effects (DEE and IEE), spin-charge currents interconversion at the Rashba interface state or the surface state of topological insulators (TIs) [1], have been drawing much attention as the qualitatively different conversion mechanism from the spin Hall effect (the bulk effect). In the IEE, the injection of the in-plane polarized spin current into the interface or the surface state gives the spin polarized electrons momenta orthogonal to their spin polarization due to the spin-momentum locking behavior which is the characteristic of the Rashba interface and the TI surface states. In this way, the spin currents are converted to the charge currents flowing in-plane. The DEE is the charge-to-spin current conversion at the interface, where the application of electric field induces the spin accumulation in the interface, and the accumulated spins diffusively propagate into the adjacent layer. Based on the above described idea, DEE and IEE have been demonstrated by using various interfaces of metals [2-4] or metal/insulator [5]. In the present study we focus metal/molecule interface as in Fig. 1(a) because of unique characters of molecules such as high permittivity, flexibility of the structure, self-assembly at metal surface, etc. We aim to demonstrate IEE at a metal/molecule interface. For this purpose, we chose lead (II) phthalocyanine (PbPc) and metal-free phthalocyanine (H_2Pc) shown in Fig. 1(b) as molecules deposited on the Cu surface. The PbPc contains a heavy metal element, lead, which is expected to contribute to the IEE because of its strong atomic spin-orbit coupling, whereas no contribution of the H_2Pc to IEE is expected, therefore can be used as a reference. The sample preparation is as follows: Firstly, bilayers consisting of 5-nm-thick $Ni_{80}Fe_{20}$ (Py) and 10- or 15-nm-thick Cu layers were grown on thermally oxidized Si substrates, and then followed by deposition of ~ 1 nm thick PbPc or H_2Pc. Finally, MgO thin film was prepared by electron-beam deposition to protect the metal/molecule interface. The multilayer fabrication method was similar to our previous paper [6]. The multilayer was patterned with a resist mask designed to leave behind a strip with dimensions of 9.5 μm×200 μm by means of Ar ion milling. A Ti (5 nm)/Au (250 nm) waveguide was structured beside the strip for exciting a ferromagnetic resonance (FMR) in the Py layer during spin pumping measurements. We measured the FMR line width for Py/Cu/PbPc and Py/Cu/H_2Pc trilayers at room temperature. The frequency dependences are shown in Fig. 2(a). For both cases, the FMR line width exhibits a linear variation with the frequency, the slope of which corresponds to the FMR damping constant. Remarkably, the slope for Py/Cu/PbPc is steeper than that for Py/Cu/H_2Pc, showing the enhanced FMR damping in Py/Cu/PbPc, which is considered due to the excess spin relaxation at the Cu/PbPc interface. Indeed, this indicates the possibility that the injected spin current can be converted to the charge current via IEE. We therefore performed spin pumping induced IEE measurement, in which the voltage along the strip was measured with sweeping the in-plane magnetic field applied perpendicular to the strip with passing 9 GHz rf current in the waveguide. The extracted symmetric components of the magnetic field H dependences of the observed voltage signals V for these two samples are shown in Fig. 2(b). A peak at the resonance frequency with relatively large amplitude of ~ 0.6 μV is observed in Py/Cu/PbPc. This spin pumping signal is attributable to the IEE at the Cu/PbPc interface because of small spin-orbit coupling in the Cu layer. On the other hand, there is no clear signal of the symmetric component in Py/Cu/H_2Pc. Considering the fact that the surface electronic state of metals is barely altered by coating with π-conjugated carbon-based molecules like benzene [7] and graphene [8], H_2Pc capping may not change the small Rashba splitting in the bare Cu surface state, and thus shows no spin pumping signal in Py/Cu/H_2Pc. In the present study, we demonstrated the first observation of IEE at a metal/molecule interface. These results envisage that the surface decollation by various molecules and their properties are potentially exploitable for both EE and IEE. For example, high permittivity of molecules may be useful to modify the interface charge distribution by applying gate voltage, which would result in the tunable conversion efficiency of IEE. We believe that our results expand the possibility of molecular spintronics. HD-02. TiO_2 as diffusion barrier at Co/Alq_3 spinterface studied by X-ray standing wave technique.

V. Phatak Londhe[1], D. Gupta[2] and N. Ponpandian[1]
1. Bharathiar University, Coimbatore, India; 2. Amity Center for Spintronic Materials, Amity University, Noida, India

Organic spintronics, a fusion of organic electronics and spintronics, represents a new research field where organic semiconductors (OSCs) are used to meditate or control the spin polarized signal. These OSCs possess extremely long spin relaxation time due to their low spin-orbit coupling.[1,2] OSCs displays immense potential in organic electronic devices such as organic light emitting diodes (OLEDs),[3,4] organic thin film transistors (OTFTs),[5,6] and organic photovoltaic devices (OPVs),[7,8] owing to their long spin coherence time, electronic as well as structural flexibility and low production costs. The most fundamental form of organic spintronic device is organic spin valve (OSV), which consists of an organic semiconductor spacer sandwiched between two ferromagnetic (FM) electrodes. In OSV, the charge carriers are injected into the OSC across the ferromagnetic/organic interface (FM/OSC), generally termed as spinterface, *via* thermal and field assisted charge tunneling.[9] Co/Alq_3 [{tris-(8- hydroxyquinoline) Aluminium}] spinteraface has been utilized more than any other FM/OSC combination for magneto-electronic applications.[10-14] The key issue in vertical organic spin valve with Co/Alq_3 spinterface is interfacial diffusion *i.e.* penetration of Co atoms from the top Co electrode to the soft organic layer of Alq_3 during the thin film deposition. One of the methods to elude this interfacial diffusion is to use a tunneling barrier as a spin filter. Nano-scale diffusion at the spinterfaces in organic spin valve thin films plays a vital role in controlling the performance of magneto-electronic devices. In the present work, role of a thin barrier layer of TiO_2 on interfacial diffusion at Co/Alq_3 spinterface was studied non-destructively using x-ray standing wave technique. Two waveguide structures: Si (100) (substrate) / Co (9.1 nm) / Alq_3 (40.1 nm) / Co (8.4 nm) and Si (100) (substrate) / Co (11.3 nm) / TiO_2 (1.7 nm) / Alq_3 (37 nm) / Co (8.5 nm), designated as OSV_SW1 and OSV_SW2 respectively, were deposited in a high-vacuum electron beam (EB) evaporation chamber containing interconnected homemade thermal evaporation (TE) set up for the growth of organic material. Top and bottom Co layers form the walls of the planer waveguide while Alq_3 layer forms the guiding layer. X-ray reflectivity (XRR) was used to find the roughness at Co/Alq_3 spinterface. Figure 1 (A) shows X-ray reflectivity of OSV_SW1 film measured using Cu K_α radiation. The reflectivity pattern exhibits sharp dips at q = 0.27, 0.34, 0.45, 0.55, 0.65, 0.75 nm^{-1}. These dips are due to increased absorption inside the cavity, as a result of excitation of wave guide modes. Figure 1 (B) shows Co X-ray fluorescence pattern of OSV_SW1 film. Co fluorescence pattern exhibits six distinct peaks corresponding to the TE_0, TE_1, TE_2, TE_3, TE_4 and TE_5 modes of the waveguide structure. This provides a clear evidence of resonance enhancement in OSV_SW1 thin film, whenever the waveguide modes were excited. Figure 2 (A) and (B) represents simultaneously measured XRR and Co XRF profiles of OSV_SW2 film respectively. In this film also the excitation of TE_0, TE_1, TE_2, TE_3, TE_4, and TE_5 modes were observed. XRR results show that the estimated *rms* roughness of Co/Alq_3 spinterface is significantly lower in OSV_SW2 film (0.62±0.03 nm) than OSV_SW1 film (1.28±0.02 nm). Experimentally measured separation between successive guiding modes formed in Alq_3 layer has been used to determine Co concentration into Alq_3. Calculated volume fraction of Co into Alq_3 comes out to be 0.033 and 0.004 for OSV_SW1 and OSV_SW2 respectively. It is noted that the incorporation of TiO_2 capping layer significantly lowers the roughness of Co/Alq_3 spinterface. This clearly indicates that the thin barrier layer of TiO_2 plays an effective role in smoothening Co/Alq_3 spinterface during the deposition. Thus, XRR and Co XRF results of OSV_SW2 film provide a clear evidence of reduction of roughness as well as interdiffusion at Co/Alq_3 spinterface. This suggests a better performance of organic spin valve at room temperature with diffusion barrier of TiO_2. Acknowledgement Author would like to thank Mr. Anil Gome for X-ray fluorescence measurements and Mr. Arun Dev for the help in making home-made thermal evaporation set-up and also for depositing OSV thin films. HD-03. Creation and Control of Spin Current in 2D Materials Heterostructures.

S.P. Dash[1]
1. Microtechnology and Nanoscience, Chalmers University of Technology, Gothenburg, Sweden

Exploiting the spin degrees of freedom of electrons in solid state devices is considered as one of the alternative state variables for information storage and processing beyond the charge based technology. However, one of the primary challenges in this field is the efficient creation, transport and control of spin polarization at room temperature. In this regard, two-dimensional (2D) atomic crystals and their heterostructures provide an ideal platform for spintronics. Graphene is an ideal medium for long-distance spin communication in future spintronic technologies. Here we demonstrate a high spintronic performance in CVD graphene on SiO2/Si substrate at room temperature. We observed a long distance spin transport over 16 μm and spin lifetimes up to 1.2 ns in large area CVD graphene at room temperature [1]. Hexagonal boron nitride (h-BN) is an insulating tunnel barrier that has potential for efficient spin polarized tunneling from ferromagnets. Here, we demonstrate the spin filtering effect in cobalt|few layer h-BN|graphene junctions leading to a large negative spin polarization up to 65 % in graphene at room temperature [2,3]. Two-dimensional (2D) crystals offer a unique platform due to their remarkable and contrasting spintronic properties, such as weak spin–orbit coupling (SOC) in graphene and strong SOC in molybdenum disulfide (MoS2). Here we combine graphene and MoS2 in a van der Waals heterostructure (vdWh) to demonstrate the electric gate control of the spin current and spin lifetime at room temperature (Fig. 1) [3]. Topological insulators (TIs) are a new class of quantum materials that exhibit a current-induced spin polarization due to spin-momentum locking (SML) of massless Dirac Fermions in their surface states. Recently, experiments were performed to detect and utilize the spin polarized surface currents in 3D TIs by using ferromagnetic contacts [1]. For such purpose the dominance of surface state electronic transport over the bulk contribution is crucial to maximize the charge to spin conversion efficiency. Here we will show an enhancement of the magnetoresistance (MR) signal due to SML by tuning the conductivity from a bulk to a surface dominated regime in $Bi_{1.5}Sb_{0.5}Te_{1.7}Se_{1.3}$ (BSTS) [2]. Our findings demonstrate an all-electrical spintronic device at room temperature with the creation, transport and control of the spin in 2D materials heterostructures, which can be key building blocks in future device architectures.

Organic multiferroic tunnel junctions (organic MFTJs) appearing a four-state nonvolatile resistance status make them promising for a low-coast memory. Extensive research activity has been devoted recently to engineer interfaces of organic/ferromagnetic (known as "spinterface") [1,2,3], due to the process of tunneling of electrons and spins governed and modulated by interfaces. However, in an organic MFTJ, it is still unclear about the detailed interfacial morphology and profiles of chemical elements distribution of conductive/tunneling channels in organic layer, which play the critical role in spin transport behavior. Here, we demonstrate the direct observation of interfacial structure revealed by scanning transmission electron microscopy (STEM) coupled with electron energy loss spectroscopy (EELS) and energy-dispersive X-ray spectroscopy(EDS) in the organic MFTJs based on $La_{0.6}Sr_{0.4}MnO_3$/P(VDF-TrFE)(*t*)/Co structures with different thickness, *t*, of P(VDF-TrFE). The results reveal there is no diffusion of metal from top electrodes into organic layer, by using Liq-N_2 cooling holder deposition technology to avoid the penetration from top electrode into organic barrier (during the growth of the top electrode, the temperature of sample is maintained at ~90K), which is different from the "top metal penetration" in the organic spin valves by traditional deposition methods. Besides, the effect of "ailing-channel" has been directly observed. Due to the roughness of P(VDF-TrFE), there are Co/Au grains deposited into potholes at the boundaries among feorroelectric P(VDF-TrFE) needle-like grains, which inducing "ailing-channels" to reduce ferroelectric behavior of the whole device. Accordingly, this "ailing-channel" can influence the spin transport behavior modulated by ferroelectricity, the tunneling magneto-resistance (TMR) sign can be changed in the thick devices (t≥19nm), but no change of TMR sign was observed in the thin device (t≤15nm). The direct STEM observation combining our consistent systematic electrical spin measurement may open up a new horizon for understanding of design organic MFTJs and other organic based devices.

There is a growing interest in spintronics for technological applications. An indispensable building block for this are pure spin currents, a flow of electrons' spin angular momentum without a net flow of charge. Organic semiconductors have recently been found to have a comparably large spin diffusion time and length [1], which makes them ideal candidates for spintronic devices. However, spin properties in organic semiconductors have yet to be fully understood. The magnetisation dynamics of a ferromagnetic material (FM) are well described by the Landau Lifshitz Gilbert equation. In addition to the precession of the magnetisation around the effective magnetic field, it also includes a damping term. The Gilbert damping parameter α is directly proportional to the width of the microwave absorption of the FM at ferromagnetic resonance (FMR). A FM can pump spins into an adjacent non-magnetic material (NM) at FMR. The effective damping is increased due to the loss of spin angular momentum from the FM into the NM. The spin mixing conductance – the efficiency of injecting spins from a FM into a NM at FMR – can be experimentally determined by measuring the increase in linewidth of the FM due to an additional NM. When the thickness of the NM layer is smaller than or comparable with the spin diffusion length λ_S of the material, there is a backflow of spins due to a spin accumulation at the interface opposing the injected pure spin current and diminishing the net spin injection. The dependence of the additional damping α' on the thickness L of the NM layer has been described for metallic spin sinks as $\alpha' = A*(1+B/\tanh(L/\lambda_S))$, where A and B denote material dependent constants. Here, we study spin injection from thermally evaporated permalloy ($Ni_{80}Fe_{20}$) into derivatives of dinaphtho[2,3-*b*:2′,3′-*f*]thieno[3,2-*b*]thiophene (DNTT), one of the best performing small molecule organic semiconductor so far (chemical structures shown in figure 1a)[3,4]. We have validated through X-Ray diffraction techniques that the thin films of the different DNTT derivatives adopt a 2D herringbone packing in-plane and stack with the long axis of the molecule perpendicular to the substrate. In order to determine the linewidth broadening due to the spin injection into the organic material, we measure the microwave absorption of the same permalloy films (9 nm) before and after deposition of the small molecule in an ESR cavity at 9.4 GHz while sweeping the in-plane magnetic field. We can measure significant linewidth broadening for all three derivatives of DNTT. As shown in figure 1b, the change in linewidth at a film thickness of 80 nm is largest for diPh-DNTT and very much suppressed for C8-DNTT. Theoretical predictions show that for DNTT and diPh-DNTT, the spin density is distributed over the whole molecule [5]. In the case of C8-DNTT, the spin density shifts only slightly towards the alkyl side chains but remains mostly on the core of the molecule. This implies that the separation of the core of the molecule from the interface to the FM due to alkyl side chains decreases the spin injection efficiency significantly. From the gradual onset of the linewidth broadening for DNTT and diPh-DNTT with film thickness, we can estimate the spin diffusion length using the model mentioned above to be 44 nm for DNTT and 27 nm for diPh-DNTT. The signal for C8-DNTT is already saturated at 10 nm implying that the spin diffusion length is considerably shorter than 10 nm. This indicates that the back flow due to the spin accumulation in the material balances injected spin current even in very thin layers. In summary, we have successfully demonstrated spin pumping into organic semiconductor small molecules. The spin mixing conductance as well as the spin diffusion length can be tuned through molecular design. Separation of the core of the molecule from the interface to the FM due to alkyl side-chains suppresses both the linewidth broadening as well as the spin diffusion length. This highlights the importance of the molecular structure direct at the interface to the FM. The vast possibilities of molecular designs for organic small molecules combined with the tunability of the spin mixing conductance bring forth potential for application-specific tailor-made organic materials.

The silicon (Si) based spin-MOSFET [1] is a promising spin device because of its high compatibility with the well-established solid-state circuit technology [1] and long spin lifetime in Si [2]. While there are studies of spin injection into microns of Si channels using the three terminal Hanle effect [3] or the four-terminal spin-valve effect [4] up to 150 K, the spin-valve ratio is extremely small (lower 0.1%) and spin-dependent output voltage is below 1 mV. Recently, we have successfully fabricated nano-scale Si spin-valve devices with a Fe/MgO/Ge spin injector / detector and a 20 nm-long Si channel by using electron beam evaporation and nanolithography. In those devices, we observed a clear spin-valve effect up to 0.8% and spin-dependent output voltage ~ 13 mV [5]. In this work, by growing a high-quality Fe/MgO/Ge spin injector / detector using molecular beam epitaxy (MBE), we have significantly improved the spin-valve effect up to 3% and the spin output voltage up to ~ 20 mV in a 20-nm Si spin-valve device, which are the highest values reported so far in lateral spin-valve devices. The MR ratio decreases with increasing the channel length, but remains higher than 1% even when the channel length is as long as 6 μm. Furthermore, we show that the nano-scale channel is critical for the observation of the spin-valve effect at room temperature, demonstrating the important role of ballistic transport in the nano-scale Si channel. We grew the Fe/MgO/Ge stack by MBE on n-type Si substrates. Then, we used the e-beam lithography and Ar ion-milling technique to fabricate the nanoscale Si spin-valve devices, as shown in the inset of Fig. 1(a). We employed the two-terminal (local) spin-valve effect to measure the spin transport properties. Figure 1(a) shows the magnetoresistance (MR) characteristics of the 20-nm Si channel device measured at 15 K with a bias voltage of 300 mV and a magnetic field applied in-plane along the Si channel. We observed inverse MR with a large change of resistance ΔR of 57 kΩ, corresponding to $\Delta R/R$ = 3%. By systematically investigating the bias dependence, temperature dependence, and magnetic field direction dependence of the MR, we have confirmed that the observed signal is *not* caused by the anisotropic magnetoresistance (AMR) of the Fe ferromagnetic electrodes, or the tunneling anisotropy magnetoresistance (TAMR) at the Fe/MgO interface, but it is caused by the spin transport through the nano-scale Si channel. Figure 1(b) shows the evolution of the MR ratio (=$\Delta R/R$) with increasing temperature in this device. The MR decreases as temperature increases, but changes its sign at temperatures higher than 200 K. From the temperature dependence of the device resistance, we found that the tunneling process is unlikely due to the direct tunneling through the MgO/Ge barrier, but it is likely due to the thermally activated tunneling process through defect sites inside the barrier. We show that the inverse MR can be explained by the spin-blockade effect of defect sites in the tunnel barrier layer at low temperatures. Figure 1(c) shows the spin-dependent output voltage ($|\Delta R/R|$)V of the device as a function of bias voltage, measured at 15 K. The inset shows the bias voltage dependence of the MR ratio. We achieved the spin-dependent output voltage of 20 mV at the bias voltage of 0.9 V at 15 K, which is among the highest values reported so far in lateral spin-valve devices. In Figure 2, we compared the MR curves of devices with different channel lengths from 20 nm to 6 μm. Figures 2(a)-2(d) show the MR curves measured at 15 K and a bias voltage of 300 mV, while Figures 2(e)-2(h) show those measured at room temperature with a bias voltage of 80 mV. At 15 K, the MR ratio systematically decreases with increasing the channel length, but remains larger than 1%. At room temperature, only the device with the 20 nm Si channel shows a clear MR effect, demonstrating the important role of ballistic transport in this nano-scale device. In summary, we have investigated the spin transport in the nano-scale Si spin-valve devices fabricated by the MBE method. We observed a large spin-valve effect up to 3%. The highest spin-dependent output voltage is 20 mV at the bias voltage of 0.9 V at 15 K, which is the highest value reported so far in lateral spin-valve devices. We observed that the sign of the spin-valve effect is reversed at low temperatures, suggesting the possibility of the spin-blockade effect of defect states in the MgO/Ge tunneling barrier. Our result is an important step towards the realization of nano-scale spin-MOSFETs. [6]

HD-07. Large local magnetoresistance at room temperature in Si<100> devices.

M. Ishikawa[1,2], M. Tsukahara[1], M. Yamada[1], Y. Saito[2] and K. Hamaya[1,3]
1. Graduate School of Engineering Science, Osaka University, Toyonaka, Japan; 2. Corporate Research & Development Center, Toshiba Corporation, Kawasaki, Japan; 3. Center for Spintronics Research Network, Osaka University, Toyonaka, Japan

A spin metal-oxide-semiconductor field-effect transistor (spin-MOSFET) is one of the emerging devices for the low power consumption in silicon-based electronics from the viewpoint of logic-in-memory architectures [1]. To realize these kinds of spintronic applications, one of the main issues for realizing the spin-MOSFETs is an observation of the high magnetoresistance (MR) ratio obtained by two-terminal local measurements at room temperature [2]. Up to now, although there are lots of studies of the local MR effect through the silicon (Si) channels, the values of the MR ratio are less than 0.8 % at 100 K [3] and 0.03 % at room temperature [4]. In this paper, we show relatively large MR ratios at room temperature in Si<100> lateral spin valves (LSVs) with a small size (0.305 μm^2) cross section in the spin-transport layer. For comparison of the crystal orientation of the Si spin-transport layers, we prepared two kinds of LSVs along Si<100> and Si<110> with CoFe/MgO electrodes on phosphorus-doped ($n \sim 1.3\times10^{19}$ cm^{-3}) (100) textured Si on insulator (SOI) (~ 61 nm) layer, as shown in Fig. 1(a). An MgO (1.1 nm) tunnel barrier was deposited on the SOI spin-transport layer at 200 °C by electron beam evaporation. Then, a CoFe (10 nm) and a Ru capping layer were sputtered on top of it under a base pressure less than 5×10^{-7} Pa. The MgO and CoFe layers were epitaxially grown on the (100) textured SOI, where the (100)-textured MgO layer was grown on Si(100). Device fabrication methods are described in detail elsewhere.[5] We have checked that these resistivity and Hall mobility of the Si spin-transport layer were almost the same by evaluating from longitudinal resistivity and Hall-effect measurements for Si<100> and Si<110> Hall-bar devices. Figures 1(b) and 1(c) show four-terminal nonlocal Hanle-effect curves for Si<100> and Si<110> LSVs, respectively, at a bias current of 0.5 mA at 20 K. These data mean that we can obtain reliable spin transport in Si layers in our LSVs, as shown in our previous work [5]. It should be noted that the magnitude of the spin signal, $|\Delta R_{NL}|$, for Si<100> is approximately twice as large as that for Si<110>. Although the detailed will be published elsewhere [6], it is inferred that this phenomenon is tentatively interpreted by the difference in the spin injection/detection efficiency associated with the valley structures of the conduction band in Si. We hereafter focus on the MR effect that is one of the most important points for realizing the spin-MOSFETs. Figures 2(a) and 2(b) display the two-terminal local-MR signals for Si<100> and Si<110> LSVs, respectively, at 20 K. Here the bias current is 0.5 mA. It should be noted that the magnitude of the local-MR signals, $|\Delta R_L|$, for Si<100> is also larger than that for Si<110>. Irrespective of measurement schemes, we can find the large difference in the spin injection/detection efficiency between Si<100> and Si<110> LSVs. We can also observe this effect even at room temperature (303 K), as shown in Figs. 2(c) and 2(d). Thanks to the crystal orientation effect, a relatively large $|\Delta R_L|$ of 2 Ω, which is the largest $|\Delta R_L|$ value reported so far, can be obtained. The estimated MR ratio is approximately 0.06 %, twice as large as that observed in the previous work [4]. For a different bias current condition, the MR ratio reached up to approximately 0.2 % at room temperature. Although the obtained value of the MR ratio is still insufficient to realize the spin-MOSFETs, the use of Si<100> spin-transport channel is more effective to develop the related Si-based devices. HD-08. Nonlinear spin detection in a biased ferromagnetic tunnel contact.

R. Jansen[1], A. Spiesser[1], H. Saito[1], Y. Fujita[2,1], S. Yamada[2], K. Hamaya[2] and S. Yuasa[1]
1. AIST, Tsukuba, Japan; 2. Osaka University, Toyonaka, Japan

Whereas electronic devices are based on charge, current and voltage, the key elements of spintronics technology are spin, spin current and spin accumulation. Nevertheless, the vast majority of spin-based devices and systems employ the conversion of spin information into electrical signals. This enables the detection of the spin information and provides an electrical output that can be linked to conventional electronic circuitry. In order to advance spintronics technology, it is thus indispensable to develop efficient methods for the electrical detection of spin and to develop a thorough understanding of the process of spin conversion. The most convenient method for the detection of spin accumulation in a non-magnetic material employs ferromagnetic tunnel contacts. At the interface between a non-magnetic material and a ferromagnetic tunnel contact, a spin accumulation is converted into a charge voltage across the contact, owing to spin-polarized tunneling. Spin detection with ferromagnetic tunnel contacts has proven to be efficient and robust, and avoids problems due to spin absorption by the ferromagnet and the conductivity mismatch. Devices using ferromagnetic tunnel contacts can be classified according to whether or not the detector contact is biased. In a very few type of devices, there is no net charge current across the detector contact, as in the non-local spin-transport device. The spin signals observed in non-local devices are well described by the theory for spin detection in the linear response regime. Consequently, non-local devices have been instrumental to prove and understand spin injection and transport in various types of materials. In most of the spintronic devices, including the technologically relevant ones, the ferromagnetic tunnel contact in which the spin conversion occurs is located in the current path and is thus biased. Examples are two-terminal magnetoresistance devices with two magnetic electrodes contacting the non-magnetic channel, various three-terminal geometries, but also the non-local geometry with a biased detector. Importantly, for devices in which the spin detector contact is biased, the observed spin signals are, without exception, surprising and puzzling, and no suitable explanation for the peculiar behaviour is available. Moreover, when existing theories are applied, the conclusions are inconsistent with those obtained from analysis of non-local spin transport devices, even if the same structure is used for the different measurement configurations. Here, it is shown that spin detection in a biased contact is inherently nonlinear. We employ Si- based spin transport devices with several Fe/MgO tunnel contacts that can be used in different measurement configurations. Data obtained in the non-local configuration (see Ref. 1) in spin-valve or Hanle mode establish the presence of a giant spin accumulation in the n-type Si channel, with the spin splitting reaching 13 meV at 10 K and 3.5 meV at room temperature. The non-local data is well described by the conventional linear response theory, from which we obtain the values of all the relevant parameters (spin-diffusion length, spin lifetime, tunnel spin polarization of the Fe/MgO contacts). Using those devices, we first present compelling data that shows conclusively that spin drift, previously proposed to explain some of the abovementioned peculiar results, is not responsible. Next, it is shown (i) that all the puzzling and inexplicable spin signals in the various devices with a biased detector have, in fact, a single common origin, (ii) that the common origin is the nonlinearity of the spin conversion at a biased ferromagnetic tunnel contact, (iii) that the nonlinearity is surprisingly strong and already appears at small to moderate bias for which charge transport is still well described by linear response, (iv) that the origin of the nonlinearity of spin detection can be understood using a simple tunnel transport model, and (v) that taking the nonlinearity of spin detection into account explains all the puzzling results, provides a unified description of electrical spin signals in devices with and without biased detector, and makes the spin signals and spin transport parameters obtained from devices with a biased detector consistent with those obtained from non-local spin-transport measurements.

Nanoelectronics Research Institute, National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan

The maturity of silicon-based technology and its dominance of the device industry provide compelling motivation to use Si for developing novel devices that integrate spin functionality. Over the past few years, the generation of a pure spin current in Si channels has been demonstrated up to room temperature using the nonlocal (NL) four-terminal scheme [1-3]. To date, the largest magnetic response in Si was achieved by using crystalline Fe/MgO magnetic tunnel contacts; the spin splitting reaches 13 meV and the spin-diffusion length attains a value of 2.2 μm at 10 K [3]. In the latter study, spin transport was investigated in the low bias regime, where it can be described as purely diffusive using the standard theory for spin injection and spin diffusion. In the high bias regime, however, the presence of an electric field in the Si channel causes spin drift that can strongly affect spin transport and spin accumulation voltages in Si [4, 5]. Here, we study the spin transport in heavily-doped n-type Si NL devices in the presence of electric fields in the high bias regime. We use a simple and reliable method to evidence the presence of spin drift and quantify it in Si NL devices. We compare our results with the spin drift-diffusion theory [4] and show that spin drift can either enhance or reduce the spin transport length depending on the direction and the strength of the electric field, but the effect is weaker than that predicted by the theory. The Si-based NL devices were fabricated on a SOI substrate having a 70 nm-thick n-type Si(001) channel. The Si channel was doped homogeneously with phosphorous at a concentration of 2.4×10^{19} cm^{-3}. The Fe/MgO magnetic tunnel contacts were deposited by electron-beam evaporation in an ultra-high vacuum molecular beam epitaxy system. The *in situ* reflection high-energy electron diffraction patterns indicated the formation of crystalline MgO(001) and Fe(001). The sample was then processed into Si NL-4T devices using standard micro-fabrication techniques (e-beam lithography, Ar-milling, SiO_2 sputtering). The NL structures consist of two central ferromagnetic electrodes (FM1 and FM2) separated by a spacing *d* and two outer non-magnetic Au/Ti reference contacts located at a distance much larger than the spin-diffusion length. The NL spin-valve and Hanle-type spin precession measurements were obtained by applying an external magnetic field along the length of the FM contacts and perpendicular to the film plane, respectively. To study the spin-drift effect in the NL-4T geometry, we use two different measurement configurations called NL1 and NL2, respectively, in which the direction of the electric field E is reversed. Importantly, in these two configurations the detector remains unbiased, which allows us to properly apply the standard theory to analyze the spin-transport data. In addition, to vary the strength of the electric field we designed devices with different contact widths of FM1 and FM2 on the same sample. This allows us to vary the current density in the Si channel J_{ch} and thus the electric field E in the Si channel, while maintaining a constant tunnel current density J_t through the FM injector. First, we characterized our devices by measuring the NL spin-valve and Hanle signals in the low bias regime. Following the analysis reported in Ref. 3, we extract a spin lifetime of 13 ns, a spin-diffusion length λ_{Si} of 1.7 μm, and a tunnel spin polarization of Fe/MgO of 40 % at 60 K, in agreement with our previous results [3]. We then performed NL spin-valve measurements using both NL1 and NL2 schemes and different injector sizes, while varying the biases. From the ratio of the NL spin-valve signals ΔV_{NL2} and ΔV_{NL1} observed in the two configurations, we extract the spin-transport length λ_E by fitting the data with a model that includes spin drift according to ref [4], and a scaling factor to adjust the magnitude of the spin drift. The results of this fitting and the spin-transport length as a function of the electric field are shown in Fig 1a and b, respectively. As predicted by the theory, a significant enhancement occurs for high electric-field spin injection, whereas a suppression of the spin signals is observed for the high spin extraction condition. In particular, we finnd that the spin-transport length is about 2 times larger than the spin-diffusion length in Si for an electric field of 150 V/cm. We find that although the theory of ref. [4] predicts the correct trends, it overestimates the effect of the electric field by about a factor of two.

HD-10. Intrinsic generation of propagating spin waves by a magnonic "black hole" in a current-driven nano-constricted wire.

M. Dvornik[1], *R. Khymyn*[1], J. Åkerman[1,3], V.S. Tiberkevich[2] and A.N. Slavin[2]

The experimental observation of a microwave magnon generation in a current-driven obliquely magnetized 15-nm thick permalloy (Py) wire constricted in the middle to the 20-nm width was reported recently [1]. The electrical measurements of the linear response of the system paired with the micromagnetic simulations suggested the auto-oscillations emerge from the *localized* eigenmode of the constriction, consistent with our results obtained for the spin Hall nano-oscillators of the similar geometry [2, 3]. Here we demonstrate by numerical simulations, that one can also generate *propagating* magnons in the very same system via the Hawking radiation [4] taking place near the "event horizon" of a magnonic "black hole" [5]. Unruh in [6] suggested that it is possible to experimentally create analogs of the black-hole-horizon in systems of different physical nature, and a detailed proposal on the creation of the "event horizon" in a magnonic system has been given in [5]. The essential ingredients of the physical systems for analog horizons are the existence of dispersive waves and a background flow velocity which can exceed the velocity of these waves [5-7]. In a magnonic system, this can be done if a spin current of a sufficient density is propagating in a magnetic material resulting in the shear of the magnons propagation. The electrical current flowing in the magnetic metal is spin-polarized because of the different conductivities of spin-up and spin-down electrons. Such a spin current exerts a torque on the inhomogeneous magnetization, proportional to its spatial gradient [8]. As a result, the spin dynamics under the action of the electric current takes place in the reference frame, moving with the velocity u, proportional to both the electric current density and spin polarization. Such a flow of spin current introduces a Doppler shift to the frequency of magnons $\omega_u(k)=\omega_0(k)-uk$, where k is a magnon wavevector [9]. If the spin current flow has a small cross-section, the Doppler shift, which is proportional to the spin current density, can increase substantially. Consequently, the negative magnon frequencies could be reached in a certain range of the magnon wavevectors if the shear velocity overcome a threshold value. The magnons in this wavevector range would have a *negative energy* with respect to the remote observer. This situation can be realized in a thin nano-constricted magnetic film, where the area of constriction creates a region with the negative magnon frequency with the minimum value of $\omega_{\min}(k_{\min})<0$, while outside the constriction region the magnon frequency remains positive for all the wavevectors, see Fig. 1. For the sample under discussion the calculated current density j~10^{13} A/m^2 is rather high which leads to the high values of the shear velocity u. Similar to the case of gravitational black hole, where the fall of the particle into the hole results in the energy gain of the antiparticle, for "magnonic black hole" the energy is pumped outside the constriction, which results in the auto-oscillations of the magnetization. Since the area with the negative frequency is an analog of the active medium in a laser cavity, the highest gain would be experienced by the magnonic eigenmodes with a characteristic size (wavelength) close to the spatial size of the magnonic "black hole". At the same time, the maximum frequency of auto-oscillations is limited by $|\omega_{\min}|$ because of the energy conservation law. To confirm the possibility of the above mechanism of magnon generation we performed numerical simulations of the magnetization dynamics in a Py nano-constriction, similar to the one studied in [1], with the magnetic field of B=0.2 T applied 75° out-of-plane and 10° in-plane. We integrated the stochastic Landau-Lifshitz equation with the ambient temperature of T=400 K using the MuMax3 solver [10], taking into account the shear by the electrical current and the corresponding Oersted field, both estimated using Comsol software. Fig. 2 shows the simulated excitation of the auto-oscillations in the nano-constriction using the applied current of I=12 mA (maximum current density of 2.8×10^{13} A/m^2), spin polarization of P=0.5 and Zhang-Li toque non-adiabaticity of ξ=0.33. As one can see, the auto-oscillations emerge as propagating spin waves at one side of the constriction. The simulations also show that the direction of the spin-wave propagation could be switched by reversing the polarity of the electrical current. Therefore, the performed simulations confirm the possibility of the Hawking radiation from a "magnonic black hole." It is worth mentioning, that in the given geometry the threshold current for the generation of propagating spin waves is substantially higher than for the generation of localized magnonic modes. Nevertheless, the threshold currents in these two cases could be made of the same order by engineering the magnonic dispersion, in particular, according to our calculations by employing the dipole-exchange backward volume waves to increase the frequency dip shown in Fig. 1.

1. Introduction The injection of spin-polarized electrons from ferromagnets into semiconductors has attracted much interest for creating spin transistors. Spin injection into bulk semiconductors such as GaAs [1], Si [2], and Ge [3] has been realized at room temperature. On the other hand, a two-dimensional electron gas (2DEG) structure of AlGaAs/GaAs has attracted much interest for its high electron mobility, and it is used for high electron mobility transistors (HEMTs). Apart from that, the 2DEG structure is useful as a channel of a spin transistor. Up to date, however, electrical spin injection into an AlGaAs/GaAs 2DEG channel has been achieved only by using GaMnAs as a spin source [4], and the demonstration of spin injection was limited below 50 K because of the low Curie temperature (T_C < ~200 K) of GaMnAs. In this study, we demonstrated spin injection into an AlGaAs/GaAs 2DEG channel up to 138 K by using CoFe (T_C > 1000 K) as a spin source. 2. Experimental method Figure 1(a) shows a layer structure of a spin injection device. Layers consisting of (from the substrate side) ud-GaAs (400 nm)/ud-$Al_{0.3}Ga_{0.7}As$ (100 nm)/n^--$Al_{0.3}Ga_{0.7}As$ (Si = 3 × 10^{18} cm^{-3} and 100 nm)/ud-$Al_{0.3}Ga_{0.7}As$ (15 nm)/ud-GaAs (50 nm)/n^--GaAs (Si = 7 × 10^{16} cm^{-3} and 100 nm)/n^+-GaAs (Si = 7.5 × 10^{18} cm^{-3} and 30 nm) were grown by molecular beam epitaxy (MBE) on a GaAs (001) substrate. Then a CoFe layer (5 nm) was grown by magnetron sputtering at room temperature. Using electron-beam lithography and Ar ion milling techniques, a four-terminal nonlocal device was fabricated (Figure 1(b)). The size of the injector and detector were 0.5 × 5 μm and 1.0 × 5 μm, respectively, and the spacing (*d*) between them was 0.5 μm. 3. Results and Discussion From the Hall effect measurement, electron mobilities ranging from 24200 to 42700 cm^2/Vs and sheet carrier concentrations ranging from 6.9 × 10^{11} to 8.5 × 10^{11} cm^{-2} were obtained at 77 K for the AlGaAs/GaAs 2DEG structure. Such relatively high electron mobilities indicate that the 2DEG channel was well formed at the interface of the AlGaAs/GaAs heterostructure. Figure 2(a) shows a clear nonlocal spin-valve signal observed at 77 K, a higher temperature than that reported in Ref. 4, which used GaMnAs as a spin source. Furthermore, the temperature dependence of the spin-valve signal was investigated. Figure 2(b) shows $|\Delta V_{NL}/I_{bias}|$ as a function of temperature, where ΔV_{NL} is the amplitude of a spin-valve signal and I_{bias} is the bias current. The spin-valve signals were observed from 4.2 K to 138 K. Interestingly, the spin-valve signal doesn't show monotonic decrease as increasing temperature and it reaches to a peak at ~80 K. This contrasts with the result observed in bulk GaAs [1], in which monotonic decrease of spin-valve signals with increasing temperature was observed. These results contribute to better understanding of spin transport in a 2DEG channel, which is indispensable for the realization of the future spin transistors which can operate at a relatively high temperature.

Skyrmions are chiral magnetic textures [1] envisioned as potential candidates for magnetic memories and logic devices [2,3]. Initially discovered in bulk crystals like MnSi and FeGe at low temperature [4,5], they have recently been observed at room temperature in thin trilayer systems consisting of a heavy metal (HM), a ferromagnet (FM) and an insulator (I) like Ta/FeCoB/TaOx [6], Pt/Co/Ta, Pt/CoFeB/MgO [7] and Pt/Co/MgO [8]. In these trilayers, skyrmions are stabilized not only by interfacial Dzyaloshinskii- Moriya interaction (DMI) which arises due to the breaking of inversion symmetry and spin orbit coupling, but also by dipolar, exchange and interface anisotropy energies. For efficient implementation of skyrmions in devices, it is imperative to reliably control its properties. By proper choice of the materials, layer thicknesses and interface quality, we can tune their static magnetic properties. Furthermore, a dynamic control is possible by using electric field effects. For example, electric field has recently been employed for creation and annihilation of skyrmions at room temperature, by tuning the interface anisotropy and saturation magnetization [9,10,11,12,13]. In our knowledge however, a significant influence of electric field on interfacial DMI [14] has not been demonstrated yet. Here we report an increase of interfacial DMI by 140 % through voltage gating in sputter deposited Ta(3)/FeCoB(0.9)/TaOx(1) (thicknesses in nm) trilayers, where skyrmions are observed under small out of plane magnetic fields (30 μT). We have patterned transparent electrodes to allow optical observations under voltage application. Our Brillouin Light Spectroscopy (BLS) measurements have shown an increase by 140% of the frequency shift (Δf) between Stokes (f_S) and anti-Stokes (f_{AS}) resonances when the sample was subjected to a voltage of -10V (electric field of -170 MV/m), as represented in Fig 1(a) and (b). In contrast to the large effect observed at -10V, only a slight increase of Δf is observed at +10V (Fig 1(b)). This frequency shift allows a direct determination of the interfacial DMI energy using $\Delta f=2\gamma_s k_{SW} D/(\pi M_s)$ (where γ is the absolute value of the gyromagnetic ratio, k_{SW} is the spin wave vector, D is the interfacial DMI energy and M_s is the saturation magnetization) [15]. Indeed by measuring the polar magneto-optical Kerr (p-MOKE) signal amplitude at the exact same location, we demonstrate that this increase of Δf is not due to a modification of magnetization under voltage, but only due to a strong increase of the interfacial DMI. This effect could thus be instrumental in controlling the skyrmion chirality. The change in DMI was found to be consistent with the change in the demagnetized stripe domain width observed by p-MOKE. The stripe width and its vatiations under voltage were used to determine the change in the domain wall energy by using the relation $\sigma_W= \mu_0 M_s^2 t/\pi \ln(L/\alpha t)$ where t is the ferromagnetic film thickness and α is a coefficient equal to 0.95 [10]. In the presence of DMI, the domain wall energy is given by $\sigma_W=4\sqrt{(AK)}-\pi D$ [9,16] where K is the effective anisotropy and A is the exchange stiffness. By using the parameters extracted from p-MOKE measurement (H_k plotted in Fig 2(d), M_s in Fig 1(c) inset, in Fig 2(a)) and BLS (D in fig1 (c)) we could thus extract the value of A, close to 1.5pJ/m. The exchange stiffness turns out to change by less than 2% under applied voltage (Fig 2(e)). We can therefore conclude that in our sample, electric field produces a huge change of interfacial DMI and has little effect on the other magnetic properties (M_s, H_k, A). We can thus tune the skyrmionic bubbles by modulating mainly the interfacial DMI through applied voltage. We will also present the influence of time scales on these effects for both long (4-15 hours) and short (few minutes) time scale durations. As the BLS measurements are performed on long time scale durations, it is thus important to compare the results obtained from p-MOKE for both long and short time scales to ensure the extent and reversibility of these effects and the potential for applications.

Magnetic skyrmions are nanoscale whirling configurations of the magnetization. Their small size and the fact that they can be manipulated by small in-plane current densities have opened a new paradigm to manipulate the magnetization at the nanoscale. This has led to proposals for novel memory and logic devices in which the magnetic skyrmions are the information carriers [1]. Initially discovered in B20 chiral magnets, they have been observed more recently at room temperature in ultrathin sputtered Heavy Metal (HM)/Ferromagnetic (FM) multilayers [2,3,4,5] as well as their current-induced manipulation [2,5,6], which have lifted an important bottleneck towards the practical realization of such devices. In particular, we recently reported magnetic skyrmions with a typical size of 100 nm in an ultrathin Pt/Co/MgO$_x$ single layer at room temperature and at zero external magnetic field. Using X-ray Magnetic Circular Dichroism combined with Photo-Emission Electron Microscopy (XMCD-PEEM), we were able to demonstrate their internal homochiral left-handed Néel structure [4]. This stack is particularly interesting for the study of magnetic skyrmions and their applications as it is characterized by a very large interfacial Dzyaloshinskii-Moriya interaction (D=2 mJ/m^2) [4] and an efficient current-induced manipulation is expected due to the large spin-orbit torques induced by the spin Hall effect in the Pt layer [7]. The use of a single ferromagnetic layer makes this stack a model system for the study of the static and dynamic properties of magnetic skyrmions, avoiding the additional complexity induced by the interlayer interactions in multilayers systems [8]. Furthermore, the small size of the skyrmions combined with the reduced Joule heating in this ultrathin multilayer make this system appealing for applications. Here we report on the manipulation of isolated room-temperature magnetic skyrmions in sputtered single-layered Pt/Co/MgO$_x$ nanotracks and nanodots using external magnetic field and in-plane current pulses. We show that the skyrmions size can be easily tuned by playing on the lateral dimensions of the nanostructures and by using external magnetic field amplitudes of a few mT, which allow to reach sub-100 nm diameters [9]. We also observed in this system a fast current-induced motion of small skyrmions (about 150 nm in diameter) in µm-wide tracks. In Fig.1.(a-c), one can see a series of XMCD-PEEM images showing a magnetic skyrmion after two consecutive 10 ns current pulses with opposite polarities and with an amplitude of $5x10^{11}$ A/m^2. The skyrmion is dragged back and forth with a motion characteristic of a left-handed Néel skyrmion : it moves against the electron flow with a component of the velocity transverse to it, an effect referred to as the Skyrmion Hall Effect [6,10]. At this current density, the mean velocity reaches 70 m/s (Fig 1.(d)). As the power dissipation due to Joule heating scales with the film thickness, the demonstration of fast skyrmion current-induced motion in a few nm thick multilayer is promising for lower power skyrmion-based memory and logic devices. However, the aforementioned experiments have also underlined the sensitivity of the skyrmions dynamics to the defects in the material as well as the edges which can impede reliable motion. In particular, our XMCD-PEEM observations highlight the important role of the pinning on the skyrmions size and stability under an out-of-plane magnetic field. Fig.2 shows a magnetic skyrmion in a 630 nm-diameter dot at zero external field (a) and for B_z = 4 mT (b). We observe that the skyrmion is pinned near the edge of the nanostructure and that its diameter decreases in a step-like fashion when the magnetic field increases, a behavior that micromagnetic simulations in a disorder-free scenario fail to reproduce (see Fig 2.(c)). Indeed, it is well known that the polycrystalline grain structure of magnetic ultrathin films is a source of local pinning for magnetic domain walls. More recently, the influence of the inherent disorder of these films on the skyrmions stability have begun to be addressed [11,12]. Here, we model using micromagnetic simulations the disorder by a granular surface with local anisotropy fluctuations (Fig.2.(d)), which allow to reproduce partly the effect of the pinning on the field dependence of the skyrmion size (Fig 2.(c)). These results also reflect that the Pt/Co/MgO$_x$ system, due to its simple structure, can be efficiently modelled, which paves the way for further experimental and micromagnetic investigations.

HE-03. Dynamics of Skyrmions in Magnetic Multilayers at Room Temperature.

S. Woo[1]
1. Center for Spintronics, Korea Institute of Science and Technology, Seoul, The Republic of Korea

In spintronics, magnetic skyrmions are the most promising candidate for the next-generation memory-type application due to their nanometer-size, topological stability and efficient current-driven motion. [1] Recent efforts have realized the room-temperature stabilization of magnetic skyrmions and their current pulse-induced displacement on nanotracks in magnetic heterostructures, [2, 3] where the strong interfacial Dzyaloshinskii-Moriya (DM) interaction leads to the stabilization of such skyrmion structure. [4, 5, 6] However, there still exist many unsolved practical limitations toward the realization of fully functional skyrmionic devices. In this presentation, we show our recent achievements with room-tempearture skyrmions observed by static and dynamic soft X-ray transmission microscopy. We first demonstrate a new type of skyrmion, called *ferrimagnetic skyrmion*. [7] Recent theoretical studies have predicted enhanced current-driven behaviour for antiferromagnetically exchange-coupled skyrmions with opposite topological charges excited in two sublattices. [8] In this work, we present the stabilization of such skyrmions and their current-driven dynamics in ferrimagnetic GdFeCo films. By utilizing element-specific soft X-ray imaging, we find that the skyrmions in the Gd and FeCo sublayers are antiferromagnetically exchange-coupled as shown in Fig 1. [7] Having established that ferrimagnetic skyrmions can form at a finite external field in this material, we next study their current-induced dynamics in the magnetic track. With their current-driven motion, which propagates along the current flow direction (against the electron flow) for both $+M_z$-core and $-M_z$-core skyrmions, we first confirm that they are homochiral left-handed Néel-type hedgehog skyrmions stabilized by interfacial DMI in Pt/ferromagnet thin films. This implies that the interfacial DMI at the Pt/GdFeCo interface plays a crucial role in stabilizing skyrmions and also driving them on the track in our ferrimagnetic structure. More importantly, their current-driven dynamics reveal that ferrimagnetic skyrmions can move at a velocity of ~60 m s^{-1}, which is comparable to the current state-of-the-art skyrmions observed in a few ferromagnetic heterostructures. [3, 9] Most strikingly, we observe a very small skyrmion Hall angle, $|\theta_{SkHE}| < 10°$, which is significantly lower than the skyrmion Hall angles, $|\theta_{SkHE}| > 30°$, observed for ferromagnetic skyrmions in Ta/CoFeB/MgO and Pt/CoFeB/MgO structures. [9, 10] Antiferromagnetic coupling between two sublayers and the corresponding largely-reduced net magnetization within GdFeCo films has led to the effective inhibition of the skyrmion Hall effect. With micromagnetic simulations, we further present that ferrimagnetic skyrmions are much more attractive than their ferromagnetic counterpart in many technological-relevant aspects, such as larger skyrmion mobility and strongly suppressed skyrmion Hall effect, mainly due to their antiferromagnetic nature. We believe that this finding experimentally highlights the possibility to build more reliable skyrmionic devices using ferrimagnetic and antiferromagnetic materials. [7] Secondly, we demonstrate the electrical creation and annihilation of a single magnetic skyrmion at room temperature, which are essential prerequisites for device application. [11] The stroboscopic pump-probe X-ray measurement serves as a key technique to reveal the deterministic and completely reproducible nature of the observation. We experimentally present that an engineered current pulses at a specific environment; unbalanced bipolar-pulse in the presence of small amount of in-plane magnetic field; can efficiently create and annihilate a single skyrmion in ferrimagnetic materials, GdFeCo, in nanosecond time scale. In particular, we reveal that the application of the weak following reversed-pulse, which eventually *forces* to annihilate a topological defect, vertical Bloch line (VBL), and turns the trivial common bubble into a non-trivial chiral skyrmion, plays a crucial role for the writing process. (See Figure 2 for schematic description of the process) Micromagnetic simulations reveal the microscopic origin behind the observed topological fluctuation with great qualitative and quantitative agreement. Our findings show that, on a technologically-relevant thin-film racetrack geometry, where the current-driven displacement of a train of individual skyrmions at speeds approaching 60 m/s has already been demonstrated, [7] the deterministic field-free writing and deleting of a single skyrmion can be easily achieved using electrical methods. We believe that this result serves as a key discovery, which has been the only essential missing piece towards the realization of skyrmion-based devices. [11]

The magnetic skyrmions are whirling magnetic configurations, found in ferromagnetic [1], ferrimagnetic [2] or antiferromagnetic materials [3], exhibiting a winding of the magnetic order with a nontrivial topology. Due to the presence of the Dzyaloshinskii-Moriya interaction (DMI), originating from a breaking of the inversion symmetry either in the bulk of the structure or at interfaces, a unique chirality in these configurations is favoured, which enables the stabilisation of periodic skyrmion crystals or even isolated skyrmions, similar to punctual defects of the magnetic configuration. So far, isolated skyrmions, as found in multilayered magnetic stacks with interface asymmetry, are seen as best candidates for potential skyrmion-based applications [4]: *i*) the symmetry of the DMI imposes so-called Néel skyrmions, which are efficiently moved by spin-orbit torques obtained from heavy metal layers incorporated in the stack; *ii*) the size dependence of the different magnetic energies associated to isolated skyrmions allow to envisage further decreasing of skyrmion diameters and the stabilization of very compact, sub-10 nm configurations which are very scalable for computation and memory applications; *iii*) the enhancement of the magnetic volume associated to the vertical dimension of multilayered skyrmions (typically a few repetitions of a 1 nm-thick magnetic layer) results in a strong stability against thermal fluctuations allowing applications at room-temperature. Several works have demonstrated the viability of skyrmions for applications such as skyrmion racetracks, in which skyrmions can be created at one location [5], moved along a bit line [6] and detected [7] or annihilated at another location. In this work, we further explore the role of interlayer interactions in multilayer configuration on the nature of the skyrmions. We will first show that due to the competition between dipolar interactions and the DMI, opposite chiralities can coexist across the thickness of the multilayer. By using micromagnetic simulations, we can quantify the strength of each interaction in each individual layer and deduce the actual profile orientation: Néel, Bloch or in-between; as well as the chirality: clockwise (CW) or counter-clockwise (CCW), as shown in Fig. 1. We then bring experimental evidence and examples of such hybrid chiral skyrmions in multilayers, by observing their surface chirality using circular dichroism in x-ray resonant magnetic scattering (CD-XRMS) in multilayers of opposite stacking order (*i.e.*, opposite DMI) [8,9]. Because of the strong absorption in the soft x-ray range, and especially when the wavelength is tuned at the *3d*-metal L edge resonance, our observation of the chirality is mostly sensitive to the top of the structure and allow to discriminate the magnetic configuration in the top layers independently from the overall structure, as shown in Fig. 2. This phenomenon has been totally overlooked in previous studies of magnetic skyrmions. Moreover, we will show that the existence of such hybrid chirality of skyrmions in multilayers has drastic consequences on their current-induced spin-orbit torque dynamics. Therefore, the spin-current injection scheme in bottom, top and intermediate layers has to be properly engineered taking into account such hybrid chirality in order to get efficient spin-torque motion of compact skyrmions at room temperature [9]. Fig. 1. Example of a cut view through the center of an isolated skyrmion configuration in a 20 repetitions multilayer of structure [X(1nm)/Co(1nm)/Z(1nm)]$_{x20}$, for a DMI strength of *D*=0.8 mJ m^{-2}. The red to blue colour in the top layer and in the arrows indicates the vertical component of the magnetisation from down (m_z=–1) to up (m_z=1). The arrows point in the direction of the magnetisation. The black to white background colour indicates the transverse component of the magnetisation from m_y=–1 to m_y=1. An evolution of the chirality can be seen through the structure, with CCW Néel skyrmion in the bottom, Bloch skyrmion in the middle and CW Néel skyrmion in the top of the multilayer.

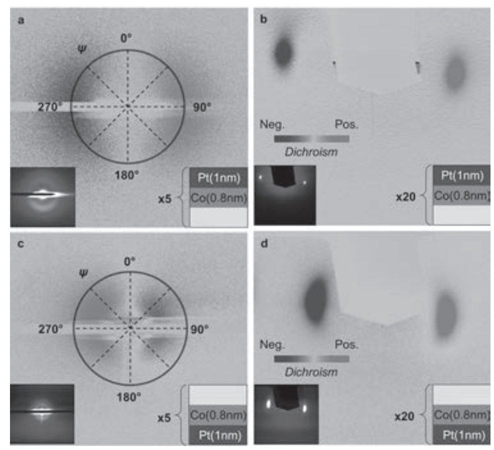

Fig. 2. Circular dichroism analysis of 4 multilayer stacks with *D*<0 (a,b) and *D*>0 (c,d); 5 (a,c) and 20 repetitions (b,d). The dichroism (difference of circularly left and right polarised photons images) is normalised and given by the colour from blue (negative) to red (positive). Left insets are the corresponding sum images (both polarisations combined). Right insets are schemes of the studied stacks. The dichroism pattern indicates the chirality of the top few layers; along the 90°-270° axis it corresponds to Néel ordering in each case, and the sequence red-blue or blue-red indicates the chirality, CW or CCW, respectively. While for 5 repetitions the chirality agrees with the sign of *D*, for 20 repetitions, which have stronger dipolar interactions, the chirality is fixed by the formation of flux-closure arrangements, as was shown in Fig. 1. Therefore a unique CCW chirality in the top layers is observed in b and d (CW chirality in the bottom, not seen), whatever the sign of *D*.

The absence of inversion symmetry in magnetic films can allow chiral interactions such as anisotropic exchange of the Dzyaloshinskii-Moriya form to exist. In ultrathin ferromagnets on heavy-metal buffer layers, such as Pt, W, and Ir, the Dzyaloshinskii-Moriya interaction (DMI) is induced by the strong spin-orbit coupling at the interface [1]. The DMI can give rise to different nontrivial magnetic states such as skyrmions and antiskyrmions [2]. These are characterized by opposite topological charges, which govern the sense of gyration in their dynamics. In most studies to date, however, the robustness of the symmetry between opposite topological charges, as expressed in the Thiele equation [3], has not been examined in detail. In particular, the roles of core deformation, the internal degrees of freedom, and the underlying symmetry of the magnetic interactions that stabilize the skyrmions remain an open question. We show here that the symmetries of the magnetic interactions, combined with spin-orbit torques, play an important role in determining how the (anti-)skyrmion core moves. In particular, the choice of the DMI can lead to qualitatively different motion for opposite charges. We present results of atomistic spin simulations, where magnetic parameters are based on density functional theory calculations, of current-driven skyrmion and antiskyrmion dynamics due to spin-orbit torques. While the expected linear displacement is found for skyrmions, we discover new dynamical regimes involving antiskyrmions: trochoidal dynamics and skyrmion-antiskyrmion pair generation, which occur above successive current thresholds. An example of the different behavior is given in the Figure, including a state diagram for different field-like and damping-like torques. By taking into account deformations of the antiskyrmion core, we derive an additional equation of motion for the internal dynamics of the core which allows us to identify the trochoidal motion as the analog of precessional motion for domain walls above Walker breakdown. *This is a novel result in micromagnetism.* When a different form of the DMI is chosen, i.e., one that favors antiskyrmions over skyrmions, the opposite behavior is found — antiskyrmions undergo linear displacement, while skyrmions undergo trochoidal motion and can generate skyrmion-antiskyrmion pairs. This illustrates the importance of the symmetry of the DMI, rather than the topological charge, in governing the dynamics. This is further highlighted when the DMI is absent altogether, where the symmetry between skyrmion and antiskyrmion motion is restored. Our results suggest new avenues for exploiting skyrmion and antiskyrmion dynamics in nanodevices. This work was partially supported by the Horizon2020 Framework Programme of the European Commission (H2020-FETOPEN-2014-2015-RIA) under Contract No. 665095 (MAGicSky).

Magnetic skyrmions have excited much interest as the basis for novel data storage applications in which information is encoded and transferred in these magnetic knot-like quasiparticles. In multilayers of ultrathin magnetic films they are stabilised by the interfacial Dzyaloshinskii-Moriya interaction [1]. Due to tunability and room temperature stability these multilayers are held to have great scope for spintronic applications [2-5]. The proposed read-out of any such skyrmion-based spintronic device will rely upon the electrical detection of a single magnetic skyrmion within a nanostructure, through, for example, a change in the Hall resistivity [6]. We have fabricated nanodiscs from multilayers of Pt/Co/Ir which can support skyrmions at room temperature and have measured the Hall resistivity whilst simultaneously imaging the spin texture using magnetic scanning transmission x-ray microscopy. In the experiment reported here, a single skyrmion in a Ta (3.5 nm)/Pt (3.8 nm)/{Co (5.0 nm)/Ir (5.0 nm)/Pt (1.0 nm)}×10/Pt (3.2 nm) multilayer nanodisc was imaged using the PolLux scanning transmission X-ray microscope (STXM) as a function of out-of-plane magnetic field. In situ Hall measurements inside the STXM were taken just before imaging the magnetic state of the device as the field was swept. The Hall resistance R_{xy} shows a clear difference between uniformly magnetised states (A and B) and a single skyrmion state (C and D). We show that the Hall resistivity is correlated to both the presence and size of a magnetic skyrmion in the nanodisc and that the size-dependent part matches the expected anomalous Hall signal when averaging the magnetisation over the disc. The additional contribution arising from the presence of a single skyrmion is 11±1 nΩcm. This shows that electrical transport measurements can be used to detect individual skyrmions in nanostructures [7]. This work was funded by the Horizon 2020 FET-OPEN project MagicSky, the FP7 ITN WALL, Diamond Light Source and the EPSRC.

Department of Electrical and Computer Engineering, Shinshu University, Nagano, Japan

Among the many magnetic objects for next generation storage technologies, the skyrmion has drawn the most attention and commentary due to its nanometric size and topologically protected stability [1]. However, the application of skyrmion motion along the nanotrack whether driven by spin-polarized electric current or a spin wave, would both face a significant obstacle, that is "Hall behavior" accompanied by a topological number of Q = +1 [2,3]. To overcome this problem, skyrmionium emerged as intriguing resolution with zero topological number and skyrmion-like structure, shows great promise for use in magnetic and spintronic applications because it does not suffer from the skyrmion Hall effect. It has been first observed on a ferrimagnetic film in the experiment of laser radiation [4]and can be moved and manipulated by spin current [2]. So far how skyrmionium driven by magnon current has not been investigated. Therefore, in this paper, we study in detail the dynamics of skyrmionium driven by a spin wave in chiral magnetic film and nanotrack. Figure 1 shows snapshots of spin-wave-driven motion process of three magnetic objects, which display significant differences when responding to a magnon current, behaving in not just the motion directions but velocities. Then we proceed an effective analysis in the framework of Thiele equation [5] to explain why skyrmionium is moving along the direction of magnon current, contrary to skyrmion. We find that the transverse component of velocity is attributed to the longitudinal scattering section of skyrmionium. Afterwards in order to explore the potential of spin waves-driven skyrmionium in future spintronics application, we further investigate the related factors influencing the skyrmionium motion in a nanotrack, including the nanotrack width, the Gilbert damping, the inner and outer radius of skyrmionium. Figure 2 presents the dependence of velocity of the skymionium on perpendicular magnetic field by changing the radius of skyrmionium in the nanotrack. Finally, we research the status of skyrmionium after stopping spin wave. In conclusion, we demonstrate that the skyrmionium not only does not have Hall behavior but also move along the magnon current, which is distinctly different from the skyrmion. Most importantly, the velocity of skyrmionium is lager than skyrmion in driving of the magnon pressure and can be effectively tuned by small magnetic field. Our results provide a base for applying magnon-driven skyrmionium in novel information storage and spintronics devices.

HE-08. A theory on skyrmion size and profile.

X. Wang[1,2], H. Yuan[3] and X. Wang[2,4]
1. University of Electronic Science and Technology of China, Chengdu, China; 2. Physics, The Hong Kong University of Science and Technology, Hong Kong, Hong Kong; 3. Physics, Southern University of Science and Technology, Shenzhen, China; 4. HKUST Shenzhen Institute, Shenzhen, China

Skyrmions, topological objects originally used to describe resonance states of baryons [1], were observed in magnetic systems that involve Dzyaloshinskii-Moriya interaction (DMI). Magnetic skyrmions are believed to be potential information carriers in future high density data storage and information processing devices [2,3]. Although much knowledge about magnetic skyrmions has been accumulated after intensive studies including skyrmion generation, the dependence of skyrmion size (R) on material parameters such as exchange energy, magnetic anisotropy energy, and DMI strength is still poorly understood at a quantitative, or even qualitative level. Here we show that the skyrmion profiles agree well with Walker-like 360° domain wall formula [4,5]. By minimizing the energy, we obtain the analytical expressions of the skyrmion size R and wall width w as functions of exchange constant A, DMI coefficient D, anisotropy constant K, and external magnetic field$B$. These results agree perfectly with micromagnetic simulations and are consistent with experiments. We consider a 2D film with Heisenberg exchange interaction (of exchange constant A), interfacial Dzyaloshinskii-Moriya interaction (DMI) (of DMI coefficient D), perpendicular easy-axis anisotropy (of anisotropy constant K), and a perpendicular magnetic field (of field strength B). We first numerically verify that an isolated Néel skyrmion is rotational symmetric and the magnetization profile along any diameter can be well fitted by a Walker-like 360° domain wall profile with two characteristic lengths, the skyrmion size and the skyrmion wall width, as shown in Fig. 1. The skyrmion profile can be described by $\Theta(r)$ and $\Phi(\phi)$, where Θ and Φ are polar and azimuthal angles of magnetization m, and r, ϕ are radial and angle coordinates in space. The total energy E is a functional of $\Theta(r)$ and $\Phi(\phi)$. Then by substituting the 360° domain wall profile into the energy functional, we obtain an expression of total energy E as a function of R and w. The equilibrium R and w can be obtained by minimizing the total energy, and the obtained results almost perfectly agree with the numerical simulation results as shown in Fig. 2. The exchange and DMI energies come from the spatial magnetization variation rate. For a skyrmion, the magnetization variation rates in the radial and tangent directions scale respectively as $1/w$ and $1/R$. The exchange energy is then proportional to skyrmion wall area of Rw multiplying the square of the magnetization variation rates $1/R^2+1/w^2$. Near the skyrmion wall region, the magnetization variation rate along the tangent direction is perpendicular to the magnetization and does not contribute to the DMI energy. The DMI energy is then proportional to wall area Rw multiplying the magnetization variation rate along radial direction ($1/w$). The anisotropy energy is mainly from the skyrmion wall area. The Zeeman energy of the skyrmion comes from the inner domain proportional to its area of $\pi(R\text{-}cw)^2$, where c is a coefficient depending on the magnetization profile, and from the wall area proportional to its area of Rw. Thus, by considering the physical meaning of each energy term as well as reasonable mathematical approximations, we obtain a simple analytical formula for the total energy in terms of R and w. The approximate formula also gives correct qualitative parameter dependence and good quantitative agreement with the simulations. The results are not limited to interfacial DMI. For bulk DMI, the only difference is Bloch-type skyrmions are preferred The radial profile as well the skyrmion size does not change.

HE-09. High speed bilayer skyrmion transport by voltage controlled magnetic anisotropy gradient.

C.C. Ang[1], W. Gan[1] and W. Lew[1]
1. School of Physical and Mathematical Sciences, Nanyang Technological University, Singapore, Singapore

Magnetic skyrmion transport mechanisms explored thus far have been primarily based on the use of spin transfer torques (STT). Experimental transport measurements based on the STT mechanisms showed that extremely high current densities on the order of 10^{12} A/m^2 are required to achieve practical speeds of more than 100 m/s[1]. Nanowires operating under such high current densities can result in both detrimental Joule heating effects and decreased energy efficiency. In addition, the propagation speed of skyrmions can be reduced significantly at elevated temperatures [2]. To overcome the aforementioned detriments, we propose the use of voltage controlled magnetic anisotropy (VCMA) gradient as an alternative transport mechanism [3]. In this work, we studied numerically the dynamics of VCMA gradient-driven skyrmions in a synthetic antiferromagnet (SAF) bilayer structure. The results in our model shows that the bilayer structure can overcome the limitation in speed caused by the skyrmion Hall effect to achieve speeds higher than STT transports. Under an anisotropy energy gradient of 600 GJ/m4 or a < 1 % change in magnetic anisotropy energy across the skyrmion, a transport speed of 840 m/s can be attained. Unlike skyrmion transport with STT, the VCMA-gradient transport also offers excellent scaling of speed with material property; VCMA gradient-driven skyrmions show an inverse relationship with Gilbert damping constant as shown in Figure 1. The transport velocity also scales linearly with the saturation magnetization. The excellent scaling properties unlocks multiple avenues for design to further optimize the skyrmion transport. A model for the bilayer skyrmion was also developed. The skyrmion motion can be described by the competition of 3 forces: the skyrmion Hall effect, VCMA gradient and skyrmion interlayer coupling. The interlayer coupling between the SAF skyrmions is a spring-like restoring force that keeps the skyrmions close, as shown in Figure 2. The interlayer coupling peaks at a quarter of the skyrmion diameter; above which the skyrmions are decoupled. Due to the spring-like coupling, oscillatory behaviour was observed, along with an increase in skyrmion mass. When a VCMA gradient is applied to drive the skyrmion forward, the skyrmion Hall effect drives the each skyrmion towards opposite edges while the interlayer coupling applies a restoring force towards the centre of the wire. The balance of these forces determines the trajectory of each skyrmion. In conclusion, our study reveals the rich skyrmion dynamics in a bilayer VCMA-gradient system. The proposed skyrmion transport mechanism was also demonstrated to achieve skyrmion speeds comparable with current-driven skyrmions while eliminating Joule heating effects. Furthermore, this mechanism is inherently dissipationless as it operates on voltage instead of current flow along the wire, promising low power skyrmionic devices.

HE-10. Magnetic Skyrmion Dynamics in Wedge-shaped Nanotrack and Its Potential Applications.

X. Chen[1], W. Kang[1], D. Zhu[1], X. Zhang[2], Y. Zhang[1], Y. Zhou[2] and W. Zhao[1]
1. Beihang University, Beijing, China; 2. The Chinese University of Hong Kong, Shenzhen, China

Magnetic skyrmions are swirling topological configuration [1], mostly induced by chiral exchange interactions between atomic spins in non-centrosymmetric magnetic bulks or in thin films with broken inversion symmetry. With the rapid advances made in this field [2-3], the development of skyrmion-based spintronics holds promise for future applications owing to the topological nature, nanoscale size, and ultralow current density for motion. Furthermore, the standby energy consumption and heat generation during the processing and transportation of information can be efficiently reduced thanks to the nonvolatility. In this abstract, we present firstly our investigations on skyrmion dynamics in terms of size, velocity, energy, stability in a wedge-shaped nanotrack via micromagnetic and theoretical studies [4]. We find some interesting results compared to previous research. For example, the size of a skyrmion decreases as the nanotrack width decreases because of the compression by the nanotrack edge (see Fig. 1a), thus this property can be harnessed to adjust the dimension of skyrmions to acheive ultra-dense storage in racetrack memory [5]. Inspired by the findings in wedge-shaped nanotracks, we draw a conclusion about the tradeoff between the nanotrack width (storage density) and the skyrmion motion velocity (data access speed) by further analyzing the skyrmion dynamics in parallel nanotracks (see Fig. 1b). Our results may provide guidelines in designing skyrmion racetrack memory and other related skyrmionic applications. We also model a novel compact neuron device based on this wedge-shaped nanotrack. Under the coaction of the exciting current pulse and the repulsive force exerted by the edge of the nanotrack, the dynamic behavior of the proposed skyrmionic artificial neuron device corresponds to the leaky-integrate-fire (LIF) spiking function of a biological neuron (see Fig. 2). We believe that our study makes a significant step because such a compact artificial neuron can enable energy-efficient and high-density implementation of neuromorphic computing hardware [6].

HF-01. Various ways to tune non-collinear magnetism in ultrathin films.

A. Finco[1], P. Hsu[1,2], L. Rózsa[1,3], A. Kubetzka[1], E. Vedmedenko[1], K. von Bergmann[1] and R. Wiesendanger[1]

In order to develop spintronic devices, a precise control of the magnetic state in ultrathin films is necessary. In particular, the stabilization of non-collinear magnetic structures is a crucial issue. In magnetic ultrathin films grown on a heavy element substrate, the competition between the interface-induced Dzyaloshinskii-Moriya interaction (DMI) and the exchange interaction enables the formation of spin spirals and magnetic skyrmions. The exact nature of the magnetic state strongly depends on the balance between the different interactions and thus being able tune them is of great interest. Starting from the Fe/Ir interface, known to generate a large DMI, we show how to obtain and tune spin spirals or magnetic skyrmions using spin-polarized scanning tunneling microscopy (SP-STM). This versatile technique allows to measure the full 3D magnetic structure of the film down to the atomic scale. Furthermore, the magnetic states can also be manipulated using the STM tip. Since the lattice mismatch between Fe and Ir is very large, the epitaxially grown double Fe atomic layer on Ir(111) exhibits a network of dislocation lines along high-symmetry directions. These lines allow to relieve the epitaxial strain in the film and it appears that they also have a significant influence on the magnetic ground state [1]. At low temperature, spin spirals with a period about 1.5 nm are guided by the dislocation lines. When atomic hydrogen is incorporated in the double layer film, the dislocation lines network disappears and is replaced by a p(2x2) hexagonal superstructure. The propagation direction of the spin spirals is thus not fixed anymore and their period increases to 3.5 nm. Furthermore, whereas no skyrmionic phase could be found in the double layer Fe on Ir(111) up to 9 T, the spin spirals in the hydrogenated samples transform into skyrmions under application of a magnetic field of 3 T. The skyrmionic phase is shown on the spin-polarized differential conductance measurement in panel (a). Ab initio calculations indicate that the H atoms must be located between the two Fe layers in order to have such an impact on the magnetic state. The presence of the H atoms modifies indeed the distance between the Fe layers and thus the hybridization of the top Fe layer with the lower Fe and Ir ones [2]. Another possibility to modify the magnetic state is to add one more atomic Fe layer. The measurement presented in panel (b) shows the magnetic state of a typical sample with an Fe coverage about three layers. As well as in the double layer film, dislocation lines form to relieve the epitaxial strain and spin spirals propagate along them. In addition, the spacing between the lines is varying over the sample surface which means that the strain relief is also not uniform. Measurements of the period of the spin spirals in the triple layer film revealed a clear correlation between the dislocation line spacing and the magnetic period. Based on a simple micromagnetic model, we attribute this observation to a modulation of the effective exchange coupling by the epitaxial strain relief [3]. Although the effect of strain relief was studied at low temperature, we also investigated the temperature dependence of the spin spirals. Whereas no spiral could be observed in the double layer above 150 K, the spirals are still stable in the triple layer up to room temperature. Moreover, their period increases drastically and becomes 15 times larger at room temperature than at 8 K (see panel (c)). In order to explain this unexpected temperature-dependent behaviour, we propose a classical spin model based on different magnetic parameters in the three Fe layers. This model allows us to reproduce the period increase using both a mean-field and a Monte Carlo approach [4]. Under application of a magnetic field, the low-temperature spin spirals in the triple layer split up into skyrmions with a typical size about 5 nm. These skyrmion have a unusual bean-shape which is dictated by the anisotropic local arrangement of the atoms forming the dislocation lines (panel (d)). We demonstrate that they can reliably be written and deleted locally by the STM tip. The strong-bias polarity dependence and the linear behavior of the threshold voltage for switching with the tip-sample distance shows that electric field plays the dominant role in the switching mechanism [5]. Our work opens new possibilities for precise tailoring of the magnetic states in ultrathin films as well as for energy-efficient manipulation of single skyrmions which may be beneficial in the development of skyrmion-based spintronic devices.

Magnetic skyrmion and skyrmionic bubbles are gaining significant interest due to their topological nature [1], which can be used for building novel memories and logic computing devices [2]. Both current and magnetic field induced dynamics of skyrmions and skyrmionic bubbles have been investigated extensively. However, from the energy consumption point of view, skyrmionic dynamics driven by an electrical field could provide long-term practical application benefits [3-6]. Here, we present our most recent results on the electrical-filed-induced motion of skyrmionic bubbles and chiral domain walls in racetracks. The racetracks, composing stacks of CoNi/Pt with asymmetric thicknesses of Pt, were fabricated with tailored wedge end. The electric field is applied at the Pt/dielectric SiO_2 interface. Both experimental and numerical study on the electric field-induced creation and directional motion of skyrmionic bubbles and chiral domain walls will be reported. We find the electric field-induced motion of skyrmionic bubbles at zero magnetic field and room temperature. Repeatable forward and backward directional motion of skyrmionic bubbles suggests robust nature of the structure. Our finding provide opportunities for developing novel skyrmion-based information processing devices with ultralow power consumption.

HF-03. Strong Dzyaloshinskii-Moriya interaction in symmetric crystalline $[Co/Pd(111)]_n$ superlattices.

A. Davydenko[1], A. Kozlov[1], M. Stebliy[1], A. Ognev[1] and L. Chebotkevich[1]
1. Far Eastern Federal University, Vladivostok, Russian Federation

When creating asymmetric superlattices [heavy metal 1 / ferromagnetic / heavy metal $2]_n$, the energies of perpendicular anisotropy and the Dzyaloshinskii-Moriya interaction (DMI), as a rule, depend weakly on the period of superlattices *n* and remain approximately equal to the energies observed in the structure consisting of one period [1]. This is expected, since both the perpendicular anisotropy and the DMI in such structures are believed to be of an interface origin. The increase in the number of interfaces is compensated by an increase in the volume of the ferromagnetic layers. However, more recently in symmetric polycrystalline superlattices $[Co/Pd]_n$, an increase in the effective DMI was observed with an increase in the number of repetitions of bilayers *n* [2]. Similar results, but in the single-crystal system $[Co/Pd(111)]_n$ with higher values of the perpendicular magnetic anisotropy and DMI, were found by our group. Crystalline [Co(0.8 nm)/Pd(2 nm)$]_n$ superlattices were grown by molecular beam epitaxy on Si(111) substrates with a Cu buffer layer. Period of superlattices *n* was varied from 1 to 20. Structural properties of superlattices were analyzed by reflection high energy electron diffraction. The structure and epitaxial orientation of all the layers remained the same as in the bottom layers. Topography and growth processes were investigated by scanning tunneling microscopy. With an increase in the overall thickness of the structures, the amplitude and period of roughness increased. Magnetic properties of the superlattices were investigated by vibrating sample magnetometer. An energy of perpendicular magnetic anisotropy slightly increased from 0.66 to 0.87 MJ/m^3 with an increasing of the period of superlattices from 1 to 20. Measurements of DMI were performed by Brillouin light scattering spectroscopy based on DMI-driven asymmetric dispersion shift of long-wavelength thermal spin waves in the Damon-Eshbach surface mode. We found an increase of effective DMI constant D_{eff} from 2 to 4.5 mJ/m^2 with an increasing of the period of superlattices from 1 to 20. In the Fig. 1 Brillouin light scattering spectrum of the [Co(0.8 nm)/Pd(2 nm)$]_{15}$ superlattice is outlined. The increase in the DMI constant more than twice led to significant changes in the magnetic structure of the samples during magnetization reversal. In the single magnetic layered structures with $n = 1$ DMI was relatively weak to influence on magnetic structure of domains, but it stabilized chiral Neel domain walls. In these samples by means of Kerr-microscopy, we observed an asymmetric growth of domains in the combination of longitudinal and perpendicular magnetic fields. Magnetization reversal in the single magnetic layered structures occurred by nucleation of oppositely magnetized domains and domain walls propagation. Increasing of the period of superlattices *n* to 3-5 led to increasing of the DMI constant. In the magnetic structure during magnetization reversal, it resulted in increasing of the density of nucleating domains. The magnetic moments in all magnetic layers of a chosen domain were oriented in the same direction due to ferromagnetic coupling between Co layers. In sufficiently high magnetic fields, chiral Neel domain walls repelled from each other forming net of topologically protected 360° domain walls [3]. Net of 360° domain walls transformed to isolated skyrmions in magnetic fields just below the saturation magnitudes. We stabilized skyrmions in such samples in zero magnetic field and detected them by magnetic-force microscopy. Micromagnetic simulations indicate that at such high values of DMI constant chiral Neel domain walls and skyrmions may be formed in $[Co/Pd]_{3\text{-}5}$ superlattices. Further increasing of the period of superlattices *n* to 10-20 led to extremely strong DMI. Strong DMI overcame perpendicular magnetic anisotropy and demagnetized superlattices in the zero magnetic fields. In the remanent state, the magnetic structure of the superlattices corresponded to demagnetized stripe domain structure with chiral Neel domain walls and stable isolated skyrmions (Fig. 2). The period of the stripe domain structure decreased with increasing of the DMI constant in $[Co/Pd]_{10\text{-}20}$ superlattices. Strong dependence of the DMI constant on the period of $[Co/Pd(111)]_n$ superlattices indicates that DMI in this system is not simply additive. Despite the interface nature, DMI from the interfacial Co atoms of the selected magnetic layer extends not only to the volume of a given layer, but also to other neighboring layers. Probably this behavior of DMI is general for magnetic superlattices, but in other systems it may be hindered by increasing amount of structure imperfections during growth of thick superlattices. In conclusion, we demonstrate the symmetric crystalline [Co/Pd(111)]n system, in which the DMI constant may be varied over a wide range by choosing the appropriate period of superlattice, making possible skyrmions and chiral stripe domain structure formation in the zero magnetic fields. The reported study was funded by RFBR (research project 18-02-00205) and the Grant program of the Russian President (MK-5021.2018.2).

HF-04. Magnetic domain texture and Dzyaloshinskii-Moriya interaction in systems with perpendicular exchange bias.

R.A. Khan[1], H. Nembach[2], M. Ali[1], T.A. Moore[1] and C.H. Marrows[1]
1. School of Physics and Astronomy, University of Leeds, Leeds, United Kingdom; 2. Quantum Electromagnetics Division, National Institute of Standards and Technology, Boulder, CO, United States

In thin film systems with broken inversion symmetry, the Dzyaloshinskii-Moriya interaction (DMI) influences the field- or current-driven magnetic switching and domain wall (DW) motion by setting the chirality of magnetic textures [1-3]. In this work, we sputter-deposited polycrystalline multilayers of Pt/Co/$Ir_{20}Mn_{80}$ and Pt/Co/$Fe_{50}Mn_{50}$ exhibiting perpendicular magnetic anisotropy (PMA) and perpendicular exchange bias (PEB). Such multilayers, comprising an antiferromagnet (AFM) material (IrMn and FeMn), are potentially of interest in spintronics because of the useful properties AFM materials possess, such as, very high frequency dynamics, zero stray field, excellent magneto-transport properties, etc. Furthermore, the coincidence of the DMI with a vertical exchange field could remove the need for an externally applied field to stabilise skyrmion bubbles. We have measured the exchange bias in SiO_2/Ta(5)/Pt(2)/Co(t_{Co})/IrMn(t_{IrMn})/Pt(3) (Fig. 1) and SiO_2/Ta(5)/Pt(2)/Co(t_{Co})/FeMn(t_{FeMn})/Pt(3) stacks (thickness in nm) as a function of the layer thickness of Co (t_{Co} = 0.2-2 nm), IrMn (t_{IrMn} = 1-10 nm), and FeMn (t_{FeMn} = 1-8 nm) layers. The stacks have been optimised structurally to obtain a strong PMA and large PEB in the as grown state. The FeMn system attains PMA for a narrower range of Co layer thickness, when compared to the IrMn system. We investigated the interaction mechanisms at the interfaces when crossing over the paramagnet to antiferromagnet (AFM) transition of the AFM layers (IrMn and FeMn) by varying the thickness of these layers. We confirm the different phases by identifying the Néel temperatures (T_N) and the blocking temperatures (T_B) of the AFM layers (Fig. 2) at different layer thicknesses. Wide-field Kerr microscopy showed that the magnetic domain morphology of the ferromagnet (FM) Co layer is influenced by the AFM Néel order. From this we infer that the changes in domain texture is brought about by the FM-AFM inter-layer exchange coupling, and the anisotropy of these layers. We also investigated the DMI in these systems, particularly how it is affected by the AFM spin order, and subsequently, by the coupling at the FM-AFM interface. We do this by measuring the DMI at three different phases: paramagnet phase, AFM phase without PEB, and AFM phase with PEB. We quantified the DMI by the Brillouin light scattering (BLS) spectroscopy technique [4-5], where the DMI is probed by taking advantage of the non-reciprocity of propagating spin waves.

HF-05. In-situ Annealing Study of Pt/Co Interface and its Effect on Perpendicular Magnetic Anisotropy of Pt/Co/MgO.

H. Xie[1], Y. Yang[1], M. Zhang[1] and Y. Wu[1]
1. Department of Electrical and Computer Engineering, National University of Singapore, Singapore

I. INTRODUCTION Heavy metal (HM)/ferromagnetic metal (FM)/oxide structures, such as Ta/CoFeB/MgO and Pt/Co/MgO, have been the focus of numerous studies owing to the enhanced perpendicular magnetic anisotropy (PMA) and large spin orbit torque (SOT). Post-annealing treatment is often necessary in fabricating devices involving these multilayer structures because it does not only enhance both the PMA of the magnetic layer and transport properties of the devices but also ensures thermal stability [1]–[4]. Previous studies often annealed the entire structure together and therefore it was difficult to evaluate the respective role of the top and bottom interfaces separately. To address this issue, in this study we investigated the annealing effect of Pt/Co/MgO using an in-situ deposition and measurement setup which allows to study the annealing effect of the two interfaces separately. Specifically, we deposited Pt/Co, Pt/Co/MgO and Pt/Co/Mg step by step and in between we annealed the samples between 100°C - 300°C and measured the anomalous Hall effect (AHE) in-situ. Deposition and measurement were both conducted in an ultra-high vacuum (UHV) system without exposing the sample to ambient. The samples were deposited on 2 × 2 mm^2 square wafers to fit the magnetic holder which provides a perpendicular magnetic field. Layers of Ta(1.5)/Pt(3) (the number inside the parentheses indicates the thickness in nm) were first deposited ex-situ using dc magnetron sputtering and then quickly loaded into the UHV system, followed by the deposition of Co or Mg using Knudsen cell cells in a preparation chamber. After deposition, the samples were transferred in-situ to the nanoprobe chamber for oxygen exposure and AHE measurements. The oxygen exposure is precisely controlled by a low-dosage oxygen source. The AHE measurements were conducted by probing the four corners of the samples using the nanoprobes. II. RESULTS AND DISCUSSION Fig. 1(a) shows the AHE loops for Ta(1.5)/Pt(3)/Co(0.6) after being annealed for a duration of 0.5h from 100°C to 300°C at a step of 50°C. The curves are shifted vertically for clarity. As can be seen, the film exhibits PMA; its coercivity decreases slightly after annealing from 100°C to 150°C and then increases and peaks at 250°C. Next, we deposited a sample with the same structure of Ta(1.5)/Pt(3)/Co(0.6), but instead of proceeding to annealing directly, we exposed the sample to oxygen at a dose of 116L (here L is the Langmuir unit with one Langmuir corresponding to an exposure of 1.33×10^{-6} mbar for one second) and then dusted the surface with a small amount of Mg to obtain Ta(1.5)/Pt(3)/Co(0.6)/O/Mg. The AHE loops of this sample after oxygen exposure, Mg deposition and annealing at different temperatures for a duration of 0.5h are shown in Fig. 1(b). In agreement with our previous report [2], oxygen exposure at small Co thickness results in a degradation of effective PMA, which recovers partially after Mg dusting. As can be seen, the annealing effect for this sample is similar to that of Ta(1.5)/Pt(3)/Co(0.6), i.e., without oxygen exposure and Mg dusting. For the third sample, the Mg dusting is performed directly on the Co layer without oxygen exposure, leading to the Ta(1.5)/Pt(3)/Co(0.6)/Mg structure. Shown in Fig. 1(c) are the AHE curves of this sample after annealing at different temperatures. Again, a similar trend of annealing effect was observed, i.e., the coercivity decreases slightly at lower temperature, and then increases and peaks at 250°C. Fig. 1(d) compares the extracted coercivity values for the three samples as a function of annealing temperature. The significant enhancement of coercivity (as we will discuss shortly it is closely related to PMA) after annealing between 200°C and 300°C could be attributed to improved crystallinity or interface sharpness by thermal annealing. Notably, the annealing effects are similar in the three samples, suggesting that for Pt/Co/MgO, the lower interface (i.e., Pt/Co) determines the magnetic and thermal property. At this specific Co thickness, adding MgO does not necessarily lead to the improvement of these properties. Since the in-plane field strength of the is-situ setup is insufficient for quantitative measurement and analysis of the PMA, we performed ex-situ experiments to investigate the annealing effect on PMA. To this end, we deposited and annealed Ta(1.5)/Pt(3)/Co(0.6)/Cu(3) in a sputter for the same duration and in similar temperature range. The samples were cooled down for 2h after annealing and then capped with 3nm Pt layer without breaking the vacuum. The 3nm Cu layer is used to avoid Co in direct contact with the upper Pt layer. After annealing, we measured the in-plane hysteresis curves using SQUID from which we extracted the anisotropy field. Fig. 1(f) shows the anisotropy field at different annealing temperature. A similar trend as the coercivity shown in Fig. 1(d) was observed, confirming that the bottom Pt/Co interface indeed plays the most crucial role in determining both the magnetic and thermal properties of Pt/Co/MgO trilayers. The difference in peak temperature is presumably caused by the temperature calibration of the two systems. The PMA of the sample annealed at 200°C is estimated to be 10.4×10^6 erg/cm^3.

HF-06. Exploring interfacial Dzyaloshinskii-Moriya interaction for in-plane thin film permalloy nanostructures using micromagnetic simulations and Lorentz microscopy.

K. Fallon[1], S. Azzawi[2], D. Atkinson[2] and S. McVitie[1]
1. University of Glasgow, Glasgow, United Kingdom; 2. Durham University, Durham, United Kingdom

Recently the Dzyaloshinskii-Moriya interaction (DMI) has received considerable attention, particularly in the case of the interface between ultra-thin ferromagnetic films and non ferromagnetic heavy metals. The interfacial interaction causes reorientation of the domain wall spin configuration into Néel type walls with a defined handedness in material systems that ordinarily display perpendicular magnetisation with Bloch type walls of no preferred handedness [1]. The DMI energy term - $D\bullet(S_i \times S_j)$, where D is the DMI vector and S_i and S_j are neighbouring spins, is responsible for the chiral twist texture. In the work presented here we are interested in the effect of this term in a thin film system with in-plane magnetisation. In particular nanostructured soft ferromagnetic thin films readily form vortex structures with an out of plane singularity at the vortex core. Such a structure provides possibilities for interesting DMI effects around the vortex core. To investigate this we have looked at the effect of interfacial DMI on vortex structures in films of permalloy with a thickness around the exchange length of the material (~ 5 nm). Micromagnetic simulations have been performed using MuMax^3 to simulate thin (8 nm) magnetic disks of permalloy with varying interfacial DMI strength [2]. The simulations indicate that interfacial DMI causes twisting of the magnetisation around the vortex core – this results in a magnetisation configuration that has a divergent component local to the vortex core and is no longer purely rotational. Furthermore, the simulations show that the strength and sign of the divergent component relates to the strength and sign of the DMI. Figure 1 contains a subset of the simulation results to illustrate the effect of DMI. The insets on the figures show the core structure on a larger scale. Comparing the two cases with and without DMI, the former has a symmetric structure whilst the latter shows a clear asymmetry. Indeed the effect of DMI appears to result in a twisting of magnetisation around the vortex core, resembling somewhat the yin yang symbol of Chinese philosophy. Hysteresis loops were calculated and show a relationship between the magnitude of the DMI and the vortex expulsion field, with a smaller field required to expel vortices in systems with a larger magnitude of DMI - see figure 2. Bilayer and trilayer samples were prepared by sputtering at the University of Durham. Each sample has a magnetic layer of permalloy and non magnetic capping layers of either platinum, iridium, gold or copper to provide a range of different DMI samples and control samples with no DMI. These samples were patterned (using a FIB microscope) to isolate disks of magnetic material from the continuous film. The vortex expulsion has been observed directly via an in situ Lorentz transmission electron microscopy (TEM) experiment using the Fresnel method to image domain walls. We note a reduction of the expulsion field for films with strong interfacial DMI (Py with Ir and Pt) compared to that for no expected DMI (Py with Cu). We also report on imaging using the quantitative method of differential phase contrast (DPC), to map the magnetic induction of the sample. Recent developments in DPC, utilising pixelated detectors, allow this technique to register beam deflections on the order of microradians and provide a spatial resolution of 1 nm [3]. Calculated images of the induction maps from the micromagnetic simulations suggest the divergent component of the magnetization provides a measurable signature from DPC. We will present details of these measurements.

Magnetic thin films possessing magnetic easy axis perpendicular to the surface have attracted a lot of interest and they are playing an important part for spin-transfer torque (STT) spintronic devices. Compared to the magnetic thin films with in-plane easy axis, the application of magnetic thin films with perpendicular magnetization anisotropy (PMA) has demonstrated high switching reliability, good thermal stability in STT spintronic devices.[1] Co can form strong interfacial anisotropy energy by combining with different metals such as Pt, Ni and Pd, among which CoNi has lowest damping constant and is widely used. Lots of methods have been reported to enhance PMA in Co/Ni multilayer, such as changing the under layer of CoNi multilayer or in situ annealing the under layer.[2] However, there are no reports for using the two dimensional transition metal dichalcogenides to engineer the PMA of the magnetic thin films. Here, we report the PMA enhancement of $[Co(0.24nm)/Ni(0.52)]_2$ multilayer by inserting MoS_2 under layer. The perpendicular magnetic anisotropy of $[Co(0.24nm)/Ni(0.52nm)]_2$ multilayer can be greatly enhanced by inserting MoS_2 under layers, which is proved by the experiments and first-principle calculation in this work. The experiments show that the coercivity in easy axis can be greatly enhanced from 120 Oe to unprecedented value of 1037 Oe by inserting MoS_2 under layers. Magnetocrystalline anisotropy energy (MAE) is about 2.2 times larger than that without inserting MoS_2 under layer. The calculations show that the MAE of $[Co(0.24nm)/Ni(0.52nm)]_2$ multilayers with MoS_2 under layer can be dramatically improved to 2.3 times the value of its pure counterpart, which is consistent with the experiments results. We also perform layer-resolved and orbital-hybridization resolved anisotropy analysis, which can help us have a better understanding of the physical origin of PMA enhancement. The layer-resolved analysis uncover that the interfacial Pt layer plays a critical role in enhancing $[Co(0.24nm)/Ni(0.52nm)]_2$ multilayer's PMA and the negative contribution to PMA from Pt layer can be significantly suppressed when inserting MoS_2 under layer. The orbital hybridization-resolved analysis further describe the origin of PMA enhancement, which demonstrates that the change of anisotropy contribution mainly comes from hybridizations between d_{xz} and d_{yz} orbitals, d_{xy} and d_{x2-y2} orbitals. These findings make the $[Co(0.24nm)/Ni(0.52nm)]_2$ multilayer have potential application where large MAE is required and also pave a new way to engineer the PMA of magnetic thin films by two dimensional materials.

Two-dimensional materials, such as graphene, black phosphorus, MoS_2, and BN, are considered to be the key materials of the post-Moore era, due to their unique properties and potential applications.[1-3] Especially the graphene-based materials have the potential to replace silicon as the novel chip material for the new generation of electronic circuits.[4,5] Graphene oxide (GO) membrane, a chemical derivative of graphene with oxygen functionalities, has attracted great interest due to its exceptional functional group and scale-up production.[6-8] Recently, it has been demonstrated that the GO membranes coating can strongly enhance perpendicular magnetic anisotropy (PMA) of CoFeB thin film, even up to 0.6 mJ/m^2 at room temperature after annealing process. Even the critical thickness of the membrane-coated CoFeB for switching the magnetization from the out-of-plane to the in-plane axis exceeds 1.6 nm. The combination of GO membranes with a ferromagnetic layer can extend the functions of the thin films and the development multifunctional graphene-composite spintronic devices. Bias-voltage applied to the interface of a magnetic metal and an insulator induces a significant change of the interface perpendicular magnetic anisotropy (PMA), through strong interface spin-orbit coupling and charge transfer. The voltage-controlled PMA has successfully applied to MTJs where the PMA in both magnetic layers are tunable and only a very small current density is needed to switch the magnetization, which is extremely encouraging in terms of reducing the power consumption for spintronic devices.[9, 10] Here, we report the voltage tailoring of the PMA of CoFeB thin film with and without coating of GO membranes. Experiments were carried out on sputter-deposited films with a layered structure of substrate/Ta(6)/$Co_{40}Fe_{40}B_{20}$(1.4)/MgAl-O(2)/Ta(3 nm), as shown in Fig. 1. The films were annealed at 300 °C in a vacuum with a magnetic field of 8000 Oe for 1 hour. A medical ultrasonic atomization nebulizer (Omron Ultrasonic Nebulizer NB-150U, Japan) was used to prepare the fine mist of GO dispersion. To improve the wettability of the surface, the samples were processed by oxygen plasma (Branson/IPC 3000 Plasma Asher, USA) for 20 min before depositing the GO membranes. During the deposition process, temperature of the samples was set to be 25 °C for keeping a proper evaporation rate of water. The deposition process was repeated 5 times, with each single deposition lasting 8 s. In order to investigate the voltage tailoring of the magnetic anisotropy, the films were patterned into Hall bar structures with the widths of 100 μm. The cervicity of the CoFeB films is measured by using the anomalous Hall effect (AHE). The Hall resistance RHall can be expressed as, $R_{Hall}=R_0/t*H+R_e/t*M_\perp$ where the first term on the right-hand side is the ordinary Hall resistance and the second term is the anomalous Hall resistance, which is proportional to the out-of-plane component of the total magnetization. As seen from Fig. 2, the coercivity Hc of the CoFeB film with GO membranes coating are equal to 70 Oe at bias voltage $V_{bias}\approx 0$ V, which is samller than that without GO membranes of 97 Oe. It is known that the coercivity of the magnetic layers can be altered by a bias voltage through the electric-field-induce perpendicular anisotropy change. Since the anisotropy is proportional to the coercivity for the coherent rotation of the magnetization reversal, the voltage would directly affect the relative coercivity. A bias voltage Vbias is swept from 0 V to 3.5 V. The coercivity Hc of CoFeB film with GO membranes decreases gradually from 70 Oe at 0 V to 63 Oe at 1.5 V, while the coercivity Hc without GO membranes decreases slightly from 100 Oe at 0 V to 84 Oe at 1.5 V. When the voltage exceeds 2.5 V, the barrier of GO membranes and MgAl-O may be broken down. Compared with the bare CoFeB/MgAl-O film, the tailoring of the PMA with GO membranes coating can be also attributed to the movement of oxygen or carbon functional groups in GO membranes. In summary, we investigated the voltage tailoring of the PMA of CoFeB thin film with and without coating of GO membranes. The anomalous Hall effect was used to characterize the magnetic properties via the application of electric fields between 0 to 2.5 V. The coercivity Hc of CoFeB film with GO membranes decreases gradually from 70 Oe at 0 V to 63 Oe at 1.5 V, while the coercivity Hc without GO membranes decreases from 100 Oe at 0 V to 84 Oe at 1.5 V. With GO membranes, the voltage-induced the movement of oxygen or carbon functional groups can also affect the PMA of CoFeB film.

HF-09. Control of magnetic anisotropy by lattice distortion in cobalt ferrite thin film.

H. Onoda[1], H. Sukegawa[2], E. Kita[1] and H. Yanagihara[1]
1. Inst. Appl. Phys, University of Tsukuba, Tsukuba, Japan; 2. National Institute for Materials Science (NIMS), Tsukuba, Japan

Introduction Improvement of perpendicular magnetic anisotropy (PMA) in thin films is required to improve density of magnetic recording and memory storage. Large PMA can be introduced via the magnetoelastic effects in a uniaxial distortion by a substrate-induced epitaxial strain [1], for example. In fact, cobalt-ferrite (CFO) thin films grown on an MgO (001) substrate suffering 0.6% in-plane tensile strain results in introducing a large PMA energy K_u of 14.7 Merg/cm^3 [2]. Likewise, CFO films grown on $MgAl_2O_4$ (001) substrate suffering 3.6% in-plane compressive strain exhibits as large as negative K_u of – 60 Merg/cm^3 [3]. Even though such large lattice strains, those induced PMA of CFO (001) epitaxial films can be quantitatively explained within a framework of magneto-elastic theory [3]. In other words, the induced magnetic anisotropy can be quantitatively explained by the phenomenological magneto-elastic effect at least in this lattice distortion range. Based on this effect, further enhanced PMA by inducing 3~4% tensile strain can be expected. Therefore, in this study, we examined various buffer layers to introduce a larger lattice strain than MgO (001) and report the magnetic anisotropy (MA), especially induced K_u in CFO (001). Experimental We have grown $Co_{0.75}Fe_{2.25}O_4$ films via the reactive rf magnetron sputtering technique using a CoFe (1:3) alloy target. The process gas used was a mixture of Ar and O_2. The flow rates of Ar and O_2 were 30 sccm and 8 sccm, respectively. The growth temperature was 500 °C. We selected NbN, CoO, (Mg, Ca)-O (MCO), MnO and Mg_2SnO_4 (MSO) as substances having a larger lattice constant than MgO. NbN, CoO, MCO and MSO were inserted between MgO (001) substrates and CFO films as buffer layers. For MnO, we prepared MnO (001) substrates and grew CFO films thereon. The in-plane and out-of-plane lattice constants of the CFO films were determined using the four axis X-ray diffractometer (Rigaku, SmartLab). The magnetization was measured using a superconducting quantum interference device, SQUID-VSM (Quantum Design, MPMS) at fields up to ± 70 kOe. The MA were evaluated from the magnetic torque curves measured over the range of 0-90 kOe by a torque magnetometer (Quantum Design, PPMS Tq-Mag). Results and Discussion Figure 1 shows RHEED patterns of MCO(001), CoO(001), MSO(001) buffer layers. As can be seen, all films showed a streak pattern, indicating the they were grown epitaxially and good surface flatness. CFO films were grown epitaxially on all buffer layers, but it was found from *MH*-loops that only CFO films on the MSO buffer layers showed perpendicular magnetization. Figure 2 shows in-plane and out-of-plane *MH*-loop of a 10-nm-thick CFO film on an 80-nm-thick MSO buffer layers. The value of the saturation magnetization was 460 emu/cm^3, which is larger than 425 emu/cm^3 for bulk CFO. This discrepancy may indicate the enhancement of the orbital magnetic moment of Co^{2+}. The in-plane magnetization was not saturated at all even when the magnetic field of 70 kOe was applied, indicating that the CFO film on the MSO buffer layer showed a strong PMA. We used the magnetic torque measurement to determine the accurate value of the MA, and then, the K_u^{eff} was 20 Merg/cm^3. The intrinsic K_u^{eff} evaluated by using Miyajima's method was estimated to be over 23.3 Merg/cm^3. Summary We grew $Co_{0.75}Fe_{2.25}O_4$ (CFO) films on various buffers having larger lattice constants than MgO one to induce larger PMA through the magneto-elastic effect. Only the MSO-buffered films showed a strong PMA and the value of the saturation magnetization value was 460 emu/cm^3, which is larger than 425 emu/cm^3 for bulk CFO. The intrinsic K_u^{eff} determined by using Miyajima's plot was estimated to be greater than 20 Merg/cm^3. Therefore, the use of MSO buffer is very promising to induce sufficiently large lattice-strain to CFO films toward giant PMA effect.

Torque magnetometer is a technique often used to quantify fundamental magnetic properties such as the magnetic anisotropy. These measurements are mainly performed on single domain samples.[1] However, recently it has been used to study magnetic phase transitions,[2] exchange biasing,[3] and non-uniform magnetization reversal.[4] Here, we use torque magnetometry to study a bilayer structure in which a lateral interfacial domain wall can be created and controlled. This class of structures has broad applications in areas such as magnetic recording media for hard disk drives,[5] permanent magnets,[6] and spin-transfer-torque Magnetic Random Acess Memory (MRAM) to allow lower switching current while maintaining thermal stability.[7] The field-induced magnetic configurations in a [Co/Pd]15 /TbFeCo exchange-spring system with perpendicular magnetic anisotropy are studied using torque magnetometry[8]. The experimental results are compared to a 1D micromagnetic simulation. The good agreement between experiments and simulations (see Fig. 1) allows us to deduce the evolution of the in-depth magnetic configuration as a function of the applied field orientation and amplitude. The chirality transition of the interfacial domain wall developing in the structure can also be determined with this technique [8].

HF-11. Effects of Heavy Metal Microstructure on Spin Transport in the Ultrathin Limit.

S.J. Brennan[1], J. Liao[1], T. Vemulkar[1], L. O'Brien[2] and R. Cowburn[1]
1. University of Cambridge, Cambridge, United Kingdom; 2. University of Liverpool, Liverpool, United Kingdom

Introduction The ability of all-metallic devices to generate pure spin currents with their low resistance-area product draws considerable research interest. In these systems, spin-orbit effects separate charge and spin currents, j_c and j_s, giving rise to many interesting effects. The prototypical all-metallic spintronic device is an (ultra)thin heavy metal/ferromagnet (HM/FM). When a j_c generates a transverse j_s from spin-dependent scattering, a local torque may be exerted on the FM. Hereby, all-metallic bilayers may be used to extract key spin-dependent parameters within each of the constituent materials, such as the efficiency of spin-to-charge current conversion (e.g. the spin Hall angle, θ) and the spin diffusion length, λ. However, sputtering HMs in the ultrathin limit can yield significantly different microstructure than in the bulk, and precise morphology is highly sensitive to the particular growth parameters, including substrate and HM surface energy, temperature and pressure. Consequently the electronic properties of the material may dramatically differ due to electron confinement, diffusive interface scattering, and reduced grain size[1], making direct correlations to spin-dependent properties challenging. We investigate the relationship between microstructure and spin-dependent properties in buffered HM|FM heterostructures. Using a range of thin buffer materials, we are able to tune the growth mode and so morphology of the HM layer. Spin-dependent properties are probed using spin Hall magnetoresistance measurements (SHMR), spin pumping and spin-orbit torque switching. We observe dramatic differences in the magnitude of j_s generation within the HM between buffered samples, which can be directly correlated to HM microstructure. In Ta/Pt/CoFeB layers, for highly-textured growth we find good agreement with models based on spin relaxation via the Elliott-Yafet (EY) and spin Hall effect via intrinsic spin scattering. However, for unbuffered Pt growth on SiO_2, we find stark differences between the measured spin and charge transport properties of the HM. This highlights the care that must be taken when determining properties such as θ and λ in thin and ultrathin films and the crucial role of microstructure in this limit. Buffering HMs in Metallic Multilayers Microstructural morphology is altered by buffering ultrathin Pt and W films grown via DC magnetron sputtering on SiO_2 and yttrium iron garnet. Growth of unbuffered Pt films on SiO_2 in the ultrathin limit is known to follow a Volmer-Weber-type (VW) mode resulting in a film of percolated grains with low texturing and large film roughness[2]. A thin 1 nm metallic under layer with high melting point seeds HM growth and enhances wetting upon deposition, which we find to increase texture, lower roughness and reduce film resistivity, ρ. In this study tantalum (Ta), tungsten (W) and ruthenium (Ru) were used as the intermediary buffer layer. Hereby, the growth mode, texture and ρ of the ultrathin Pt and W films are controlled and correlated to spin-dependent scattering. Cross-sectional transmission electron microscopy was performed to directly observe film morphology, which was further corroborated using atomic force microscopy and x-ray diffractometry to determine texturing and film roughness. Spin-Dependent Transport and Pumping SHMR and spin pumping measurements were conducted to determine the dependence of θ and λ on microstructure morphology. With additional current-induced SOT measurements of the j_s absorbed in the FM film, both back diffusion and transmission of j_s at the Pt|CoFeB interface were quantified. Magneto-electronic circuit theory (MCT) is used to model spin currents and accumulations at the HM|FM interface. In the ultrathin film limit ρ (charge-), θ and λ (spin-) dependent parameters are found to diverge significantly from those in the bulk HM. Stack ρ was found to agree with Fuchs-Sondheimer[3, 4] and Mayadas-Shatzkes[5] theory, indicating an increase of ρ at low thicknesses due to diffuse surface and grain boundary scattering. In this regime simple SHMR models yield effective θ and λ, which are convoluted over measured thicknesses and thus inappropriate for extracting these parameters. Although ρ, θ and λ vary at low thickness in all devices, buffering resulted in a dramatic increase in the observed SHMR signal, exemplified by the SHMR measurements of Ta/Pt/CoFeB and Pt/CoFeB in Fig. 1. Despite the VW growth mode of the unbuffered Pt/CoFeB, the results appear to agree well[6] with standard bi-layer SHMR MCT assuming a fixed $\rho_{HM,Bulk}$; however, this fails to account for the increase in SHMR signal (due to the divergence of ρ) at low thicknesses for the Ta buffered Pt|CoFeB stack. The MCT tri-layer model with varying ρ_{Pt} fit to experimental data indicates agreement with the EY spin scattering mechanism and implies an intrinsic-dominated spin Hall scattering in Pt films. Revisiting the results of unbuffered Pt/CoFeB films, it is apparent that despite the observed close agreement between theory and experiment, the role of microstructure greatly complicates a precise determination of θ and λ, even in seemingly simple bilayer films. The results presented are in broad agreement with those recently published[7] and provide further evidence in resolving the long-standing reports of highly varied θ and λ of Pt (and other HMs) observed in literature.

HG-01. Nonlinear Modeling of the Flux Linkage in Two-Dimensional Plane for the Planar Switched Reluctance Motor.

G. Cao[1], N. Chen[1], S. Huang[1], S. Xiao[1] and J. He[2]
1. Shenzhen Key Laboratory of Electromagnetic Control, Shenzhen, China; 2. GE Global Research, Schenectady, NY, United States

I. Introduction Planar switched reluctance motors (PSRMs) are an attractive candidate in precision two-dimensional (2-D) positioning devices for applications in microscale manufacturing, semiconductor lithography, etc., because they show the superiorities of simple structure, low cost, low heat loss, high precision, high reliability, and eco-friendly feature [1]–[4]. The flux linkage is the base of the electromagnetic model and control for switched-reluctance-type motors. Therefore, the accurate modeling of the flux linkage plays a key role to achieve precise motion control of switched-reluctance-type motors. However, the flux linkage is hard to be modeled accurately for switched-reluctance-type motors, because they have highly nonlinear magnetic field caused by the inherently double-salient structure and switched excitation. Especially, the accurate flux linkage is much more difficult to be built for the PSRMs owing to their planar structure, because the tolerances of the tooth width, pole pitch, air-gap, etc. are more obvious for planar structure compared to rotary and linear structure. The nonlinear modeling of the flux linkage is continuously concerned for switched-reluctance-type motors [5]–[8]. From the state of the art in the switched-reluctance-type motors, only the model of the flux linkage versus the one-axis position in a pole pitch was built. The model under a pole pitch applied to all position is not accurate, because the manufacturing tolerances are inevitable for practical motors. However, the model is suitable for rotary switched reluctance motors (SRMs), because the manufacturing tolerances are smaller due to the lager pole pitch and smaller number of pole pairs for rotary structure. For the PSRMs, the mover moves in a 2-D plane with long stroke, the manufacturing tolerances are much hard to be reduced against the rotary and linear SRMs. Based on the above description, a nonlinear modeling of the flux linkage in 2-D plane is more appropriate for the PSRMs, which is a promising effective method to achieve precision motion for the PSRMs. In this paper, a nonlinear modeling of the flux linkage in 2-D plane is proposed for the PSRMs by using backpropagation neural network (BPNN), where the current and 2-D positions are the inputs and the flux linkage is the output. The BPNN has the strong ability to deal with the nonlinear modeling with multiple inputs [9], [10]. II. Structure The overall structure of the prototype of the PSRM developed in our laboratory [1]–[4] is shown in Fig. 1. III. Nonlinear Modeling of The Flux Linkage in Two-Dimensional Plane For the mover in phase-*lj* (l=X, Y, j=A, B, C) of the PSRMs, the flux linkage depends on the current of phase-*lj* and the *x*- and *y*-axes position in 2-D plane. By using BPNN, the nonlinear flux linkage in phase-*lj* is modeled. The inputs of the NN are the current of phase-*lj* and the *X*- and *Y*-axes position. The flux linkage in phase-*lj* is the output of the NN. A four layers BPNN is employed to express the flux linkage model. The developed structure of the BPNN is 3-15-15-1. The sample set from experimental measurement is applied to model the BPNN. A dc-excitation method is applied to obtain the flux linkage [11], which is capable of providing a great many of data points. Measuring the current and voltage in phase-*lj*, the flux linkage in phase-*lj* can be calculated with the following equation: $d\Psi(x, y, i)/dt = u(t) - Ri(t)$. (1) IV. Results and Discussion *A. Results* From experiment, the flux linkage in phase-XB versus phase-XB current versus *x*-axis position versus *y*-axis position is obtained, where the current ranges from 0 to 9 A, *x*-axis position ranges from 0 to 14.4 mm, and *y*-axis position ranges from 0 to 21.6 mm. For the sample set with 179755 data points, 50% of data points is chosen as the training data set to build the BPNN expressing as the flux linkage, and the remaining data points are used as the testing data set to assess the generalization performance of the BPNN. Keeping the current in a constant of 5 A, the BPNN-based flux linkage and measurement flux linkage are presented in Fig. 2. The testing results of the BPNN-based flux linkage model and the corresponding errors are shown in Figs. 3-5. *B. Discussion* From Fig. 2, the phase-XB flux linkage is related to the phase-XB current and *X*- and *Y*-axes position; the phase-XB flux linkage mainly depends on *X*-axis position and is simultaneously affected by *Y*-axes position; the phase-XB flux linkage at the same current, the same *Y*-axis position and the same *X*-axis relative position between stator and mover is different for different *X*-axis pole pitches. The above issues mainly result from the manufacturing tolerances. The errors between the BPNN-based and real flux linkage are listed in Table 1. The maximum absolute errors of training and testing are 1.774 and 1.669 mWb, respectively. Under the conditions of the current less than 1 A, the maximum relative errors and the mean relative errors of training and testing are 79.82% and 82.96%, and 8.42% and 8.57%, respectively. Under other conditions, the maximum relative errors and the mean relative errors of training and testing are 1.69%, 1.65%, 0.45% and 0.44%, respectively. For the current less than 1 A, the relative errors are larger because the flux linkage is very near zero at the condition; however, the maximum absolute error is less than 1.774 mWb, and the mean relative error is less than 8.57%. Hence, the built nonlinear flux linkage model has small training and testing errors; the effectiveness of the model for the PSRM is verified experimentally.

I. Introduction The global trend towards the implementation of hybrid and electrical vehicles ((H)EVs) is challenging from the perspective of energy supply and the use of materials with high fluctuation of prices in the international market (e.g. rare earth elements). This article attempts to set the base for a methodology for evaluating the performance of a machine in terms of the recyclability of the permanent magnets (PMs). In this regard, two approaches are available; evaluation of the disassembly process [1] [2] and the energy consumption over the life cycle of the machine [3][4]. The second approach is selected for this study. II. Experimental measurements Measurements were performed on an outer rotor surface mounted PM machine which is generally used in electrical bikes or small city cars [5]. The set-up is presented in figure 1. A resistive load was connected to the machine operating as generator, and values of input and output power were measured. The results of efficiency at different values of torque and speed are summarized in figure 2. III. 2D FEA simulations A. Disassembly In order to obtain the energy consumption over the life cycle of the machine, it was necessary to determine its efficiency map. Therefore, simulations were carried with the main dimensions obtained during the disassembly process. The magnet remanence was measured with the Physical Property Measurement System® from Quantum Design. The properties of the electrical steel in the stator were unknown. However, a standard SiFe lamination was selected. B. Elaboration of efficiency maps Measured current was applied to the simulations. Once the measured and the calculated values were contrasted, the elaboration of the efficiency maps was performed. Since a large amount of points is required to determine the efficiency at any value of torque and speed, the following expression was used: $T=3/2(\Psi_m I_q p)$ Where Ψ_m is the magnet flux linked with the stator windings calculated with FEA, I_q is the current applied in the q-axis and p is the number of pole pairs. Thus, the copper losses were obtained neglecting the effect of the harmonics induced by the modulation of the converter. For obtaining the core losses at any speed, curve fitting was applied to the losses calculated in 2D FEA simulations. IV. Study case The main goal of DEMETER project [6] is the study of the recyclability and reuse of magnets in (H)EVs. Therefore, a study case was defined in order to validate the methodology proposed here. Recycled magnets are expected to have lower remanence. Hence, the remanence adopted for this study case was assumed to be B_r=1 T. Similar values of current were applied to a new set of simulations. In order to obtain similar values of torque, the axial length of the machine was increased. Furthermore, the thermal aspects of having higher copper losses were disregarded for the analysis. The procedure described above was followed for the elaboration of the efficiency maps. V. Results analysis and comparison In addition to the measurements of torque and speed, a no-load test was performed. Such test was intended for enhancing the analysis of the results in the presence of deviations between the measurements at load and the calculated values in simulations. It consisted in running the machine just by pulling the shaft and recording the backemf waveforms in an oscilloscope. A time decaying back-emf wave-form was obtained, and the friction losses were obtained with the expression: $T(t)=J\, d\omega_m/dt + T_L(t)$ Where J is the inertia of the machine, ω_m is the mechanical angular speed and $T_L(t)$ is the load torque. At no load condition $T(t)$ is equal to zero and $T_L(t)$ is composed by the mechanical, iron and magnet losses. The inertia J was estimated with the main dimensions of the machine. The losses as function of the speed of the machine were approximated by curve fitting. On the other hand, the no-load losses from measurements were estimated as: $p_0 = P_m - P_o - p_{cu}$ Where P_m is the input power measured in the power analyser, P_o is the output power read in the torque transducer and p_{cu} are the copper losses calculated as the resistance of the windings times the square of the applied current. Absolute deviations of efficiency of approximately 5% were obtained. Such deviations may be originated due to the effect of some uncertainties: - The alignment of the set-up and oscillations in the readings in the torque transducer. - The specific losses of the laminations, which remained unknown in the calculations. VI. Conclusions The use of magnets with lower remanence will result in an increment of the copper losses. As a consequence of the increment of the resistance of the windings with increased length of the machine for supplying the same amount of torque. Therefore, a larger consumption of energy is expected if a driving cycle like the ECE-15 is considered due to the large intervals of acceleration (i.e. high torque, low speed). For future work it has been defined the study of the energy consumption of the machine analysed here under the European urban driving cycle ECE-15 [7], which corresponds to the initial 200 seconds of the NEDC. For such analyses, it will be required the assumption of some vehicle parameters, such as weight, acceleration, etc., corresponding to a small city car [8]. Additional study cases will be included in order to enhance the evaluation of the impact of the use of recycling magnets in HEVs.

HG-03. Axial Magnetic Force Analysis of Conical-rotor Permanent Magnet Synchronous Motor.

J. Wang[1], S. Huang[1] and *C. Guo*[1]
1. College of Electrical & Information Engineering, Hunan University, Changsha, China

Abstract-The general axial force is suppressed method for the permanent magnet synchronous motor (PMSM) direct-drive blower, pump and turbo-expander, is increase balance devices such as compression spring and special bearing, to counteract its influence, resulting in both complex system structure and higher manufacturing cost. Aiming to solve above issues, this paper presents a novel structure of conical-rotor permanent magnet synchronous motor (CR-PMSM) and studies its axial magnetic force in detail. Which features its axial force is suppressed, simple, and improve efficiency of CR-PMSM. 3-D finite-element model (3-D FE) is used to simulate the magnetic-field distribution and axial magnetic force according to conical-rotor axial displacement and *dq*-axis currents. A prototype machine is designed and built, in order to validate the theory. I.INTRODUCTION Thanks to its simple structure and high energy transfer efficiency, the PMSM direct-drive high-speed blower, pump and turbo-expander, etc., have been widely accepted. However, the axial tension produced by the high speed flow running through the blades of blower, pump and turbo-expander (could be as large as 150N for a 1.6kW and 6000rpm small turbo-expander) usually needs balance devices to counteract its influence, which significantly increase the system complexity and cost. Thus, the CR-PMSG is developed, which features its axial force is suppressed. Therefore, CR-PMSGs have been investigated in recent years. For example, in [1], 3-D finite-element (3-D FE) model is used to simulate the magnetic-field distribution of air gap, flux weakening in CR-PMSM according to rotor axial displacement, instead of changing the current angle. This method is effective in increasing the maximum speed. However, axial magnetic force has not been analyzed; In [2], a novel type of bearingless PMSM of consists of two conical air gap bearingless PM half-motors, mounted on a single shaft.is presented. The value of the axial force depends, besides of the motor geometry, on the PM air gap flux density, air gap cone angle and *d*-axis current. However, the effect of *q*-axis current on axial force is not analyzed. In this paper,the CR-PMSM was analyzed and the effectiveness of two methods on dealing with problems concerned with non-uniform distribution of magnetic field along axial direction in electric motor was studied, which were sectional calculation (SC) method and EF method. The analyzed results were verified by no-load back electromotive force (EMF) experiment of the electric motor. Then, in order to determine the axial magnetic force of CR-PMSM is defined by theoretical analysis. 3-D FE model is adopted to simulate the magnetic-field distribution and axial magnetic force according to rotor axial displacement and *dq*-axis currents. II.Magnetic Field Analysis of CR-PMSG In order to comparative analysis by SC and 3-D EF method, the CR-PMSM is divided into 10 sections, each with a length of only 5.2 mm, and a 1/4 3-D EF model has been established. Its taper angleα, pole pairs p, core length L_{ef}, maximum axial displacement Δz and rated speed n are 6°, 2, 52mm, 4mm and 6000r/min, respectively, as shown in Fig. 1 (a) and (b). When stator is aligned at conical-rotor (Δz=0), the flux density of air gap is shown in Fig. 2 (a), the peak value of radial flux density is about 0.8T while it is 0.25T for the axial one (B_z). Besides, it also can be seen that both waveforms have a 90°, phase difference between each other, comparative difference 0.1T of air gap flux density by SC and 3-D EF method. The no load phase back EMF of CR-PMSG is measured and depicted in Fig. 2 (b), of which the RMS value is about 238V. Compared with the 3-D FE result, it has a quite slight difference (3%), which confirms the accuracy of developed 3-D EF model. When stator is not aligned at conical-rotor (Δz>0), back-EMF is essentially linearly reduced, the performances will be analyzed in detail in the full paper. III. Analysis of Results for Axial Magnetic Force As can be seen from Fig. 2(a), axial magnetic force is being in the air gap. The axial magnetic force can be calculated by the principle of virtual displacement, the air-gap magnetic field (B_δ) can be expressed as a combination of the permanent magnet magnetic field and armature reaction magnetic field. Thus, B_δ is equivalent to the superposition of permanent magnet magnetic field (B_0) and magnetic fields (B_{1d} and B_{1q}) generated by I_d and I_q, respectively. The axial magnetic force simulations with varying *dq*-axis current and conical-rotor at different axial locations are performed, the simulation and measured results are presented in Fig. 2 (c) and (d), similar to the results introduced in [4] the axial magnetic force only has a quite obviously raise with the increase of *d*-axis current. IV.Conclusion In order to suppress the axial force, a CR-PMSM for direct-drive blower, pump and turbo-expander have been developed in this paper. It is found that air gap flux density only has a quite slight increase with the axial directio, and the *d*-axis current plays a quite important role in balancing the axial force produced by the high speed flow. However, it is still quite challenging to derive the expression of axial force with respect to *dq*-axis currents, which will be the priority of future work.

HG-04. Analysis and experimental validation of performance for a switched reluctance motor with pre-fabricated soft magnetic core.

V. Krishnan[1], K. Selvam[2] and K. Radhakrishnan[3]
1. EEE, avviyar college of engineering, Puducherry, India; 2. Research and Development, Greenergy solar solutions, Pondicherry, India; 3. EEE, Sri Venkateswara college of Engineering, Tamilnadu, India

Abstract-Soft magnetic composite (SMC) materials and SMC electromagnetic devices have undergone a significant development in the past decade [1]. Much effort has been carried out on designing and prototyping different types of electrical machine. The basis for soft magnetic composites is bonded iron powder and the powder is coated, pressed into a solid material using a die [1]-[3]. However, it has the drawback that the properties will in most cases be different from those obtained form compaction and machining process. To investigate "pre-fabricated SMC blank"products, this paper presents the design and analysis of a switched reluctance (SR) motor with a pre-fabricated SMC blanks of low mass density to replace the existing induction motor in a dishwasher pump. This can be fast and low cost approach is to machine the component from a preform blank. Finite element analysis (FEA) study has been conducted to accurately determine key motor parameters, and performance predictions are validated by the experimental results on the prototype model. Pre-fabricated SMC core and prototype motor Three pieces of pre-fabricated SMC blanks (Somaloy1000 3P) each for stator and rotor are considered and to fabricate stator and rotor these three pieces have to be bonded together using epoxy glue [1]-[3]. The bonded stator and rotor blank has been subjected to precession machining to yield the stator and rotor of design dimensions. Glimpses of the fabrication process and experimental setup have been illustrated in Fig.1 and 2. Experimental validation Dynamic characteristics Fig. 2 shows the experimental setup for measuring the motor performance. The SMC motor prototype is on the first, and a mechanically coupled dynamo load cell is on the second. A load cell is mounted on the dynamo which is directly connected to high speed dynamo controller for measuring the shaft torque and speed [4]. Fig. 3 plots the mechanical characteristics, i.e., the motor speed against the dc link voltage of power converter with certain load. The motor can successfully deliver a torque of 1.2 Nm at 3000 rpm while the converter is supplied with a dc link voltage of about 85 V. Fig. 4 shows phase current wave form comparison of measured and FE calculated. Thermal study The comparison of measured and FE predicted hot spot results in all the windings and stator core temperatures of SMC prototype are as given in Table I. Six type-T thermocouples embedded in six stator windings and remaining two thermocouples fixed in stator core and outer casing of the prototype. The operating conditions for the experimental thermal study are given in Table II. Vibration study The vibration spectrum generated in the SMC prototype is measured using the accelerometer to validate the estimations. To measure the vibration the accelerometer pickup point's location are behind a stator pole and between two poles [2], [5] and [6]. The operating frequency of the accelerometer is selected according to the switching frequency. The Fig. 5 shows the measured acceleration and its spectrum of the SMC prototype. The FE predicted mode shape vibration frequencies and measured spectrum frequencies of SMC prototype for modes 2 and 4 are compared in Table III. The measured vibration spectrum of the SMC prototype is captured at a speed of 2947 RPM, 68 V. Conclusion and discussion The following inferences are observed from the measured dynamic characteristics of SMC prototype machine: The prototype provides a stable output on a full operating range, even though the problems of large magnetizing current and inferior magnetizing curve with lower μr-max values of 850. The dynamic performances are fully dependent on the nature of the stator core and losses of the machine. It is also revealed that during the dynamic operating condition, the initial current drawn by the SMC machine is higher due to the requirement of higher level of magnetization energy in bulk material than in laminates for a cycle of the source frequency. The comparative analysis of measured temperature rise values of the SMC prototype machine and simulation results shows: the SMC machine temperature rise is lesser than conventional machine. This is due to the SMC stator core is a smooth surface that allows a good thermal contact between the winding and the core assembly. Moreover this lead to more efficient electromagnetic coupling as well as more efficient heat transfers ability and cooling capability. This enhances the thermal limit of the SMC prototype motor. The comparative analysis of measured vibration frequencies of the SMC prototype machine and FEA results of natural mode shape frequencies of stator and rotor shows: the marked reduction in the natural frequencies of the stator and rotor assembly of SMC machine due to the cushioning nature of the insulation binder which has a very good viscous-elasticity property and iron powder cores would present a higher damping factor in the radial and circumferential directions compared to a similar laminated structure. As observed from the measured vibration spectrum, only two mode frequencies (mode 2 and mode 4) are dominant in the spectrum and other mode frequencies are suppressed since the acceleration particles in the SMC stator structure are evenly distributed due to the distributed insulation around the iron particles.

HG-05. Study on Static Magnetic Characteristics of a Switched Reluctance Motor with 12/10 Poles under Different Operation Modes.

Y. Hu[1] and W. Ding[1]
1. Xi'an Jiaotong University, Xi'an, China

This paper mainly focuses on the static inductance and flux linkage characteristics of a switched reluctance motor (SRM) with 12/10 poles when it respectively works as a six- and a three-phase mode. The single and double excitations are also individually taken into consideration for the two modes. The simulations are experimentally verified by using an indirect flux measurement method. The consistency between the simulations and experimental results verifies the validity of the theory.

I. INTRODUCTION

It is observed that an SRM with 12 stator poles and 10 rotor poles is able to work as a six-phase motor but also a three-phase motor by changing its winding connection. In general, multiphase SRMs are characterized by higher energy density, less torque ripple and better ability at fault tolerance; while the conventional schemes, such as three-phase or four-phase SRMs are characterized by the simplicity and low cost of the drive system [1, 2].

In order to probe into the performances of an SRM with 12/10 poles at different winding connections, it is necessary to make an investigation about its individual inductance and flux linkage characteristics under six- and three-phase modes.

The content of this paper will be organized as follows: the relevant achievements will be summarized and commented in this section; the inductance characteristics of 12/10-pole SRM working as a six- or a three-phase motor will be comparatively discussed in section II by considering single and double excitation modes; section III will focus on the experimental verification on flux linkage characteristics with different situations; conclusions will be presented in section IV.

II. INDUCTANCE CHARACTERISTICS OF A 12/10-POLE SRM UNDER DIFFERENT MODES

As far as a 12/10-pole SRM is concerned, it is noticed that the step angle is 6° for six-phase mode and 12° for three-phase mode. Normally, the six-phase motor operates with two or more phases excitation, while the three-phase motor operates at single-phase excitation but current overlap is inevitable. Therefore, both single and double excitation modes for six- and three-phase operations will be studied in this paper.

A. Inductance Characteristics of Six-Phase Mode with Single Phase Excitation

Single phase excitation is first given for a six-phase motor. Taking phase A as an example, Fig.1 shows the self inductance of phase A and mutual inductance of other phases with different currents and rotor position. Among them, subgraph (a) shows the self inductance of the excited phase A; subgraph (b) shows the mutual inductance between the excited phase A and phase B whose is the upcoming phase of phase A; and subgraph (c) shows the mutual inductance between the excited phase A and phase C whose is the upcoming phase of phase B. And the magnetic path of the motor with single phase excitation is also illustrated in Fig.1 (d).

Fig. 1 The inductance characteristics and flux path under single excitation (a) Self inductance; (b) Mutual inductance between phase A and phase B; (c) Mutual inductance between phase A and phase C; (d) Flux path

B. Inductance Characteristics of Six-Phase Mode with Double Phase Excitation

The magnetic path of the motor with double phase excitation has two types--long and short flux path modes, which are determined by the polarities of the two adjacent excitation poles.

1) Long flux path mode

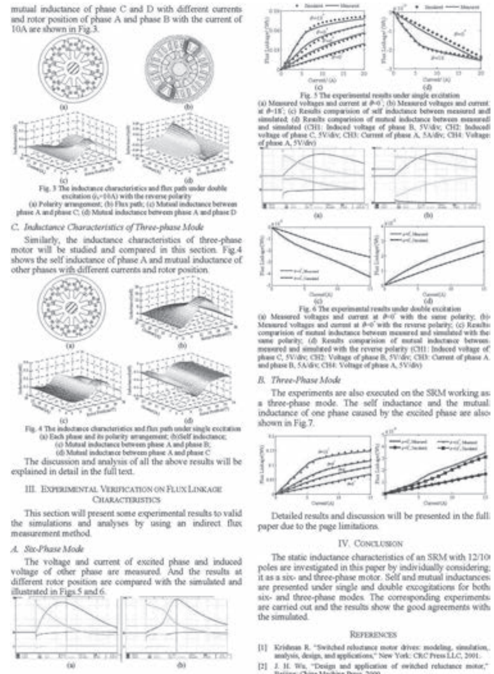
When the polarities of the two excitation poles are the same, long flux path will be obtained. Taking phase A and B as an example, Fig.2 displays their polarities, flux path, mutual inductance of phase C and D with different currents and rotor position of phase A and phase B with the current of 10A.

Fig. 2 The inductance characteristics and flux path under double excitation (i_s=10A) with the same polarity (a) Polarity arrangement; (b) Flux path; (c) Mutual inductance between phase A and phase C; (d) Mutual inductance between phase A and phase D

2) Short flux path mode

When the polarities of the two excitation poles are reverse, short flux path will be obtained. The polarities, flux path,

Fig. 1. Study on Static Magnetic Characteristics of a Switched Reluctance Motor with 1210 Poles under Different Operation Modes_1



mutual inductance of phase C and D with different currents and rotor position of phase A and phase B with the current of 10A are shown in Fig.3.

Fig. 3 The inductance characteristics and flux path under double excitation (i_s=10A) with the reverse polarity (a) Polarity arrangement; (b) Flux path; (c) Mutual inductance between phase A and phase C; (d) Mutual inductance between phase A and phase D

C. Inductance Characteristics of Three-phase Mode

Similarly, the inductance characteristics of three-phase motor will be studied and compared in this section. Fig.4 shows the self inductance of phase A and mutual inductance of other phases with different currents and rotor position.

Fig. 4 The inductance characteristics and flux path under single excitation (a) Each phase and its polarity arrangement; (b)Self inductance; (c) Mutual inductance between phase A and phase B; (d) Mutual inductance between phase A and phase C

The discussion and analysis of all the above results will be explained in detail in the full text.

III. EXPERIMENTAL VERIFICATION ON FLUX LINKAGE CHARACTERISTICS

This section will present some experimental results to valid the simulations and analyses by using an indirect flux measurement method.

A. Six-Phase Mode

The voltage and current of excited phase and induced voltage of other phase are measured. And the results at different rotor position are compared with the simulated and illustrated in Figs.5 and 6.

Fig. 5 The experimental results under single excitation (a) Measured voltages and current at θ=0°; (b) Measured voltages and current at θ=18°; (c) Results comparision of self inductance between measured and simulated; (d) Results comparision of mutual inductance between measured and simulated (CH1: Induced voltage of phase B, 5V/div; CH2: Induced voltage of phase C, 5V/div; CH3: Current of phase A, 5A/div; CH4: Voltage of phase A, 5V/div)

Fig. 6 The experimental results under double excitation (a) Measured voltages and current at θ=0° with the same polarity; (b) Measured voltages and current at θ=0° with the reverse polarity; (c) Results comparision of mutual inductance between measured and simulated with the same polarity; (d) Results comparision of mutual inductance between measured and simulated with the reverse polarity (CH1: Induced voltage of phase C, 5V/div; CH2: Voltage of phase B, 5V/div; CH3: Current of phase A and phase B, 5A/div; CH4: Voltage of phase A, 5V/div)

B. Three-Phase Mode

The experiments are also executed on the SRM working as a three-phase mode. The self inductance and the mutual inductance of one phase caused by the excited phase are also shown in Fig.7.

Detailed results and discussion will be presented in the full paper due to the page limitations.

IV. CONCLUSION

The static inductance characteristics of an SRM with 12/10 poles are investigated in this paper by individually considering it as a six- and three-phase motor. Self and mutual inductances are presented under single and double excogitations for both six- and three-phase modes. The corresponding experiments are carried out and the results show the good agreements with the simulated.

HG-06. Demagnetization under normal operation in variable flux PM-assisted Synchronous Reluctance Machines.

I. Manolas[1], A. Kladas[2], D. Svechkarenko[1] and R. Chin[1]
1. Corporate Research Sweden, ABB, Västerås, Sweden; 2. School of Electrical and Computer Engineering, National Technical University of Athens, Zografou, Greece

In the field of electrical machine design, the mainstream approach is to fix the key electromagnetic design parameters in a way that yields an acceptable performance over the operating range. Moreover, these parameters should ideally remain unaltered for accurate control and behavior prediction. However, this approach might be revised radically as novel magnetic materials emerge along with the capabilities of power electronic converters. Indeed, it should be possible to design a machine with configurable electromagnetic properties during operation. Variable flux memory machines (VFMMs) [1], [2] utilize permanent magnet materials that change the intensity of their magnetization and "memorize" various flux density levels. This is achieved via employing low coercive force (Hc) materials and applying appropriate current pulses through the standard machine windings for a very short time during normal operation. This yields adjustable torque/power profiles with wider speed ranges and increased efficiency, even during field weakening operation. In this paper, Permanent Magnet assisted Synchronous Reluctance Machines are considered incorporating low coercive force magnets (e.g. AlNiCo). The objective of this work is to focus on the demagnetization that occurs under normal operation, when the magnetization levels in the machine should be adjusted - for instance, during high speed operation. As an outcome of this study, a proper demagnetization strategy is proposed that achieves the required magnetization levels in the machine with minimum stator current requirement (converter overload) and minimum possible disturbance on the mechanical load side (transient torque overshoot) [3]-[5]. To capture the complex phenomena related to the permanent demagnetization of PM materials, a non-conventional hysteresis-based finite element simulation tool needs to be developed, which should be able to reflect the permanently changed magnetic properties of the PM after a short-time high-amplitude current pulse. In this case, the resulting operating point will no longer lie along the original BH curve, but along the demagnetized recoil line at the worst operating condition and a special set of three sequential simulations is developed to handle such cases. The first simulation creates a mesh of elements on the PMs and generates from the manufacturer's hysteresis material properties an element based demagnetization curve. That is subsequently supplied to the second simulation that makes an element based calculation of the demagnetization in the magnets. The output is an element mesh containing single values and directions of coercivity (Hc) that reflect the demagnetized states. This is subsequently fed to the final simulation that makes the real application performance calculation employing the imported demagnetization states. Using the aforementioned simulation method, it is possible to consistently capture the machine performance in terms of torque, current, voltage and no-load back-EMF before and after a short high-current pulse intended to cause demagnetization. Under conventional simulations, after applying and removing the high current pulse the machine performance would be restored to the original level (impossible to simulate permanent demagnetization). However, in reality the performance should show degraded. Thus, via the introduced method, the machine is simulated under a current pulse that intends to alter the magnetization level. The three parameters considered are the amplitude of the current pulse, its time duration and the direction of the imposed field to the rotor governed by the current angle. The effectiveness of the magnetization change strategy and its impact on the normal machine operation is investigated versus these three parameters. Coming to the conclusions, firstly due to the machine inductances there is a minimum pulse time duration required to allow for an effective change of the magnetization. For the machine examined this minimum duration was found to be 5ms. Moreover, it is self-evident that by increasing the current pulse amplitude the demagnetization becomes more effective. However, the relation is not linear, and once the current exceeds a certain upper value, the permanent magnets become fully demagnetized - thereafter the machine turns into a pure Synchronous Reluctance Machine. Finally, when it comes to choosing the appropriate current angle for the pulse, the deciding criterion is to avoid any disturbance on the mechanical load side – neither torque overshoot nor sag. This is always feasible through proper choice of the current angle. Therefore, a coordination between the chosen current angle and the imposed current amplitude for the demagnetizing pulse is found to achieve the predefined demagnetization target minimizing the current requirements and the mechanical disturbances. To exhibit the feasibility of the suggested strategy and the superior machine performance that the VFMM concept yields, a demonstrator variable flux memory PMaSynRM is simulated over the complete speed range.

HG-07. Design Procedure for a 4-pole, External Rotor Synchronous Reluctance Motor (Ex-R SynRM) for the Application Mechanical Constraints.

R. Azhagar[1] and A. Kavitha[1]
1. Electrical and Electronics Engineering, College of Engineering, Anna University, Chennai, India

ABSTRACT This paper presents a step by step design procedure of developing a 4-pole, External-Rotor Synchronous Reluctance Motor. Here, this is a first attempt to derive the analytical design equation from the fundamentals of motor design for the given mechanical constraints. Initially, the stator bore diameter has been predicted from the torque requirement with certain assumptions on the design data. Then the stator slot dimensions are predicted for the rounded semi-closed slot type by considering distributed winding. Then the external rotor geometry with circular shape flux barrier has been considered for the study and its performance characteristics are predicted using finite element analysis. The results are compared with analytical calculations and finally, a feasible rotor geometry is proposed with further investigation. INTRODUCTION In recent times, Direct Drive Motors (DDM) are gaining confidence in high torque, low-speed application due to its increased efficiency, reliability, maintainability and responsiveness [1]. The most application uses Induction motor as drive along with mechanical reduction like a belt, pulley, chain, and gear. This domestic appliance called wet grinder uses single-phase induction motor is used either with a belt or gear mechanism which generates a lot of noise and vibration. The load characteristic of the application requires constant torque at very low speed to maintain the batter at room temperature. This is important to achieve better fermentation which makes the batter soft to get a good taste. One of the major concern is that long time for grinding which increases the power consumption [2]. The external rotor configuration provides many advantages over the internal rotor and it is more suitable for an application where the outside body (wind turbine, fan) made to rotate. Here, the drum is the rotating body which kept outside. Also, the larger inertia of external rotor provides constant speed operation for varying load condition [4]. DESIRED APPLICATION REQUIREMENTS The motor design needs to fit into the dimensions of the drum used in the grinder application whose maximum available diameter is 250 mm. The diameter and axial length of the motor are chosen in such way that it can fit inside the periphery of a drum with clearance between motor and housing to provide natural cooling. The stack length is chosen as 40 mm which can fit inside the housing and also to provide space for winding overhang. The shaft torque requirement of the application is 12 Nm at the low speed of 150 RPM with the peak torque of 14 Nm. DESIGN OF EX-R SynRM The initial design dimensions are derived from the analytical design equations. The step by step procedure of design algorithm is shown In Fig 2 [7]. In this study, the geometry of rotor barrier has been chosen such that it follows the shape of flux lines with a solid rotor. The profile of barrier is designed for circular shape with three number of barriers and its dimensions are optimized to maximize the saliency ratio [5, 6]. FINITE ELEMENT ANALYSIS (FEA) OF Ex-R SynRM The motor considered for the study is analyzed using a 2-Dimensional (2D) FEA simulation under static and transient conditions. It is a 4-pole motor having 3-phase distributed winding in 36 slots shown in Fg.1. A.Static Analysis (Rotor is Standstill) In this, the rotor of the Ex-R SynRM is kept at a mechanical rotor position corresponding to d and q-axis to predict the d and q-axis inductances. The d-axis inductance (L_d) predicted with d axis excitation current I_d as (I_a=I, I_b=-I/2, and I_c=-I/2) while Lq is predicted with q-axis excitation current Iq as (I_a=I, I_b=-I/2, and I_c=-I/2) by varying current from 0 to 25 Amps. B.Transient Analysis (Rotor is Rotating) Here, the rotor of the Ex-R SynRM is kept at various mechanical rotor position (0 to 45 deg) corresponding to the current angle in electrical degrees (0 to 90 deg) and predicted torque. This helps in identifying the current angle which produces maximum torque. ANALYSIS OF RESULTS To optimize the position and size of the barriers in the rotor of the SynRM with torque ripple reduction as the prime objective.The initial model with three rotor barrier is taken as reference. Initially, the position of the second barrier is adjusted in order to minimize torque ripple. This is done by adjusting the span of the barrier (increasing or decreasing the angle by few degrees(say 2 deg) The same procedure is attempted with other barriers and their effect on the transient torque is studied.The models which produce least torque ripple is selected at each level and next iterations are done with that model. As a next step, the barrier thicknesses are varied uniformly and non uniformly for all three barriers and studied the effect.Finally, the end of barrier shape also studied and proposed a rotor which provides high saliency ratio, average torque, and less torque ripple. The simulation results of the above study are tabulated in Table 1.

HG-08. Design of a High-Effective Fault-Tolerance Double-Stator Magnetless Vernier Machine for Direct-Drive Robotics.

J. Yu[1] and *C. Liu*[1]
1. School of Energy and Environment, City University of Hong Kong, Hong Kong, China

Introduction Regarded as the succedaneum of human handlers, robots accommodate tremendous advantages of labor saving, high reliability and ideal alternatives on dangerous work [1]-[4]. Since gearboxes give rise to high frictional loss, noise and vibration [5], direct-drive robots have become more and more attractive with low acoustic noise, free maintenance and high efficiency. Meanwhile, the machines employed for the direct-drive robotics are required with high controllability, high fault-tolerance and sufficient torque capacity. Considering the high material cost and flux uncontrollability of the PM, DC-excited machines have been dedicated more attention [6][7]. This paper proposes a high-effective fault-tolerance double-stator magnetless vernier (DSMV) machine for direct-drive robotics. By virtue of the integration of DC-winding excitation, double-stator structure and vernier topology, the DSMV machine accommodates the merits of cost-effectiveness, high flux controllability, adequate torque density under low-speed operation and low torque ripple to 3.90%. Moreover, through the fault-tolerance operation, the torque performances of both one-phase and two-phase deficiencies recover to the normal level, with torque ripple slightly deteriorated. Both theoretical derivation and demonstration are given for the validation of the DSMV machine design and the high-effective fault-tolerance operation. Machine Design and Fault-Tolerance Operation Principle Fig.1 presents the topology of the proposed DSMV machine, in cross-section and exploded perspectives. The double stators accommodate 18 split flux modulation poles (FMPs), with 24-pole segmented rotor in the middle. Polyester is embedded between rotor irons as fixation. Two sets of concentrated armature windings are allocated in the embedded slots, while DC-windings are coiled in series-opposing connection on FMPs. The winding arrangement makes full use of the machine space. Moreover, to improve the machine flux property, the DC-windings incline an angle instead of perpendicular to the FMPs. In addition, the discrete segmented rotor leaves out the rotor yoke, which contributes to rotor weight reduction, efficiency improvement and flux path shortening [8]. Meanwhile, the iron-only rotor increases the robustness and decreases the manufacturing difficulty of the machine. Furthermore, high-effective fault-tolerance operation of open-circuit faults is adopted. Through phase and amplitude reconstitution of the intact armature currents, the MMF of the machine can remain constant and realize torque performance recovery under faulty conditions [9]. For instance of A-phase deficiency, the normal and remedial MMFs are governed by Equation. (1). N is the phase armature winding turn number, is the phase currents displacement, Ia, Ib and Ic are normal phase armature currents, while I′b and I′c are remedial phase armature currents. With BLAC conduction scheme, the armature currents comply with Equation. (2), where I is the phase current amplitude and θ0 is the initial phase angle of phase A. Based on Equation. (1), the remedial armature currents can be deduced as Equation. (3). For double-stator machines, the fault-tolerant operation is also applicative as two single-stator machines. Analysis & Results Considering the target application, the machine outer stator diameter is 160 mm, the stack length is 120 mm, rated DC current is 5 A, and rated speed is 200 rpm. Under different conditions, the DC current can be modified accordingly for flux modulation. Fig. 2 shows the torque performances of the DSMV machine. Fig. 2(a) presents the torque performances under different rotor pole arc angle γ. Within the rational range, γ=2.8° is the optimal alternative to achieve the maximum torque average and the minimum torque ripple. Also, torque performance comparison as the current phase angle α varies is demonstrated in Fig. 2(b). The smallest torque ripple occurs at α=8°, while the largest torque average turns out at α=11°. The final α is determined to be 10° as a compromise. As a result, the optimal steady torque in Fig. 2(c) accommodates the average of 11.79 Nm and the ripple of 3.90%. The cogging torque amplitude is also presented in Fig. 2(c) with only 0.72 Nm. Furthermore, the results of one-phase and two-phase fault-tolerance operations are shown in Fig. 2(c) and (d) respectively. For the two cases of one-phase deficiency, the torque performances deteriorate into 10.86 Nm, 21.57% and 10.69 Nm, 26.16%. While the corresponding remedial performances recover to 11.78 Nm, 4.00% and 11.74 Nm, 7.04%. It can be analyzed in the same manner in two-phase fault-tolerance cases. With remedial operation, the torque average recovers from 8.99 Nm, 9.54 Nm to 11.74 Nm, 11.74 Nm accordingly. Meanwhile, the torque ripple reverts from 76.93%, 39.47% to 8.31%, 6.89% respectively. Therefore, through fault-tolerant operation, the DSMV machine can operate at one- and two-phase deficiency condition with the same torque level and slightly higher torque ripple. Other machine performances will be analyzed in the full paper. The work was supported by a grant (Project No. CityU21201216) from Hong Kong Research Council, Hong Kong, China.

HG-09. Analysis of Local Demagnetization in Magnet for PM-Assisted Synchronous Reluctance Motors.

H.T. Anh[2] and M. Hsieh[1]

1. Department of Electrical Engineering, National Cheng Kung University, Tainan, Taiwan; 2. Department of Systems and Naval Mechatronic Engineering, National Cheng Kung University, Tainan, Taiwan

Abstract — This digest investigates the demagnetization risk of permanent magnet-assisted synchronous reluctance machines (PMa-SynRM). PMa-SynRM is often designed with multilayer PMs/flux barriers to increase saliency and reluctance torque. Weaker or less PM (than that for IPM motor) is embedded into the rotor of PMa-SynRM, which can be demagnetized during high-performance operation (e.g., high armature reaction or current phase advance control). Demagnetization possibility of PM depends on factors such as temperature, armature current and design operating points and mostly occurs combining some of the above factors. The temperature distribution across the PM can be different and the operating points at different locations in the PM can also vary. This very likely causes local demagnetization within a PM. This work proposes a method to evaluate the demagnetization risk within a PM for all the PM layers of PMa-SynRM rotors. A model based on the magnetic circuit is first developed to calculate the operating points across the PM at the no-load and loaded condition. The magnet temperature distribution is then estimated with a commercial software. With the temperature and loaded operating points of the PM, the risk of local demagnetization can be predicted. This is validated using finite element analysis. From the analysis, a design method that can avoid demagnetization is then proposed. Experimental studies are conducted to validate the simulations. *I. Introduction* PMa-SynRM is known as a good candidate for traction motors of electric vehicles (EVs) due to its decent torque density with low PM usage and cost, high efficiency and a wide speed range [1, 2]. PMa-SynRM is often designed with weaker or less PM than that for IPM motor; therefore, potential demagnetization during high-performance operation (e.g., high armature reaction or flux weakening) can occur [3]. PM demagnetization may be caused by the factors such as temperature, armature current magnitude, design operating points and deep flux weakening [3-4]. Ref. [3] shows that the risk of demagnetization of PM is different at each PM position for PMa-SynRM. However, this has not been sufficiently studied. Methods to predict local demagnetization and approaches to design the rotor that can avoid demagnetization have not been well proposed. Ref. [4] determined that the temperature distribution on V-shaped PM surface of the interior permanent magnet synchronous machine (IPMSM) is non-linear, where the highest temperature locates at the center of PM surface. Also, the temperature may also vary at different PM layers. Therefore, the cause of local demagnetization in each PM can be the combination of the temperature distribution across the PM and the PM operating points in the PM under load condition. This has not been clearly studied. This paper investigates the risk of local demagnetization in a PM for PMa-SynRM. The developed magnetic equivalent circuit is capable of identifying the operating points in the PM. The temperature at different PM layer and the temperature distribution across the magnet are calculated using 3-D finite element analysis. With the above analysis, the combined temperature and operating point information can be obtained for determination of local demagnetization in a PM, as well as for different PM layers. Finally, the design method to avoid demagnetization is proposed. Experimental studies are conducted to validate the simulations. *II. The Target Machine and Method* The prototype of a 10 kW PMa-SynRM is considered for study and the magnet positions are as labelled in Fig.1. This PMa-SynRM is designed with five flux barriers per pole and only four of them are considered to be added with PMs (except the outermost one) to reduce the torque ripple and increase the reluctance torque. The main specifications of the motor are given in Fig. 1. As stated, the magnetic equivalent circuit is developed to calculate the detailed operating point in a PM and FEA is to obtain the temperature distribution. The details will be reported in the full paper. *III. Results and Conclusion* Fig. 2 shows the operating points for each PM and for different PM layers at no-load and load condition. As can be seen, for example, the label "4th PM Load" indicates the load condition for PM at position 4. There are four points for each PM and they represent the operating points at four different locations in the PM. In Fig. 3, the temperature limit of a PM related to the output torque within a speed range is presented. This would clearly show that the temperature limit of PM would limit the motor performance. The magnet temperature increases as the motor torque increases, leading to the possible local demagnetization or even entire demagnetization. Detail analysis and experimental results will be given in the full paper.

HG-10. An Integrated Motor-Drive and Battery-charging System Utilizing Doubly Salient Electro-magnet Machine with Split Field Windings.

T. Zhang[1], *J. Wei*[1], P. Liu[1], W. Tao[1] and B. Zhou[1]
1. Jiangsu Key Laboratory of New Energy Generation and Power Conversion, Nanjing University of Aeronautics and Astronautics, Nanjing, China

Abstract: In this paper, an integrated motor-drive and battery-charging(IMB) system for doubly salient electro-magnet machine(DSEM) is proposed to be implemented onboard for electric vehicles(EV). The field windings distribution of a 12/10 DSEM is arranged for the constant self-inductance, and adopted as the inductance of the front-end DC/DC converter to eliminate the traditional filter inductance and excitation loss of the machine in the driving mode. The armature windings could be exploited as the filter inductances in the charging mode. The simulations and experiments are accomplished to verify the feasibility of the independent field current control method for the proposed system. I. Introduction The IMB system is a critical onboard equipment for electric vehicles due to low bulk, weight and high convenience[1]. As the armature windings of the machine could be adopted as the filter inductance, the less permanent magnet machines, such as induction motor and switched reluctance motor, are the better candidates for EV than permanent magnet machine with higher phase inductance. However, the filter inductance is still necessary in the front-end DC-DC converter for voltage boost and recharge of the battery. Literature [2] proposed a method that one phase winding is multiplex as the inductance of the DC-DC converter, and another two phase windings are exploited in the single phase AC power source in the charging mode, but the unbalanced phase current leads to the undesired torque and vibration. DSEM with the inherent features of simple structure and high robustness characteristics is an attractive candidate of the machine in EV. This paper proposes a novel IMB system with the cascade inverter topology for DSEM, where the field windings of DSEM are split and integrated as filter inductances in the front-end DC/DC converter. II. System configuration and control strategy The proposed IMB system is shown in Fig.1. The field windings of DSEM are arranged in each slot of the stator to decouple the field windings and armature windings, then, the self-inductance of the phase windings can be maintained constant, which is different to traditional DSEM. The split field windings of DSEM are accomplished by the series connection of the nearest coils, and they are divided into two sections F_1 and F_2, which have the same amplitude of self-inductance to be multiplexed as the filter inductances in the front-end DC/DC converter. In the driving mode, the DC/DC converter works in the interleaved boost mode while S_7 is open. The voltage equation based on power relations can be deduced as $2i_F\,(d_1u_b\text{-}k_e\omega i_P)=\Delta P_C$, where i_F and i_P are the currents of field windings and armature windings, d_1 is the duty circle of S_1 and S_2, u_b is the battery voltage, k_e is a back-EMF coefficient, ω is the speed of DSEM, ΔP_C is the power variation of DC bus capacitor. Accordingly, the voltage of the DC bus can be controlled by d_1 directly while the power of the capacitor is constant, then the currents of two field windings can be separately controlled by S_4 and S_6. As the double-closed-loop control method is employed for DSEM, and it could be sorted as the constant power load for the DC/DC converter. Hence, the independent field current control method with the capacitor power control algorithm are designed for the IMB system. In the braking mode, S_1, S_2, S_4, S_6 turn off and S_7 turns on, then the front-end DC/DC converter works as a buck converter, and the field winding currents are regulated by S_3 and S_5. The DSEM works in the generating mode and the reference armature winding currents are regulated to maintain the DC bus voltage. In the charging mode, S_1, S_2, S_4, S_5, S_7 turn off and S_3 turns on, two field windings and the battery work in series and the current is regulated by S_6, where the front-end converter works as a buck converter. SVPWM is employed to energize S_8 to S_{13} as a three-phase PWM rectifier. III. Verifications The simulation is carried out based on a 20kW 12/10-pole DSEM, where the self-inductance of field windings and armature windings are 2.2mH and 1mH respectively. The switching frequency is 8kHz. The battery voltage is 250V. The simulation results of driving and braking operations including the DC bus voltage, the field winding currents and the speed are shown in Fig.2(a)-(c). In the driving mode, the bus voltage ripple is lower than 5% with a 220uF capacitor, the field current can be controlled separately and the ripple can be decreased by the interleaved topology. In the braking mode, the regenerated power of DSEM comes back to recharge the battery. In the charging mode shown in Fig.2(d), the field windings' currents are equal and in opposite directions to suppress the excitation field to eliminate the output torque of DSEM, and the constant recharging current could be achieved with a low current ripple of 15%. The experiment is implemented to validate the proposed system on the prototype of a 12/10-pole 5kW DSEM, and the detailed results will be presented in the full manuscript. IV. Conclusion This paper proposes a novel IMB system for DSEM, where the field windings are arranged and integrated in the front-end DC/DC converter to improve the efficiency. The driving, braking and charging methods are presented and validated by simulations and experiments.

HG-11. Electromagnetic Performance comparison of multi-layered Interior PM machines for EV Traction Applications.

M. Xie[1]
1. Nanjing University of Aeronautics and Astronautics, Nanjing, China

I. Introduction Multi-layered Interior permanent magnet (IPM) machines are attractive for the electric vehicle (EV) applications especially on the 2016 BMW i3, and 2017 Prius [1], [2]. This paper compared the electromagnetic performance of three Multi-layered IPM machines. The electromagnetic performance including the no-load air-gap density, torque density, torque ripple, d- and q-axis inductances, saliency ratio, characteristic current, core loss, magnet eddy-current loss, and the efficiency. II. Main Body Fig. 1 shows the magnet configurations of three multi-layered IPM machines. The two-layered IPM machine with “U−” model is model I which similar to the 2017 Prius, the two-layered IPM machine with “2−” model is model II which similar to the 2016 BMW i3, and the three-layered IPM machine with “U▽” is model III. The total volumes of the permanent magnets (NdFeB) in three models are identical. The rated power of the machines is 48 kW, the continuous rated torque (rated torque) is 100 Nm, and the maximum speed of the machines is 12000 r/min. The harmonics of air-gap density of model III is smaller than that of the model I and model II due to the increase of rotor magnet layers. The FEA predicted average torque of model I is 104.2 Nm, the model II is 88.5 Nm, the model III is 104.9 Nm. The average torque of model II is lowest due to the magnets of model II is buried deeply, the utilization of magnets is lower than the model I and model III. The FEA predicted torque ripple and core loss of three multi-layered IPM machines are analyzed and compared. The model III has the lowest torque ripple and core loss because the harmonics of air-gap density of model III is the lowest. The magnet eddy-current loss of three multi-layered IPM machines are investigated at 12000 r/min. The magnet eddy-current loss of model II is lowest due to the magnets of model II is buried deeply, none have the tangential magnets, the effects of the armature-reaction flux is lower than the model I. The model III has the highest magnet eddy-current loss. A prototype IPM machine with model III is manufactured to verify the results of the analysis. Fig. 2(a) shows the photographs of the rotor and windings. The simulated and measured average torque of the prototype machine are shown in Fig. 2(b). The total iron loss and efficiency are simulated and measured, they have good agreement. III. Conclusion This paper has analyzed and compared the electromagnetic performance of three multi-layered IPM machines for electric vehicle applications. The torque density of model II is the lowest due to the magnets of model II is buried deeply, the utilization of magnets is lower than the model I and model III. The magnet eddy-current loss of model II is the lowest due to the magnets of model II is buried deeply, none have the tangential magnets, the effects of the armature-reaction flux is lower than the model I and model III. The model III has the lowest torque ripple and core loss because the harmonics of air-gap density of model III is the lowest.

HG-12. Design and Characterization of a single-phase Main Exciter for Aircraft Starter-Generator.

J. Li[1], Z. Zhang[1], Y. Liu[1], J. Lu[1] and Z. Chen[1]
1. Nanjing University of Aeronautics and Astronautics, Nanjing, China

I. INTRODUCTION An aircraft three-stage starter-generator (SG) may includes three separate brushless generators, namely, a permanent magnet generator (PMG), a single-phase main exciter (ME), and a main starter/generator (MSG). A SG may be used to start the engines or auxiliary power unit (APU) when operating as a starter, and to supply electrical power to electric consumer when operating as a generator [1]. For getting optimal performance, the single-phase ME needs to satisfy the required current output in both generating mode and starting mode [2]. Therefore, the design and characteristic analysis of ME in two modes is remarkably necessary. In this paper, a single-phase main exciter for aircraft SG in both generating mode and starting mode is proposed and investigated. II. CONFIGURATION AND OPERATION PRINCIPLE In a general way, aircraft SG mainly operates in generating mode for powering electrical loads on-board. As shown in Fig. 1, a chopper controlled by generator control unit (GCU) is used to control the excitation current I_{ef} of ME. With the rotating of the rotor, the ME's rotor windings generate AC current which is rectified by a rotating rectifier into the field winding of MG.. It can be seen that the MG field current I_F is regulated by I_{ef} directly. The ephemeral but important function of SG is to produce motive power on the shaft in starting mode. When SG is in stationary or at low speed, AC power should be supplied to the ME stator winding via a ME inverter, as shown in Fig. 1. Fig. 2 shows the topology of proposed single-phase ME with excitation windings on stator and three phase armature windings and rotating rectifier on rotor. The excitation current I_{ef} of the ME is converted to the excitation current I_F of MG, thus the brushless rotor is realized. III. PERFORMANCE AND ANALYSIS The parameters for the design of single-phase ME are given in Table I. Fig. 3 shows the equivalent circuit of ME. For the ME, its load is the resistance R_F and self-inductance L_F of the field winding of the MG both in generating mode and starting mode. A. Generating mode Fig. 4 shows the performance of the proposed ME. The iron core is close to the saturated zone when the excitation current I_{ef} is 20A. Due to the variation range of working temperature of aircraft SG is relatively wide, typically from -60 degree centigrade to 180 degree centigrade, the R_F is changed from 0.179Ω to 0.424Ω. That is to say, the load of ME is approximately changed 2.37 times. The output design of ME has constant current source characteristic, especially with light load (I_{ef}=4A). Meanwhile, the output voltage U_F of ME will be changed obviously in order to keep the field current I_F constant. B. Starting mode The SG is used to start the engine up to 3000rpm. The ME excitation winding is connected to line-to-line voltage 200V/400Hz of 3-phase 115V /400Hz AC source. In this case, the ME is worked as a transformer where ME stator is primary side and rotor is secondary side. As is shown in Fig. 5, with speed ranges from 0 to 3000 r/min, the simulated waveforms of excitation current I_{ef} is almost the same, the self-inductance L_{ef} keeps about 5.4mH. Due to the frequency of U_{ef} is high, the resistance of ME excitation winding can be negligible. Thus, the excitation I_{ef} is directly proportional to self-inductance L_{ef}. IV. EXPERIMENTAL VERIFICATION A prototype single-phase main exciter for aircraft SG has been designed and developed as shown in Fig. 6. Fig. 7 shows the excitation voltage U_{ef} and excitation current I_{ef} waveforms with 1000r/min and the numerical value of excitation current I_{ef} versus speed. It can be seen that the simulated waveform agrees well with the measured one. IV. CONCLUSION In this paper, the characteristic of single-phase main exciter both in generating mode and starting mode has been analyzed and established. In generating mode, the output of ME has constant current source characteristic with the temperature ranging from -60 degree centigrade to 180 degree centigrade. In starting mode, the ME can be worked as a transformer. The feature of excitation current I_{ef} and self-inductance L_{ef} is also discussed. Both simulation and experiment are explored, and the simulated results agree well with the measured one.

HH-01. Broadband modeling of magnetic components with saturation and hysteresis for circuit simulations of power converters.

B. Wunsch[1], S. Skibin[1], T. Christen[1] and V. Forsstrom[2]
1. ABB Corporate Research, Baden, Switzerland; 2. ABB Oy Drives, Helsinki, Finland

Abstract: A model of magnetic components is presented which includes saturation and static hysteresis and covers a wide frequency range. A dedicated setup measures the B(H)-curves for extraction of the model parameters and for model validation. The magnetic model is then described in terms of a spice circuit and used in transient system simulations of power converters. Simulations and measurements of core losses, and filter performance of common mode chokes are discussed. Introduction Magnetic components like single-phase chokes, common mode chokes, or transformers are essential parts of power electronic converters. For faster and more cost efficient design of these components, or even for virtual prototyping of filters accurate simulation models of magnetic components are required that can be placed in transient system simulations of power converters [1], [2], [3]. In this work, a circuit model of a common mode inductor is presented that captures static hysteresis, saturation, and high-frequency behavior. The example material chosen is the nanocrystalline core W517 made of Vitroperm 500F of Vacuumschmelze, which is used for filtering common-mode noise [6]. Magnetic property tester The core under test (CUT) contains two windings. The primary winding is excited with a controllable current, while the secondary winding is left open and used for measurement of induced voltage. The H-field and B-field are calculated based on the primary current and secondary voltage, respectively. The voltage source is realized by a switching mode SiC-based inverter with H-bridge topology. It allows modulation of different current waveforms exciting the CUT. For characterization of saturation and static hysteresis of the CUT low frequency measurements are required. In this case a large inductor is introduced in series with the CUT and the core is excited by triangular current ensuring small frequency content. For validation measurements the large inductor is removed and the core is excited by rectangular voltage with high switching frequency. Simulation models The magnetic model is obtained in three steps [3], [7]. First a linear circuit is created that describes the effect of eddy currents induced by the magnetic field in the core. The field distribution in conductive, laminated cores can be solved analytically as long as a constant permeability is assumed. A physical circuit representation is given by a linear Cauer network of inductors and shunt resistors [5], [7]. Alternatively the circuit parameters of the Cauer network can be adjusted to fit the linear impedance of the core obtained by small signal measurements using an impedance analyzer [3]. Next an inductor model with saturation and static hysteresis is created. The saturation of the inductors is described by a nonlinear reversible field. In order to capture static hysteresis, a Preisach model is used [8]. We determine the required parameters by fitting a set of B(H)-curves measured at low frequency with different B-field amplitudes. We then create a circuit model of the inductor, which is valid at low frequencies, captures the nonlinear B(H)-characteristic, and includes the Preisach model. The linear wide-band frequency-dependent model can then be combined with the nonlinear low-frequency model by replacing the linear inductors of the Cauer network by magnets described with the Preisach model. The resulting model includes eddy currents, saturation, and static hysteresis. We assess the accuracy of the obtained model using the magnetic property tester for large-signal large-frequency excitations and compare simulated and measured B(H)-curves and losses. Use in EMC simulations In this work we report on simulations and measurements of the performance of CM chokes placed at two distinct locations in a power converter with a nominal power rating of 355 kW at 500 V rms. The converter is connected at its input side to the 50 Hz 400 V rms three phase AC-grid, and at its output side it is connected via a shielded cable to a free running motor. In the first analysis the CM-choke is part of the EMC filter placed at the AC input of the converter. We measure and simulate the CM-noise and the core loss under various operation conditions of the converter. For certain operations the CM choke is temporarily saturated. In the second analysis the CM choke is placed on the motor cable where the CM current is much larger than at the AC input. Consequently the magnetic core is repetitively brought to saturation. The large power loss of the magnetic core causes a significant heating of the CM choke. Both the common mode current waveform and the power loss are simulated and compared to measurement. Conclusion A model of magnetic cores is proposed that captures high-frequency effects as well as saturation and static hysteresis. A dedicated measurement setup was developed in order to experimentally characterize the magnetic behavior for the extraction of the model parameters and for the validation of the model. The model was then used to create a circuit model of common mode chokes that is used in transient system simulations of power converters to design filters, which enables virtual filter design.

HH-02. Temperature Dependence in the Jiles-Atherton Model for Non-Oriented Electrical Steels: An Engineering Approach.

S. Hussain[1], A. Benabou[3], S. Clenet[2] and *D. Lowther*[1]
1. Elec and Comp Eng, McGill University, Montreal, QC, Canada; 2. L2EP, Arts et Metiers ParisTech, Lille, France; 3. L2EP, Universite Lille 1, Villeneuve d'Ascq, France

Modern electrical machines may run for a prolonged time under extremely high temperatures which affect the magnetic behaviour of the electrical steels used in their cores [1]. However, these effects on the magnetic properties of the ferromagnetic material are often neglected in the computer-aided design (CAD) simulations and should be taken into account in the design of modern electrical machines to optimize their performance. Physics-inspired hysteresis models, such as the Jiles-Atherton (JA) model [2], seem to be promising candidates to incorporate temperature effects and can be embedded in finite element (FE) based CAD simulations. The JA model explains the hysteresis loss mechanism with the help of domain wall motion. The two modes of domain wall transitions (both the bending and translational motions) result in a reversible and an irreversible component of magnetization, respectively. The total magnetization is computed using a first order differential equation with five material parameters (M_s, a, α, c, k) known as the JA parameters [2]. M_s is the saturation magnetization, α is the inter-domain coupling coefficient, a determines the shape of the anhysteretic curve, c is the domain wall flexibility coefficient, and k represents the hysteresis effect. These five parameters are determined from the major B-H loop using curve fitting techniques. Although the accuracy and the physical aspects of the JA model and its parameters have been widely questioned [3], this is the most computationally efficient and easy-to-implement hysteresis model available in the literature and can be coupled with FE simulations to incorporate the effects of hysteresis in the field solutions. This work presents an engineering approach to use the JA model for estimating the B-H loops of non-oriented (NO) electrical steels at high operating temperatures. We have measured the B-H loops (B_{max} = 1.5 T) for 35WW300 NO electrical steel at seven temperatures within a limited temperature range (i.e., 50^{o}C to 330^{o}C) using a high-temperature Brockhaus Single Sheet Tester placed in an electric oven. The studied temperatures are well below the Curie temperature of electrical steels (T_c > 700^{o}C) and are the ones that steels could face in machines operating under extreme conditions. The JA parameters (a total of 35 JA model parameters, i.e., five at each temperature) are identified from the measured B-H loops using the nonlinear least squares method [4]. The optimization function, used in this case, is the square of the difference between the measured and computed data points. In this work, we also present a methodology to reduce the number of parameters to fit the temperature variations of the JA parameters based on their evolution. The first parameter to consider in this analysis is M_s which decreases (for a constant applied magnetic field intensity, H) with the increase in temperature. The evolution of M_s for the studied electrical steel shows a variation of less than 4 % for the given temperature range and is ignored here, i.e., M_s =1.2678 x 10^6 A/m. It is consistent with the Weiss Molecular theory [1] which states that if the operating temperature is well below the Curie temperature, T_c (i.e., T/T_c < 0.5), as in our case, the variation of M_s is negligible [1]. The parameter c seems to increase slightly at relatively high temperatures. However, a small change in c does not have a significant effect on the area of the B-H loop. Hence, the parameter c is also assumed to be constant, i.e., c = 0.02. It is important to mention here that M_s and c are identified using the B-H loop measured at the lowest temperature of interest, i.e., 50 ^{o}C. The rest of the JA parameters (i.e., a, α, and k) are then identified from the measured B-H loops at other temperatures. The reduction in the number of unknowns simplifies and speeds up the identification procedure. Two of the three remaining JA parameters (i.e., a and α) linearly increase with the temperature and can be modelled using first-order polynomials (i.e., with two unknowns only). In the case of soft magnetic materials, the parameter k is similar to the coercivity [5] which gives a hint about the decrease in its value with the increase in temperature. For the given temperature range, a quadratic dependence of the parameter k on temperature was observed for this material. The details on the number of unknowns for each JA parameter, their values and the quality of the fit are given in Table 1. As an example, measured and computed hysteresis loops (using the proposed approach) of 35WW300 NO electrical steel are compared in Fig. 1 at 300^{o}C. The error, defined as a relative difference in the measured and computed loops using the proposed approach, stays well within 6% for the whole temperature range. The same approach was applied to similar material i.e. B35AV1900 NO electrical steel ($B_{H=2500A/m}$ = 1.68 T, $P_{loss,\ B = 1.5\ T}$ = 1.91 W/kg) and similar results were obtained. The proposed engineering approach has been tested for NO electrical steels only and works for a limited temperature range. The identification of the JA parameters has been made simple by reducing the number of parameters and measurements to estimate them. The JA parameter information at temperatures close to 0 ^{o}K [6], [7] is not required. Since this is an experimental approach, the identification of the JA model parameters using analytical formulae may be ignored [6], [7].

HH-03. A Hybrid Algorithm for Parameter Extraction of Energetic Hysteresis Model.

R. Liu[1] and L. Li[1]
1. School of Electrical and Electronic Engineering, North China Electric Power University, Beijing, China

Magnetic materials are widely used in motors, reactors, power-frequency and high-frequency transformers and other electrical devices, which are of great significance for the safety, efficiency and stability of power system. Since the most distinguishing features of this kinds of materials is hysteresis characteristics, an accurate mathematical modelling of the hysteresis loop is a prerequisite for the design and optimization of magnetic cores in electrical devices. As far as now, various hysteresis models have been proposed in the related literatures [1]. Among them, the energetic hysteresis model developed by Hans Hauser is very promising for its simple formula and accurate representation of hysteresis loop [2]. Many factors, such as stress, temperature, frequency and magnetization direction can be incorporated in this model. However, determining the model parameters with reasonable accuracy and efficient computation is still a major challenge. The existing methods for parameter identification of energetic model have been divided into two categories. The first one is using the formulas proposed by Hans [3]. This method not only needs the data of original magnetization curve and major loop, but also involves the solving of transcendental and approximate equations, which could result in inefficient solution and low accuracy. In order to overcome this problem, a curve fitting method is proposed [4], which uses simulated annealing (SA) method to identify parameters based on the objective function of minimum error between measured and calculated hysteresis loops. However, it has the intrinsic drawback of stochastic optimization algorithm that the convergence rate is extremely slow near the global minimum, and there is no guarantee to reach the optimal point [5]. This paper proposes a hybrid algorithm which combines the most appealing features of two kinds of optimization methods viz. the stochastic approach of SA and the deterministic nature of Levengerg-Marquardt (L-M) algorithm. Since SA has an ability to avoid traps in local minima, it is used to approach to the area where global optimal solution is located in the initial iteration period of this hybrid algorithm. Then a normalization of the sensitivity function is built to improve the convergence of L-M algorithm, which can converge quickly towards global minimum. Based on the introduced commutation criteria, the current best solution of SA algorithm is transferred to normalized L-M algorithm as its initial parameter. The simulation and experimental results show that the proposed hybrid algorithm leads to a considerable reduction in computation time and higher accuracy, so it can be used to precisely and quickly extract the parameters of energetic hysteresis model. The test is carried out on the same benchmark model [4], and the root-mean-square error (RMSE) of calculated loop is taken as the objective function. Besides, the value of this parameters are already known, and the bounds of the parameters are taken in a wider range to verify the robustness of the proposed hybrid technique. Firstly, SA is used to identify the parameters. The reduction of RMSE varying with iteration number is shown as Fig. 1. It is evident that the RMSE almost does not change after 23th iteration. This result confirms that SA has a good global search capability, but its local optimization capability is poor, and the maximum error of optimized parameters is up to 27.8%. The final best calculated loop by SA is shown in Fig. 2. However, when it comes to hybrid algorithm, the L-M algorithm takes over the calculation from SA when iteration number reaches 29, and then it converges to the global optimal parameters in just 6 interation. Fig. 2 gives the calculated loop by the hybrid algorithm. The parameters match exactly with that of benchmark model curve.

I. INTRODUCTION Power electronic devices such as inductors and transformers are required to be driven with high frequency according to downsizing. Mn-Zn ferrite is one of the high-frequency magnetic materials. The dimensional resonance occurs in Mn-Zn cores due to the increase of the dielectric constant and significantly affects the eddy current loss [1]. The equivalent RC circuit of Mn-Zn ferrite was modeled by the grains and their boundary layers and can explain the effective dielectric property by the contribution of the capacitance [2]. The boundary layers with high-resistance suppress the eddy current in the grains at low frequencies, while as frequency increases the suppression of the eddy current decreases by charge accumulation on the surface of the grains. The calculating method of the frequency dependent dielectric property by the capacitance was proposed and the dimensional resonance was reproduced by applying the method to the magnetic field equations of linear magnetic materials by using a cylindrical approximation [3]. In order to analyze the eddy current loss of complex shaped inductors at high frequencies, we apply the dielectric effect to the A-ϕ method of the finite element magnetic field analysis. On the other hand, the magnetic hysteresis loss increases according to the increase of the magnetic flux density in the core. Therefore, we used the play model [4] to express the magnetic hysteresis for finite amplitude of magnetic flux. For confirming the calculation accuracy, core losses of an EI-shaped inductor was calculated and the frequency dependent loss was compared with experimental results. In the simulation, the core loss was divided into hysteresis loss in DC, eddy current loss and excess loss, and their contributions were analyzed. II. METHOD The current density of the grains is j_1 as follows [3]. $j_1 = \sigma_1(E\text{-}rq/\varepsilon)$ (1) Where, σ_1 is the electrical conductivity, E is the average electric field in the grains, q is the charge density accumulated in the surface of the grains, ε is a dielectric constant in the boundary layers and r is the ratio of the thickness of the boundary layers to the diameter of the grains. Since the volume of the grains is much larger than the boundary layers, the j_1 can be approximated as the current density of the whole magnetic material. Therefore, as shown in the equations (2)-(3), the j_1 can be substituted into the magnetic field equations of the A-ϕ method. Where, the magnetic field $H(B)$ depending on the flux density is calculated by the play model, c_β is a coefficient of excess loss, μ_0 is the vacuum permeability and J_0 is an exciting current. $\sigma_1(\partial A/\partial t+\nabla\phi+rq/\varepsilon)+\nabla\times H(B)+\nabla\times\nabla\times(c_\beta/\mu_0)(\partial A/\partial t) = J_0$ (2) $\nabla\sigma_1(\partial A/\partial t+\nabla\phi+rq/\varepsilon) = 0$ (3) The total loss P_c can be expressed by the sum of hysteresis loss in DC, eddy current loss and excess loss respectively as shown in the equation (4). $P_c = V_{EI}\sigma HdB+V_{EI}\int(j_1^2/\sigma_1+rj_2^2/\sigma_2)dt+V_{EI}\sigma(c_\beta/\mu_0)(\partial B/\partial t)dB$ (4) Here, j_2 is the current density in the grain boundary layers, σ_2 is the electrical conductivity and V_{EI} is volume of the EI-shaped core. The integration by magnetic flux density is calculated in one loop and the time integration is calculated in one cycle. III. RESULTS For the simulation, we initially fitted the material parameters using several measurement results. The σ_1, σ_2, r, ε were derived from the frequency dependent conductivity of the thin plate. In addition, the hysteresis parameter of the play model [4] is from the B-H curve at the low frequency (10 kHz) and the c_β is from the fitting the loss of high frequency (1000 kHz) using the toroidal core. In the simulation, we used the EI-shaped core shown in Fig.1. The average magnetic flux density in the core region wounded by the coil was controlled to be constant while varying the frequency. Figure 2(a) shows the frequency dependence of the core loss at the flux density 50mT and 100mT. The simulation results of the core loss agree well with measurements. Figures 2(b) and Fig. 2(c) show the simulation results of the core losses of different contributions at 50mT and 100mT respectively. At the low frequencies, the loss rate of the hysteresis is large, for example, it is 54% at 50 kHz in Fig. 2(c). The excess losses are the largest and are approximately proportional to the frequency. The eddy currents are very small at low frequencies, but their loss gradient in the frequency increase up to 1000 kHz. It should be noted that such sharp increase in the eddy current loss as a function of frequency cannot be reproduced by a simulation of homogeneous material without the dielectric effect [5]. Since the frequency of the dimensional resonance is about 1200 kHz, the macroscopic phenomenon that the resistance of the boundary layers seems to be short-circuited by charge accumulation in the capacitance results in the increase of eddy current at the high frequencies. It was found that the finite element magnetic field analysis which considers the dielectric effect and the magnetic hysteresis can accurately predict the losses of the EI-shaped Mn-Zn ferrite core and analyze the loss divided into different kinds.

HH-05. Prandtl-Ishlinskii Modeling for Giant Magnetostrictive Actuator Based on Internal Time-delay Recurrent Neural Network.

Y. Wang[1], R. Xu[1] and *M. Zhou*[1]
1. Department of control science and engineering, Jilin University, Changchun, China

Micro and nano technology is an indispensable part of modern science and technology. Because of the excellent advantages of high energy density, rapid response and large mechanical force, GMA becomes more promising in precision positioning, microelectronic, and biomedicine field[1, 2]. However, the relationship between input current and output displacement of GMA is hysteresis nonlinearity, which shows that the output of GMA not only relates to the current input value, but also relates to previous output value. Besides, the hysteresis nonlinearity is rate-dependent, so that the output of GMA depends on the input frequency. The intrinsic rate-dependent hysteresis nonlinearity of GMA is the main sticking point preventing its application in the high precision positioning [3, 4]. Therefore, modeling of GMA has long been difficult to study and attracted the attention of researchers. In this paper, the Prandtl-Ishlinskii (PI) model with the parameters self-tuning ability is established by the internal time-delay recurrent neural network (RNN) to describe the hysteresis nonlinearity of GMA. PI model consists of play operator and density function. Play operator is a continuous hysteresis operator, whose output depends on not only the current input but also the previous input. Nevertheless, play operator is rate-independent. Identifying the applicable density function is an important part of modeling PI model of GMA. Neural network has the features of the nonlinear mapping property and high parallel process ability. Therefore it is suitable to be applied to identify the nonlinear model. In this paper, the internal time-delay RNN is used to replace the density function of PI model. The PI model structure identified by the internal time-delay RNN for GMA is shown in Fig. 1. The internal time-delay RNN is set by the input layer, output layer and hidden layer. Where output of play operator $v_i(t)$ is the ith input sample of the network at time t, $y^*(t)$ is the output of the network. ${}^1w_{ji}$ and ${}^2w_j$ are the weights of input layer and output layer, respectively, ${}^hw_{jk}$ is the weight for the nodes of hidden layer. Compared with feedforward neural network, it has property of memory because there is time delay recurrent existed in the hidden layer. Due to the inherent feedback structure of internal time-delay RNN, it possesses the dynamic characteristics and can adjust the parameters of PI model adaptively. The simulation results of PI model identified by internal time-delay RNN at the different input frequency are shown in Fig. 2. The red solid lines are hysteresis loops measured in the experiments, the blue dotted lines are the hysteresis loops of PI model based on internal time-delay RNN, and the blue solid lines are the modeling error curves. To facilitate simulation, the normalized data is adopted. As shown in Fig.2, the maximum modeling error rate at 1Hz, 10Hz, 50Hz and 100Hz is 0.81%, 1.07%, 1.41% and 2.14%, respectively. The PI model identified in this paper can accurately describe the hysteresis nonlinearity of GMA with the increase of input frequency. Therefore, the ability of precise modeling by PI model based on internal time-delay RNN is certified. The proposed PI model can be used to eliminate the hysteresis nonlinearity at the compensation control of GMA and promote the application of GMA in precision positioning field in the future.

HH-06. Vector Hysteresis Modeling of Soft Magnetic Composite by the Improved Preisach Model Considering Anisotropic Characteristic.

X. Zhao[1], H. Zhang[1], *L. Li*[1], F. Xiao[1], X. Liu[1] and Y. Li[2]
1. North China Electric Power University, Baoding, China; 2. Hebei University of Technology, TianJing, China

1.INTRODUCTION Two dimensional (2-D) magnetic flux exist in rotating electric machines and T-joints of three-phase power transformers and may cause local overheating in these devices. The soft magnetic materials, such as electrical steel sheet and soft magnetic composite (SMC), are usually used in the fabrication process of ferromagnetic core. Therefore, it has been focus of attentions to measure and model 2-D magnetic properties of soft magnetic materials in recent years [1-2]. Compared with the Stoner-Wohlfarth hysteresis model, the Preisach model has the advantage over parameter identification and numerical implementation, and it has been widely used in modeling 2-D vector hysteretic characteristics. Due to the defects of classical vector Preisach model, simulation cannot agree well with measurement, therefore it is necessary to improve the classical vector model. In this paper, by introducing the function *z*, the classical Preisach model is improved to model the 2-D vector hysteresis of SMC considering the influence of anisotropy, the simulated results by the improved model is coincided with the measured ones. The proposed method is meaningful for exploring the rotating magnetic and loss characteristics of electric motor and power transformer. 2. IMPROVED VECTOR PREISACH MODEL It is necessary to improve the classical vector Preisach model since there are some problems when the model is applied in the realistic vector hysteresis modeling. the measured loci of *H* are flower-shape rather than circle due to inherently anisotropic property in magnetic materials. The improved model [3] is presented as follows. $f(t)=\int e_\theta(\iint_{\alpha\geq\beta} v(\alpha,\beta)\delta_{\alpha\beta}|u_\theta(t)-\phi| z(\theta(t)-\phi)d\alpha d\beta)d\theta$ (1) $z(\theta-\phi)=\mathrm{sign}[\cos(\theta-\phi)]|\cos(\theta-\phi)|^{1/\omega}$, $\omega\geq1$ (2) As shown in (1) and (2), the classical Preisach model is improved to simulate the vector hysteresis more accurately by means of the auxiliary function *P*. $P(\alpha,\beta)=1/\pi*\int[\omega\beta^{\omega-1}F(\beta,\beta')+\beta^{\omega}(dF(\beta,\beta')/d\beta)]/(\alpha^{2\omega}-\beta^{2\omega})^{1/2}d\beta$ (3) where a new parameter ω is introduced and both ω and function P should be determined through the identification procedure. Correspondingly, the expression of input should be also changed, $B_{\phi i}=|B|\delta|\cos(\theta_B-\phi_i)|^{1/\omega}$, $\omega\geq1$, i=1,2,....N (4) the measuring system mainly includes the following four parts [4], three orthogonal core poles with six flexible excitation windings, three power amplifiers and generators, multi-channel differential amplifier circuits, and a digital signal processing device with data acquisition card driven by the LabVIEW software, and the sensing structure consisted of six combined B-H sensing coils tightly attached on each surfaces of the cubic specimen. The entire structure of the tester is shown in Fig.1. The 2-D hysteresis loops along *H*x- and *H*y- axes of SMC material are measured by the cubic sensor at low frequency, with the specimen excited by rotating magnetic field. 3. RESULTS AND ANALYSIS The limiting hysteresis loop of SMC material is measured by the experimental setup in Fig.1 to generate first-order reversal curves (FORCs) [5]. Thus, the auxiliary function *P* in (3) is obtained and identification of the improved Preisach model can be achieved by means of numerical implementation. Consequently, hysteresis curves corresponding to different rotating excitations are computed and compared with the measured results. Fig.2 shows the comparison between measurement and simulation. From the comparison in Fig.2, it is noticed that agreement between the measured and simulated result is basically approached, which proves the effectiveness and accuracy of the improved Preisach model. 4. CONCLUSION An improved vector Preisach model is presented to simulate 2-D vector hysteresis curves considering anisotropic property of SMC material. Numerical implementation of the improved model is realized based on the measured limiting hysteresis loops and the corresponding FORCs. The improved vector model is used to simulate hysteresis loops of SMC specimen excited by 2-D rotating magnetic field. 5. HH-07. Modeling the role of magnetic charges on field cooling memory in low anisotropy polycrystalline materials.

Measuring the temperature-dependent magnetization following a magneto-thermal protocol using DC magnetometry techniques is a universal tool to investigate non-equilibrium magnetism [1]. The role of magnetic charges is most prominent in ideally soft magnetic materials or soft polycrystalline materials with small anisotropy as the rapid buildup of these charges near the grain boundaries creates internal demagnetizing fields which oppose the anisotropy fields [2]. We present a model to demonstrate the effect of the buildup of magnetic charges during the negative field cooling (NFC) routine on the magnetization of polycrystalline gadolinium around the spin-reorientation temperature region monitored during the first positive field warming (NFC|PFW) routine. The model shows that the sizable negative magnetization trapped during the NFC routine could be modeled as an assembly of non-interacting Stoner-Wohlfarth (SW) particles with an appropriate distribution of blocking temperatures. The model is applied to polycrystalline gadolinium which is known to have uniaxial anisotropy, a first-order anisotropy constant which changes its sign around the spin-reorientation region (220 – 260 K), and a temperature-dependent easy axis orientation as shown in Figure 1(a) [3–5]. The drastic effect of the cooling field memory sustained by the magnetic charges are most obvious during the spin-reorientation temperature region where the easy axis orientation is approaching 0^{o} and the trapped magnetization rotates easily towards the negative direction of the anisotropy axis. For an ideal assembly of non-interacting single-domain Stoner-Wohlfarth (SW) particles, the magnetic moment will be locked along the cooling field direction if the field magnitude is strong enough. Heating the sample from this well-defined magnetic state will cause an irreversible transition when the thermal energy k_BT is comparable to the anisotropy energy barrier KV, where k_B is the Boltzmann constant, T is the temperature, K is the effective anisotropy constant, and V is the volume. Coupling the SW model with Néel's theory of thermal relaxation leads to a generalized model for the temperature dependence of magnetization [6]. It can be shown that the temperature-dependent normalized magnetization in the anisotropy axis direction is given by [7, 8]: $dm/dT = (f_0/\Delta T/\Delta t) \times \{(1-m) \times \exp(-U_{21}/k_BT) - (1+m) \times \exp(-U_{12}/k_BT)\}$, (1) where U is the energy barrier between the two states of energy minima, f_0 is the fluctuation rate between them, and $\Delta T/\Delta t$ is the rate of change of temperature during the measurement. Figure 1(b) shows the normalized magnetization in the anisotropy axis direction versus increasing temperature for an assembly of SW particles under three different field cooling routines. For polycrystalline gadolinium, a magneto-thermal protocol has been applied where the sample is cooled down from a temperature higher than the Curie temperature (300 K) to a low temperature (5 K) while a negative field (μ_0H_{FC}=−50 mT) is applied [9]. The sample is then heated to 380 K under a small positive field (μ_0H_A=+5 mT), cooled back to 5 K, and finally heated to 380 K. The difference between the two warming sequences reflects the temperature dependence of the anisotropy and its effect on the buildup of magnetic charges near the grain boundaries. At the beginning of the first warming sequence (NFC|PFW), the assembly of SW particles at 5 K, representing the trapped magnetization after field cooling, has a negative magnetization (M_{NFC}). The strength of the negative cooling field (H_{NFC}) is proportional to M_{NFC}. From 5 K to 220 K, the anisotropy becomes less negative and the easy cone half-angle increases from about 40^{o} to around 80^{o} which allows M_{NFC} to rotate towards the plane perpendicular to the anisotropy axis decreasing its component along the negative direction of the anisotropy axis. From 220 K to 250 K, the anisotropy changes its sign and the easy axis cone half-angle approaches zero which allows M_{NFC} to revert, increasing its component along the negative direction of the anisotropy axis. Above 250 K, thermal demagnetization takes over and M_{NFC} goes to zero. The second warming sequence (PFC|PFW) occurs not only after the initial negative cooling field has been removed but also after its memory has been erased by increasing the temperature above the Curie temperature. Figure 2 shows (NFC|PFW), which includes the contribution of M_{NFC} as modeled by the generalized model for an assembly of SW particles of temperature-dependent anisotropy in a zero applied field, and (PFC|PFW). The model captures the main features of the magneto-thermal protocol measurements on polycrystalline gadolinium and supports our hypothesis for the significant role magnetic charges play when their internal demagnetizing field is comparable to the anisotropy field, which is the case for low-anisotropy polycrystalline gadolinium around the spin-reorientation region.

HH-08. Vector Magnetization By A Distribution Of Easy Axes.

A. Jamali[1], E. Della Torre[1] and *A. Aslani*[1]
1. Department of Electrical and Computer Engineering, The George Washington University, Falls Church, VA, United States

I.Introduction We recently developed a vector magnetization model for uniaxial media [1]. In this model, magnetization is vector sum of the reversible and irreversible components. The irreversible magnetization that is parallel with easy axis and does not change in direction is modeled by scalar Preisach model and the reversible component changes by Stoner-Wohlfarth model [2]. The model is developed for behavior of the perfectly aligned hysterons. In this paper, we improved the model by using a distribution in the hysteron easy axes. The net magnetization then is the weighted vector sum of the individual magnetizations. The previous model had three major inconsistencies with experimental results discussed below. II.Squareness Unitary magnetizations curves can be plotted by keeping the direction of the applied filed constant and plotting the projection of the magnetization along the applied field with respect to the applied field magnitude. The squareness is defined as the ratio of saturation remanence to saturation magnetization and it measures how square is the hysteresis loop. Let α and Φ be the polar and azimuthal angles of the easy axis respectively and θ be a the angle between magnetization and easy axis, by considering $p(\alpha,\Phi)$ as the probability density function, the general expression to calculate unitary magnetization is introduced in [2]. As shown in Fig.1, by applying the method of averaging over orientation and using a uniform distribution for both α and Φ, the squareness of the unitary magnetization curves will be decreased and it results in smoother and more realistic curves. III. The jumps in lag angle Lag angle curve is the magnetization angle versus applied field angle [3,4]. We showed that for the normalized applied field, h, less than 0.5 the magnetization is not strong enough to follow the applied field and oscillation mode will occur and rotation mode is for the values h more than 0.5 [1]. Also we showed that there is a need to break down this range to $0.5<h<1$ and $h>1$. In the previous model, for the normalized applied field in the range of $0.5 <h<1$, we calculated jumps in lag angle. These jumps are not experimentally validated. The mathematical source of the jumps is the multiple intersections of a circle of radius h with the astroid representing the bifurcation curve of the uniaxial anisotropy [1]. If we rotate the hysteron easy axes (equivalent with rotation of the astroid) then different intersections will be derived. Fig.2 shows how the discontinuity of the lag angle curves can be diminished by using a uniform distribution for α and Φ. IV. Magnetization drop at the critical angle For the values of $h>1$, the previous model correctly predicted the lag angle magnetization behavior. The problem in this range is the small magnitude of magnetization at the critical angle, that is where the magnetization changes from lagging to leading. At this angle, the magnetization vector is parallel with the applied field. This magnitude can be written as a function of the standard deviation of $p(\alpha,\Phi)$.

HI-01. Analysis on variable inductances of planar coils sandwiched by soft magnetic layers.

Y. Wen[1], P. Li[1], F. Song[1], S. Yu[1], L. Bian[2] and Y. Wang[1]
1. Instrument Science and Engineering, Shanghai Jiaotong University, Shanghai, China; 2. Mechanical Engineering, Nanjing Technology University, Nanjing, China

It is well known that the inductance of a planar coil can be enhanced while it is coverd by soft magnetic layers due to the high permeability of the material. As the permeability of a soft material is related to undergoing magnetic flux, in this way the resultant inductance can be variable along with external fields. This fact suggests a practical approach to tune inductances of magnetic film planar inductors. Soft magnetic materials such as amorphpus and nanocrystalline films have extremely large permeabilities, whose maximum values reach an order of several ten/hundred thousands. This performance indicates that the variation of permeability in materials of these types is abundant with a variation ratio ready to the order of 10^3~10^5 when the external field varies. If the magnetic film inductor can fully follow the variation, it will have a considerably large inductance tunability comparable to the variation range of the material permeability. In state of the art, the inductance or the magnetic impedance tunability ratio of a magnetic film device is much less than that of magnetic film permeability. Unlike a coil being put into an infinite magnetic medium or enclosing a loss-free magnetic core, the inductance of a planar coil covered by soft magnetic layers is not increased by a factor equal to the material relative permeability. In fact, it has been seen that the resultant inductances of planar coils either fabricated on soft magnetic substrates [1] or covered by soft magnetic layers [2], are only enhanced at most several or several ten times no matter how large the material permeabilities are. To enhance the quality factor of an inductor, it is preferably expected to raise the inductance through employing the high permeability of ferro-magnetic material rather than increasing the turns of a coil. However, it seems ineffective to improve the inductance of a planar inductor only by using a magnetic material with higher permeability. The underlying key point is that the inductance of a planar coil covered by magnetic layers depends on the permeability in a quite complicated way closely connected with the geometrical parameters of both the coil and the soft magnetic layer. Fig.1 depicts the measured variable inductances of two identical planar coil respectively sandwiched by amorphous and permalloy films with same geometries. The gap between magnetic layers is 180 mm, film thickness 90 mm, film width 9000mm. The coil conductor width is 65mm. The maximum relative permeability of amorphous film is much higher than that of permalloy film. However, as seen in Fig.1, the maximum inductances in two cases demonstrate a small difference. For reference, the inductance of the naked planar coil is also displayed in Fig.1. It is clear that at low magnetic field, the inductance is merely enhanced 10+ times when the coil sandwiched between amorphous films at the maximum permeability. The gain is much less than the maximum permeabilities. This result shows that the magnetic film inductors only make part use of material permeabilities. The part of higher values including the maximum permeability have no effect on the resultant inductances. Hence, the variable range of the inductance in a magnetic film inductor is quite limited and can only follow part of the permeability variation. Korenivski [3] gave models describing the self-inductance of a conductor sandwiched by a magnetic material following Patton's analysis [4]. From the models, the inductance of a magnetic film planar inductor is ready to obtain as the inductance of a coil is the summation of self and mutual inductances of composing conductors. In terms of Korenivski's model, as the permeability of magnetic layers is increasing the inductance will get saturated. This point was also revealed in the planar coil with a magnetic substrate [1]. In cases, saturation occurs when the relative permeability is as low as 10~100. Actually, the inductance saturation is also closely related to the geometry of magnetic layers and the width of conductors in a planar inductor. The gap between magnetic layers and the width of magnetic layers determine the saturated value of the inductance. The higher is the saturated value, the larger is the permeability in which proximity the saturation occurs. The magnetic layer thickness along with the gap affects the rate of reaching saturation. More important, it is the ratios of these parameters to the width of coil conductors rather than the parameters alone effect on the inductance. To clarify the effect of these parameters on the final inductance, the curves from the model are shown in Fig. 2. The ratios of gap, film thickness and film width to conductor width are respectively referred to as r_g, r_tm and r_wm. Our analysis concludes that it is possible to develop a magnetic film planar inductor making full use of the magnetic material permeability, which inductance can follow the permeability variation from the maximum to the minimum by designing appropriate device geometry. Thus the inductance is variable in an abundant range comparable to the magnetic film permeability variation. Such inductors with considerably large tunability can find extensive application not only in electronic circuits but also in sensors.

HI-02. Layout Optimization of Indoor Substation Considering Power Transformer Spatial Acoustic Radiation Characteristics.

D. Wang[1], L. Ying[1], W. Wang[2] and J. Wang[1]
1. School of Electrical Engineering, Wuhan University, Wuhan, China;
2. Central Southern China Electric Power Design Institute Co.,Ltd, Wuhan, China

I. Introduction To improve the power network structure and guarantee the power quality in load center as well as city center, compared with outdoor substation, the whole indoor substation become the preferred choice for designers. So correspondingly, the purposeful substation layout optimization during the design process based on the acoustic radiation characteristics of power transformer will be considered as an efficient and cost-effective way to diminish the influence of power transformer noise. In this paper, a 3D multi-physics coupling model of a SZ11-50000/110 oil-immersed power transformer (Fig.1(a)) and the whole indoor substation model(Fig.1(b)) were developed. The former was used to describe the mechanism of the overall vibration/noise generation, transmission and radiation process, then far-field characteristics and directivity characteristics were obtained by calculation to quantify and visualize the external sound field of power transformer. After that, specific design recommendations were abstracted from these visual but quantitative analysis results to optimize the substation layout in the whole indoor substation. The optimization effect was presented through the comparison. II. Numerical Calculation Method The electromagnetic-mechanical-acoustic coupling models of power transformer and indoor substation were built with COMSOL Multiphysics. Firstly, the magnetostrictive effect contains electromagnetic and mechanical process can be calculated with the core and windings model. Secondly, the vibration caused by magnetostriction was transmitted to oil tank walls through both insulation oil and clamp with padding on the oil tank bottom, eventually turned into audible noise in the air. A.Magnetostrictive Effect Calculation Inside the core, the magnetostriction component along any direction can be calculated as a nonlinear function of the magnetization using Eqs.(1) and (2)[1]: (These two equations can be seen in photo attachment1) (1) (2) B.Sound Field Calculation In a running power transformer, the speed of sound and density may in general be space dependent but only slowly varying with time. So, we can use the scalar wave equation (Eq.(3))to describe the changes of sound field induced by the vibration of the power transformer: (This equation can be seen in photo attachment1) (3) III. Results, Discussions and Conclusion A. Spatial Acoustic Radiation Characteristics Keeping the load rate was 60%, the spatial acoustic radiation characteristics of this running transformer were characterized with far-field plotting about main frequencies at different height and directivity plotting in different vertical plane were shown in Fig.2(a)-(d). Through the comparison between Fig.2 (a) and (b), Fig.2(c) and (d), following characteristics can be obtained: i. In a same horizontal plane and at a certain frequency, the sound pressure level maximum value beside two long oil tank sides is larger than the maximum value beside two short sides. ii. At the height of ventilating window center (6m), the sound pressure level at a certain frequency is greater than the same value at the corresponding angle on the height of oil tank center(1.5m). iii. In the vertical planes above the oil tank, the coverage of low frequencies noise is larger than the coverage of higher frequencies while the sound pressure level of higher frequencies noise are greater than the corresponding values of low frequencies noise. So, specific design recommendations could be abstracted as follows: i. The transformer rooms, especially the room walls beside two long sides of oil tank, should be separated from the noise sensitive area with other rooms. ii. Compared with to the shutters near the bottom of transformer rooms, the ventilating windows at the 6m height should even more avoid facing towards the noise sensitive area. iii. Part of sound absorbing material applied to the inner walls' bottom as the original design should be attached to the roof to damp the more noteworthy noise especially the higher frequencies noise and reduce the corresponding reflection. B. Layout Optimization Effect and Discussion Based on the suggestions above, the location of transformer rooms, the direction of ventilating windows and installation position of part sound absorbing material were adjusted and optimized. The comparison diagrams were shown in Fig.3 and Fig.4. By contrast, after optimization, on the premise that the sound pressure levels in the non-sensitive area still meets the standard, the sound pressure level of every main frequency at the boundaries of sensitive area were about 4dB less than before and all less than 40dB, this means the noise radiation level of whole indoor substation meets the environmental standard [2] without increasing the building materials cost, and the new substation will not change the original soundscape around it. C. Conclusion i. Multi-physical field coupling method is an effective way to explore the power transformer magnetostriction noise generation mechanism and radiation characteristics. ii. The sound pressure level distribution in horizontal plane is asymmetric and from the region beside two short sides of tank, to the region beside two long sides then to the region above tank, corresponding maximum value of sound increases gradually. iii. Reducing the noise radiation level of new indoor substation may not increase the construction cost on the premise of rational optimized design.

HI-03. 3D Magnetic Properties Measurement of Silicon Steel under Biased Magnetic Excitation along Laminated Direction.

C. Zhang[1], B. Jiang[1], Y. Li[1] and Q. Yang[2]
1. Hebei University of Technology, Tianjin, China; 2. Tianjin polytechnic University, Tianjin, China

I.Introduction Silicon steels are widely applied in the magnetic cores design, such as power transformer, electrical machine, and electromagnet. Magnetic properties of silicon steel are key factors in design and performance optimization of the electrical apparatus. In the past several decades, magnetic properties testing methods under 1-D and 2-D magnetization have been proposed for single sheet silicon steel specimen [1]. For grained oriented (GO) and non-grained oriented (NGO) silicon steel, rotational magnetization loss was measured and qualitative analyzed. However, their testing and analyzing scopes were focused in one direction or in one plane [2]. While in application, the silicon steels are made into laminated structure, which may cause magnetic interaction between the vicinity layers. Magnetic properties along the perpendicular rolling direction and effects of the laminated layers might be ignored in traditional testing approach. In this condition, big error may occur in material modeling and the calculation of core loss. Also, rotational magnetic fields existed in cores of rotating AC machines and T-joints of three-phase transformers, which cause rotational core losses may amount to more than 50% of total core loss [4, 5]. Therefore, 3-D magnetic properties of the laminated silicon steel in the complex rotating magnetization conditions should be taken into account. II.Novel 3-D magnetic testing system (A).3-D magnetization structure and its sensing system The improved 3-D magnetization structure consists of three orthogonal C-Shaped cores, 6 multilayer excitation windings, which were wounded around the six orthogonal magnetic poles. In order to reduce the gap influence, six thin pieces with the same material and same laminated direction around the cubic specimen were fabricated to improve significantly uniformity of the magnetic field at the specimen surface. (B). Automated measurement procedure Because the magnetic measurement system is nonlinear, the digital feedback for magnetic measuremnt has the advantage to make sure the standard excitation magnetic field. The controlling of 3-D magnetic property measurement is performed in LabView environment. The output excitation signal is controlled by PID controller, which feedback is the EMF of B_x and B_y. The saving procedure is delayed for 1 sec to make sure that the magnetization process is settled down. Even if the difference between magnetic strength under between CW and CCW rotation is only 1%, the averaged value will amplify the difference and give totally wrong losses. The automated program makes sure that the flux density difference between CW and CCW rotation is not larger than 0.3% so that the core loss is caculated correctly. III.Experimental Measurement and Discussion By using the 3-D magnetic property tester, experiments of high grain oriented silicon steel have been carried out under alternating and rotating in sheet plane and laminated direction magnetization conditions. Measurement Setup The magnetic pole in *z* axis of 3D magnetic properties apparatus is excited by a DC current source, and the *x* or *y* axis magnetic pole is excited by a power amplifier. The lamination direction of silicon steel is hard to be magnetized. Because of skin effect of magnetic field, the dynamic magnetic field only at low frequency (< 0.1 Hz) can go through the laminated direction of silicon steel uniformly. In order to measure the 3-D magnetic properties of the laminated silicon steels, the novel excitation model is designed, in which the alternating magnetic field in sheet plane and static magnetic field in lamination direction are summed in the vector space. When the applied current in *z* axis is swiftly transferred from zero to the specified one, the magnetic flux density in *z* axis can be calculated by the flux meter which EMF of *z* coil is measured by the solenoid method. (B) Measurement and Discussion Fig. 2 shows that the larger static magnetic field excited in laminated direction of silicon steel, the more difficult the rolling and transverse direction are magnetized. Furthermore, the saturation magnetic flux density is lower and its alternating core loss is increased, when the static magnetic field is applied in laminated direction. IV. Conclusion Improved 3D magnetic property measurement system for laminated material with AC and DC excitation was developed. In this paper, the DC and AC magnetic excitation in different direction was simultaneously excited on the laminated silicon steel sheet. In conclusion, the core losses of rolling direction were significantly increasing when the static magnetic field was excited along the laminated direction.

1. Dept. of Electrical & Electronic Engineering, Saga University, SAGACITY, Japan; 2. School of Electrical Engineering, Wuhan University, Wuhan, China

1. Introduction Ferrite cores are widely used in transformers and inductors, etc. for high frequency electronic devices because of high magnetic permeability and low conductivity. In the magnetic field analyses of such magnetic devices using a ferrite core, the frequency-domain analysis is often carried out using measured effective complex permeability under different frequencies. However, the harmonics caused by the magnetic nonlinearity of the ferrite core cannot be evaluated by using the frequency-domain analysis. To carry out the time-domain analysis of ferrite core taking account of the nonlinearity of the core, the modeling method of the effective complex permeability characteristics, which decreases in high frequency region due to dimensional resonance, should be established. In this paper, a simple finite element magnetic field analysis model taking account of eddy current and displacement current is proposed. The suitable conductivity and permittivity which can realize the effective complex permeability is investigated by using the catalogue data of a toroidal MnZn ferrite core. 2. Analysis Model and Method In this paper, our investigation is carried out using the data in the catalogue [2] of a toroidal MnZn ferrite core (TDK/EPCOS: T37). In [2], the real part μ_s' and imaginary part μ_s'' of complex relative permeability with different frequency, measured using the toroidal core (outer radius: 16 mm, inner radius: 9.6 mm, height: 6.3mm), and its conductivity σ = 5 S/m are shown. The frequency characteristics of the complex permeability in the catalogue are tried to be represented by using the magnetic field analysis. The ac linear steady state axisymmetric magnetic field analysis taking account of eddy current and displacement current is carried out using the *A* method (*A*: magnetic vector potential) with the first order square edge finite element method and the phasor method. The fundamental equation is shown as follows: $\mathrm{rot}(v\,\mathrm{rot}\dot{A})=-j\omega\sigma\dot{A}+\omega^2\varepsilon\dot{A}$ where v is reluctivity and ω is angular frequency. The superscript (.) denotes the complex variable. The first term in the right-hand side is the eddy current and the second term is the displacement current. The permeability μ_{so} of ferrite core is set to be 6100 by referring μ_s' at 10 kHz because μ_s'', which is generated by hysteresis phenomena and eddy current effect, is relatively small and it can be neglected at 10 kHz. The original conductivity σ_o is set to be 5 S/m following the catalogue [2]. The original relative permittivity ε_{so} is set to be 300 which is a typical value of MnZn ferrite core. The conductivity σ and relative permittivity ε_s are adjusted to realize the frequency characteristic of the effective complex permeability. 3. Results and Discussion First, the frequency characteristics of the complex effective permeability μ_s' and μ_s'' calculated using the original conductivity σ_o and relative permittivity ε_{so} are compared with those in catalogue data. The tendencies of the calculated permeability are similar with the catalogue data. Namely, both the real and calculated μ_s' do not change in lower frequency region and they decrease in higher frequency region. Moreover, both the real and calculated μ_s'' increase in lower frequency region and they decrease in higher frequency region. However, the peak positions are shifted and the gradients are different with each other. Therefore, to realize the real frequency characteristics, the conductivity and relative permittivity should be changed. The frequency characteristics of the complex effective permeability μ_s' and μ_s'' calculated using the modified conductivity $\sigma = 4\sigma_o$ and permittivity ε_s = 400 ε_{so} are compared with those in catalogue data. The calculated complex permeability has relatively large error in the low frequency region. However, the frequency characteristics of the complex permeability in catalogue data can be represented roughly overall by changing both the conductivity and permittivity. As basic investigation, only linear ac steady state magnetic field analysis of a simple model is carried out in this paper. However, the time domain analysis taking account of nonlinear magnetic characteristics for more actual model can be carried out using the suitable conductivity (i.e. $\sigma = 4\sigma_o$) and permittivity (i.e. ε_s = 400 ε_{so}) obtained from the simple method proposed in this paper.

HI-05. Rapid Design of Litz Wire Through Inverse Surrogate Modeling.

H. Chen[1,2], Y. Du[2] and Q. Cheng[1]
1. Department of Electrical and Electronic Engineering, Southern University of Science and Technology, Shenzhen, China; 2. Department of Building Service Engineering, The Hong Kong Polytechnic University, Hong Kong, Hong Kong

Abstract — The practical litz wire design needs either experimental characterization or 3D numerical simulation. Both of these methods are time and cost consuming. In order to improve efficiency, this paper presents an inverse surrogate process to design the litz wire for a given frequency range. The method builds a fast inverse surrogate between frequencies and design parameters. The surrogate is built from existing designs or simulations. Once the inverse surrogate is established, the optimum design at a given frequency can be obtained immediately. The obtained design is then refined using a frequency correction process to fix frequency misalignment. The method is applied to a five-strand litz wire optimization problem to demonstrate its efficiency. *Index Terms— litz wire; inverse surrogate*. I. Introduction Litz wire uses complex twisting configurations to balance currents between strands. It has been widely used for enabling low-resistance in windings and power electronics. However, applying litz wire effectively is not an easy task. Inappropriate selection of litz wire may lead to higher resistance than a simple solid wire. In practical design, experimental tests are always adopted. The experimental characterization procedures require intricate test equipment, as well as many litz wire samples to be manufactured. It is obviously time and cost consuming. Design using 3D numerical simulations was also proposed [1]. However, simulating such a complex structure repeatedly in an optimization routine can be very computationally expensive. In order to design the litz wire efficiently, we apply an inverse surrogate technique [2] to derive the design parameters of litz wire for a given frequency. The method builds the inverse surrogate of the litz wire based on the existing test results or simulations at sampled designs. Then, the optimum design at a desired frequency is obtained by the inverse surrogate. II.Inverse Surrogate Modelling Let $x \subseteq R^n$ be a vector of design parameters of a litz wire of interest, and let $R_f(x)$ be the response (here, resistance at a specific frequency) of the high-fidelity EM simulation or experimental characterization test. It is assumed that the structure is designed for a certain operating frequency f_0 so that given performance specifications are met for this frequency. The task is to find the optimum design to a different operating frequency f without using an optimization routine. We use the notation to denote the optimum design at the operating frequency f. It should be emphasized that litz wire design is far from trivial because of nonlinear relations between design parameters and frequencies. From a practical point of view, it would be desirable to realize the design at a possibly low cost. In this work, an inverse surrogate is employed to design a litz wire. The inverse surrogate $x_c(f)$ is defined as $x_c(f,P) = [x_{c.1}(f,p_1), ..., x_{c.n}(f,p_n)]^T$ where $x_{c.k}(f, p_k)$ is the kth design parameter of the litz wire with p_k being the coefficients. The matrix $P = [p_1, \ldots, p_n]$ is the aggregation of coefficient vectors for the entire surrogate. The inverse surrogate is obtained as follows. 1) For each sampled frequency, f_j, $j = 1, \ldots N$, find the optimum design $x_{c.j} = [x_{c.j.1} \ldots x_{c.j.n}]^T$ using an optimization routine. 2) For each design parameter x_k, $k = 1, \ldots, n$, find the inverse surrogate coefficients by solving nonlinear regression problems as follows p_k = arg min $\Sigma\ (x_{c.k}(f_j,p)-x_{c.j.k}\ )^2$ Once the inverse surrogate is obtained, $x_c(f)$ returns the values of design parameters for the litz wire at a given operating frequency f. The actual operating frequency of the design $x_f(f)$ may be slightly different from f of $x_c(f)$ and is equal to $f+\Delta f$. Δf is a frequency misalignment result from an inverse surrogate. Therefore, a correction should be accounted by the following relation as $x_f(f) \leftarrow x_c(\mathrm{f}\text{-}\Delta f,P)$ The final design is then corrected by evaluating the surrogate at the operating frequency f. III.Numerical simulation Results The proposed method is employed to design a wire with five strands as shown in Fig. 1. The diameter of the wire is 10 mm. The number of strand is set to 5, and the length of the wire segment to 20 cm. The design parameter helical pitch is optimized to find a litz wire with minimum resistance at a given frequency. The inverse surrogate is constructed using five training designs as shown in Fig. 2. The optimum helical pitch at 1 MHz is xx twists/cm. HI-06. The Effect of Different Core Materials on Transformer Inrush Currents.

W. Sima[1], *Y. Liu*[1], M. Yang[1] and D. Peng[1]
1. State Key Laboratory of Power Transmission Equipment & System Security and New Technology, Chongqing University, Chongqing, China

The inrush current phenomenon is one of the most common low-frequency transients, which occurs due to the core saturation of transformers. Large inrush currents could impair the transformer lifetime, the grid power quality, and the grid protection devices. There are four major factors that affect the transformer inrush current: a) the remanence in the transformer core; b) the applied voltage waveform to the transformer terminal; c) the source impedance and the transformer leakage impedance; d) the magnetizing inductance. The core materials with different magnetizing characteristics have an impact on the magnetizing inductance of the transformer, and then affect the inrush current. Several materials are used to make transformer cores including oriented silicon steels, non-oriented silicon steels, amorphous alloys, nanocrystalline alloys. Particularly, amorphous alloys and nanocrystalline alloys are increasingly used in power distribution transformers due to their excellent low-loss performances. However, their potential harm (e.g. the inrush current) to the power grid is not fully studied during the low-frequency transients of the transformer. Therefore, it is essential to research the transient characteristics of these types of transformers including the inrush current. An accurate transformer model is crucial to study the inrush current performance of transformers. The generally accepted model for a two-winding transformer is the T equivalent circuit (T model). It has been used successfully for many years in steady-state studies and some low-frequency transients. However, when the core suffered saturated and deep saturated, the π equivalent circuit (π model) is better. The reason is that the parameters of the π model have a direct relationship with the physical components of the transformer. Therefore, the π model is used in this study. Four single-phase toroidal transformers with different core materials are built to study the effect of the core materials on the inrush current performance of transformers. Core materials of these transformers are the oriented silicon steel, non-oriented silicon steel, amorphous alloy and nanocrystalline alloy, respectively. A circuit is established for inrush current tests including an ac voltage source, a zero-crossing switch, and the transformer. The maximum inrush current (no remanence) is excited when the zero-crossing switch is switched on (voltage is zero). To make the results comparable, all these transformers are demagnetized by gradually reducing the applied voltage from the rated voltage to zero before tests to remove their remanences. Experiments are conducted to excite the core using a zero-crossing switch and to obtain the maximum inrush currents. Results show that: a) for the oriented silicon steel and non-oriented silicon steel transformers, first peaks of inrush currents are as high as 10-20 times of the rated currents; b)for the amorphous alloy and nanocrystalline alloy transformers, the values are dozens of times of their rated currents. It shows that the core materials have significant influence on the inrush current performance of transformers. The conventional T and π models share a disadvantage that the data of the flux-current curves are rarely known much beyond the knee. To further explain the reason of the different inrush current peaks influenced by the core materials, an improved π model considering the deep saturation is proposed based on the conventional π model by modifying the flux-current curves of its magnetizing branches. Its circuit is same as the conventional π model, and parameters in the non-saturated region are acquired by open- and short-circuit tests. Based on the principle that the transformer core is excited into deep saturation by a dc source, an ac coupling signal is used to measure the data of the magnetization curve in the saturation region, and then the entire magnetization curve is obtained. A method to distribute the data of the curve to two magnetizing branches of the π improved model is presented. The non-linear behavior of magnetizing inductances is described precisely, then the improved π model for single-phase transformers considering deep saturation is established. The inrush current performances of four transformers are investigated by simulation on the ATP/EMTP platform. A zero-crossing switch is used and the remanence of the transformer is set to zero. Results show that: a)the error of the improved π model is less than 5%, which proves the accuracy of the model; b) same as the conclusions obtained by the experiments, the amorphous alloy and nanocrystalline alloy transformer generate higher inrush currents than those of the non-oriented silicon steel and oriented silicon steel transformer. The reason is that the flux-current curves of magnetizing branches have more flat saturation regions for the first two transformers. The effect of different core materials on transformer inrush current is investigated though the ways of experiments and simulations in the paper. It concludes that there are significant differences for inrush currents of transformers with different core materials, and the reasons are discussed in detail.

HI-07. A Novel High-Q-value Inductor with Vacant Space for a High-frequency Non-isolated DC-DC Converter.

Y. Konno[1], T. Yamamoto[1], Y. Chai[1], S. Kawahara[1], T. Kenta[1], Y. Bu[1] and T. Mizuno[1]
1. Department Electric and Electronic Engineering, Shinshu University, Nagano, Japan

I. INTRODUCTION Recently, demand for a highly efficient miniature non-isolated DC-DC converter has increased, driven by demand for use in the power-supply circuits [1]. To miniaturize the non-isolated DC-DC converter, the use of high driving frequencies is an effective means of downsizing passive elements such as capacitors or inductors [2]. The demand for downsized inductors has particularly increased because the inductor has a big ratio among the volumes of circuit [3]. However, the loss of inductors increases along with driving frequencies. Thus, we considered means of reducing copper loss in inductors by applying a vacant space. In this paper, we considered the structure of the most suitable vacant space and evaluated an inductor. II. STRUCTURE OF AN INDUCTOR AND ANALYTICAL RESULTS The inductance of the inductor is 60 nH when subjected to conditions of specific 5 MHz, 5 V to 1.2 V, and 20 A output current in a non-isolated DC-DC converter. Fig.1 shows the structure of the analytical model of the inductor; Fig.1 (a) shows the inductor without vacant space while Fig.1 (b) shows it with vacant space. The inductor has N = 1 turns and the two copper plates connected in parallel. The characteristics of core used has a complex permeability of μ' = 9.4,μ'' = 0.02, as measured for the toroidally formed magnetic composite material using an impedance analyzer (Agilent 4294A+16454A). This core was made by the mixing amorphous alloy powder; its mean diameter is D_{50} = 2.6 mm and epoxy and the mixing ratio of the magnetic composite material is 57vol%. Magnetic-field analysis is conducted using the finite-element method in a cylindrical coordinate system (ANSYS Maxwell). As shown in Figs.1(a) and (b), the maximum current densities of the copper plate is decreased from 170 to 82 A/mm^2 to provide the vacant space. Thus, the current density is concentrated at the corner and the surface of the copper plate because of the magnetic flux caused by the copper-plate interlink itself, as shown in Fig.1(a). Providing a vacant space, however, reduces the magnetic flux interlinking the copper plate, as shown in Fig.1(b). Fig.2 shows that the Q value changed with the size of the vacant space. As shown in Fig.2(a), the Q value became largest when the vacant space had dimensions of dl = 0.1 mm,dt = 0.75 mm. However, the inductance is 57 nH when the vacant-space size is dl = 0.1 mm,dt = 0.75 mm and does not reached 60 nH. Thus, we found the most suitable vacant-space size to be dl = 0.1 mm,dt = 0.5 mm with an inductance of 64 nH. The Q values of the inductor without a vacancy and with a vacancy were found to be 265 and 318, respectively; therefore, the Q value of the inductor with vacant space increased by 26% compared with the no-vacancy case. As shown in Fig.2(b), the resistances of the inductor without a vacant space and with the most suitable vacant space were 8.83 and 6.31 mΩ, respectively; therefore, the resistance of the inductor with vacant space decreased by 28.5% compared with that without the vacancy; and the resistance-reduction ratio of 28.5% is consistent with a 19.3% reduction due to the copper loss and a 9.2% reduction due to the iron loss. Calculation of the resistance-reduction ratios showed that that due to the copper loss was more significant than that due to the iron loss. III. FABLICATION AND MEASUREMENT RESULTS OF AN INDUCTOR We fabricated two inductors, one with a vacant space size is dl = 0.1 mm, dt = 0.5 mm and one without a vacant space. The core of the inductor of size 20 × 20 × 10 mm and rectangular parallelepiped form was fabricated and its size is different analysis model as shown Fig.1. As shown Fig.2, an impedance analyzer (Agilent 4294A) was used to measure the inductor; it was found that the Q values of the inductor without a vacancy and with a vacancy were 102 and 139, respectively; therefore, the Q value of the inductor with vacant space increased by 36% compared with that without the vacancy. IV. EFFICIENCY OF NON-ISOLATED DC-DC CONVERTER APPLIED THE INDUCTOR We examined to apply the inductor to non-isolated DC-DC converter. The EPC9031(Efficient Power Conversion) is used for GaN FET and driver circuit. The drive condition assumed the switching frequency is 5 MHz, 5 V to 1.2 V. The efficiency of the DC-DC converter applied the inductor without vacant and with vacant were 77.6% and 78.4% at 20 A, respectively; therefore, the efficiency of inductor with vacant space is increased by 0.8% compared with that of the without vacant. And the maximum efficiency of inductor with vacant space is 85.0% at 5 A. V. CONCLUSION We considered a technique to increase the Q value of an inductor used in a non-isolated DC-DC converter by providing a vacant space. As result of magnetic-field analysis, the Q value of the inductor was increased by 26% compared with that without a vacant space in the case when this space was slightly smaller than the width of a copper plate. The measured Q value of the inductor without a vacancy is increased by 36% compared to the case without a vacancy. And the efficiency of the DC-DC converter applied the inductor with vacant space is increased by 0.8% at 20 A output current compared with that of the without vacant. The above results show the usefulness of decreasing copper loss to provide a vacant space.

HI-08. Vibration and Acoustic Noise Emitted by Three-phase Iron-core Reactors under PWM Voltage Excitation.

J. Li[1], H. Gao[2,1], S. Wang[1], J. Hong[1] and M. Liu[2,1]
1. State Key Laboratory of Control and Simulation of Power System and Generation Equipments, Tsinghua University, Beijing, China; 2. State Key Laboratory of Reliability and Intelligence of Electrical Equipment, Hebei University of Technology, Tianjin, China

Abstract Body: The demand for dry-type air-core reactors (DARs) is growing due to the increasing use of power electronics in transmission and distribution grids and the implications of dispersed energy generation. For DARs used in power electronic grid such as High Voltage Direct Current (HVDC) and Flexible Alternating Current Transmission Systems (FACTS), the contents of harmonic currents are significant. The injection of high frequency harmonic current will significantly strengthen the vibration and acoustic noise pollution of DARs, and threaten safety and reliability of power transmission and distribution system. Therefore, it is necessary to investigate in depth the vibration and noise of the DARs supplied by power electronic transformation and output systems, and then proposes targeted measures to reduce the vibration and acoustic noise. According to coupling way between the magnetic field and the structural order, structure mode is discussed by engaging finite element (FE) method and both natural frequency and modal shape for a dry-type air-core reactor (DAR) are obtained in this paper. On the basis of harmonic response analysis, electromagnetic force under PWM (Pulse Width Modulation) voltage excitation is mapped with the structure mesh, the vibration spectrum is gained and the consequences represents that the whole structure vibration predominates in the radial direction, with less axial vibration. Referring to the test standard of reactor noise, the rules of emitted noise of the DAR are measured and analyzed at chosen switching frequency matches the sample resonant frequency and the methods of active vibration and noise reduction are put forward. Finally, the low acoustic noise emission of a prototype DAR is verified by measurement. 1. A modal analysis is first performed to determine the structural vibration characteristics, including natural frequency, modal analysis and damping ratio, during the magnetic field-structure coupling calculation of the DAR. The parameters of modal analysis can provide basis for vibration analysis, structural optimization and fault diagnosis of structural design. The motion equation in structural dynamics is [1]: $[M]\{d''\}+[D]\{d'\}+[S]\{d\} = [F]$ (1) where, $[M]$ is the mass matrix; $[D]$ is the damping matrix; $[S]$ is the mechanical stiffness matrix; $\{F\}$ is the force vector; $\{d''\}$ is the acceleration vector; $\{d'\}$ is the velocity vector; $\{d\}$ is the displacement vector. 2. Due to the structural free vibration is simple harmonic vibration, $\{d\} = \{\o\}\sin\omega t$ can be represented the displacement function, which is further known that $\{d''\} = -\omega^2\{\o\}\sin\omega t$, ω is the angular frequency. Next, $([S]-\omega^2[M]\{\o\} = \{0\}$ (2) Eq. (2) is the characteristic equation of free vibration of the DAR structure, and the purpose of modal analysis is to solve the eigenvalues ω_j and the corresponding eigenvectors $\{\o_j\}$ of the characteristic equation. The eigenvalues ω_j are the natural circle frequency, and the natural frequencies $f_j = \omega_j/2\pi$. Here, the eigenvectors $\{\o_j\}$ are the modal shapes of the j-order modal in structural dynamic analysis. 3. Due to complex structure of DAR, the calculation model needs to be simplified to reduce the difficulty in the modal analysis and the electromagnetic force calculation. The magnetic-solid coupling vibration calculation model is established by adopting ANSYS finite element (FE) software and considering windings, upper and lower spiders, duct sticks and insulation parts. 4. Based on the full method [2], structural vibration of the DAR is analyzed by sweep frequency analysis, and the frequency range is [6 Hz, 600 Hz], which covers the former 1000th modes in the modal analysis. For given natural frequencies at different modal orders, the whole structure displacement deformation of the DAR under electromagnetic harmonic response is calculated, as shown in Fig. 1. In the DAR acoustic noise experimental measurements, a high-precision voice sensor made in American PCB Piezotronics, Inc. (378B02), is adopted [3]. In noise spectrum analysis of the DAR, the SIEMENS LMS vibration and noise test system is used as the noise spectrum measurement device. The SPL and spectrum of DAR acoustic noise are obtained by using vibration and acoustic noise measurement devices system at given PWM voltage excitation (the modulation frequency f_a=50 Hz, the modulation index m_a=0.5, the switching frequency f_s=600 Hz and peak flux density B_p=1.5 T), as shown in Fig. 2. Conclusion: The vibration and acoustic noise of a DAR are analyzed and investigated by means of numerical calculation and experimental measurements in this paper. On the basis of the coupling of the magnetic field and the structure order, the mode, electromagnetic force and structural vibration of the DAR are simulated by FE method, and the emitted noise level is measured. The results show that the vibration displacement is small and about 10^{-4} m in the natural frequency, the vibration of the DAR is mostly radial displacement, and the axial vibration is smaller. In experimental measurements of the acoustic noise, the noise radiation of the DAR structure is dominated by 20 Hz sound pressure, followed by the sound pressures of 120 Hz and 360 Hz, and is given priority to with low frequency sound pressure. This research is helpful for the design and application of low-noise and high-performance reactors.

HI-09. A Novel Structure Design of Iron Core for Power Transformers Considering Joints Forms and Magnetostriction.

J. Li[1], S. Wang[1], H. Gao[2,1], M. Liu[2,1] and J. Hong[1]
1. State Key Laboratory of Control and Simulation of Power System and Generation Equipments, Tsinghua University, Beijing, China; 2. State Key Laboratory of Reliability and Intelligence of Electrical Equipment, Hebei University of Technology, Tianjin, China

Abstract Body: Power transformers and reactors are important devices in power transmission systems. But their cores and windings could produce vibration and acoustic noise by magnetostrictive effect, Maxwell electromagnetic stress and Lorentz force. Noise has become a bad environmental pollution source in some situations, and its vibration and noise reduction has become an urgent problem need to be solved. The shapes, materials, magnetostriction and joints forms of iron cores, the limitations of test, modeling, and experimental measurement of vibration and noise characteristic, are all the difficult reasons to analyze the vibration and acoustic noise of transformers and reactors. 1. The magnetostrictive modeling can be divided into two steps based on the magnetic field force and materials deformation, so the magnetic field force will be fed into the structural finite element with Maxwell electromagnetic force produced on the interface between the iron core and the air to calculate the deformation of the magnetic materials and to make the model more general and consistent. In order to fully verify the correctness of the model in the magnetostrictive analysis, and to ensure the simplicity of test and avoid unnecessary interference factors, the most simple magnetostriction tests will be carried out by using a single closed circle or rectangular electrical steel sheet, as shown in Fig. 1(a). The tests will measure the relationship between magnetostriction and magnetic field of different magnetic materials, different saturations, different sizes and different shapes. 2. The joint is a necessary form for the stacking of large transformer iron cores, and the main joint form is the step jiont at present. The introduction of the joints causes the magnetic force lines to flow through the different laminations and to make the local magnetic field complicated. From simple to complex process is adopted in this paper, and the verification is gradually complicated. Based on the study of a simple sheet with no joint showed in Fig. 1(a)and (e), a sheet with joint will be used to analyze the vibration and modeling calculation, as shown in Fig. 1(b). Maxwell electromagnetic force caused by the the joints and magnetostrictive force due to the magnetostriction of sheet are all actually included in the model. Later, further complicated two or more pieces of sheets are designed up and down on the joint of the simple circle or rectangular sheet, as shown in Fig. 1(c) and (d) to simulate the joints forms in the iron cores of transformers with the magnetic flux transition circulation though the joints. Meanwhile, the separation of the Maxwell electromagnetic force and the magnetostrictive force from the overall analysis can be worked out by using mathematical method, and the separated curve will be given in the end. 3. In order to improve the effect of vibration and acoustic noise deduction sharply, a novel structure design of iron core for power transformer is put forward, with the core and winding position interchange, compared to conventional power transformers, as shown in Fig. 2. Compared with traditional transformers, this structure has many advantages: firstly, the short magnetic circuit reduces the deformation caused by magnetostriction; secondly, the circular ring core does not have joints to avoid the vibration and acoustic noise caused by the joints; thirdly, the radial deformation of circular ring is greatly reduced; the last, the long cantilever structure that causes deformation in the traditional iron core can be eliminated. These advantages together will realize the new low vibration and low acoustic noise transformers. 4. The test prototype of power transformer with laminated core is processed in different stacking modes. The vibration acceleration and displacement of power transformer iron core are measured with high precision laser acceleration sensors, and the modal test is carried out by using Finite Element (FE) software. Based on the comparison between simulation and test data, the effect of vibration and noise reduction is analyzed and established to verify the novel iron core structure design of the power transformers, and to give further reference and guidance to the engineering applications.

HI-10. Comprehensive Analysis and Control of Maximum Power and Maximum Efficiency for Multiple-Objective Wireless Charging Systems.

Z. Zhang[1], R. Tong[1], W. Ai[1], S. Chang[1] and J. Wang[1]
1. School of Electrical and Information Engineering, Tianjin University, Tianjin, China

INTRODUCTION Recently, wireless power transfer (WPT) is getting increasing attentions, for it is able to provide a brand new method for power transmission. The limitations of traditional cable charging method such as tangled and inconvenient power cords, and a limited number of charging interface are well overcome. As for the WPT system, one of the major concern is the power transmission efficiency and the transmitted power influenced by various transmission distance and the variety of loads. Especially in multi-receiver condition, there existing variety of loads with different requirements. Based on the impedance alteration method [1], a comprehensive analysis regarding to the relationship among the equivalent load, output power and efficiency in multi-receiver system is conducted, and a novel load alteration strategy aiming at better satisfying different requirements in different load consistence is proposed based on the aforementioned analysis. PROPOSED LOAD ALTERATION ANALYSIS AND CONTROL STRATEGY The block diagram and experiment prototype is depicted in Fig. 1 (a) and Fig. 1 (b). The equivalent load witch is in series with inner resistance in primary circuit is related to the load, operating frequency, mutual inductance and the paralleled capacitance. Due to the inner resistance of power supply, the maximum output power can be reached while the equivalent load equals the inner resistance. However, the output efficiency of power supply is only 50% for the inner resistance consumes the other half part of total power. On the other hand, the efficiency increases as the load gets larger, and the output power decreases simultaneously on contrary. The relation between equivalent load and paralleled capacitance is delineated in Fig. 1 (c). Furthermore, the varieties of requirements and the type of load causing different cases to deal with. For instance, when the priority of efficiency is higher than that of output power. In order to reach high efficiency, the equivalent load should be large enough to get a large portion of power. In contrary, when the priority of power is higher than that of efficiency. So as to get the maximum output power, the equivalent load should be altered to equal the inner resistance. In other occasions, the equivalent load is designed to be altered for better balance of power and efficiency for different requirements. Based on the above analysis, a novel control strategy is carried out in terms of the priority of transmitted power and transfer efficiency. The assortment of different load is depicted in Fig. 1 (d). CASE STUDY AND SIMULATION To validate the proposed control strategy, a simulation is done in MATLAB-Simulink. According to the assortment of loads, there are totally 4 cases witch match the 4 cases of loads consistence. Load of every secondary circuit is set to 50Ω and inner resistance is set to 1Ω. The paralleled capacitance and the resonance capacitance are adjusted by capacitor array. Case1: high power and high emergency: When there is a majority of loads that demand large power urgently, the equivalent load is alter to equal the inner resistance. As shown in Fig. 2 (a), voltage of both loads and inner resistance reach the maximum value 17.1V and 2.41V, and the power of load is equal to that of inner resistance. Case2: high power and low emergency: The equivalent load can be altered larger to for higher efficiency in the case that the majority of load demands large power but not urgently. As shown in Fig. 2 (b). voltage of both loads and inner resistance get lower with respect to case1, namely 14.8V and 1.5V. Power of loads is greater than that of inner resistance. Case3: low power and high emergency: In this case, the equivalent load can be altered larger as long as the power demand is satisfied. As shown in Fig. 2 (c), voltage of both loads and inner resistance decreased to 5.1V and 1.02V, Meanwhile the proportion of load power increases. Case4: low power and low emergency: When the loads mainly consist with load that demands less power with less urgency, equivalent load is altered to its maximum value. As shown in Fig. 2 (d), voltage of both load and inner resistance reach the lowest point 0.47V and 9.9×10^{-4}V, the power proportion of load gets the maximum value 99.9%. CONCLUSION By comprehensively analyzing the relationship among equivalent load, output power and transfer efficiency, this paper proposed a load alteration strategy to alter equivalent load in accordance with various requirements in multi-receiver WPT system. The simulation results are in well agreement with the theoretical designs and analysis, which verify the feasibility and correctness of the proposed strategy and furtherly proves that the proposed control strategy can effectively satisfy power and efficiency requests under different conditions of loads. Therefore, the proposed alteration strategy poses a huge difference in multi-receiver WPT systems. Besides, the detailed parameters, theoretical analysis, simulated results, and experimental waveforms will be presented in the full manuscript.

HI-11. Analysis of High Frequency Effects of Excitation Winding in High Frequency Rotating Tester with Nanocrystalline material.

Y. Li[1], A. Li[1], *C. Zhang*[1] and Q. Yang[1]
1. State Key Laboratory of EFEAR, Hebei University of Technology, Tianjin, China

Abstract—In this paper, a segmented winding with copper foil was designed in order to reduce the influence of high frequency and distribution capacitance in excitation winding. By analyzing the skin effect in excitation winding, an equivalent model for the AC resistance of the foil winding is established, which determined the optimum thickness of copper foil under different excitation frequency. The method of installing annular ferromagnetic plate to restrain the proximity effect is proposed, which increases the frequency of the excitation to 20 kHz. I. Introduction In multi-phase power transformers and rotating electrical machines, the rotating magnetic flux may cause the increase of core losses, leading to local overheating and damage of the equipment. Nevertheless, the traditional measurement method of magnetic properties for nanocrystalline is ring specimen method, which is still far from accurately describe high frequency rotating magnetic properties of nanocrystalline in engineering practice. The main difficult to test the magnetic properties for nanocrystalline at high-frequency is that the core losses of magnetic circuit increase acutely with the increasing frequency and the influence of high frequency effects. [1] [2] In this paper, a segmented excitation winding with copper foil was designed, which can reduce the influence of high frequency and distribution capacitance. With the segmented copper wingding, the establishment of the high frequency rotating magnetic become more easily. II. Design of the segmented copper winding *A. Analysis of the distribution capacitance* The 2D magnetic tester with foil winding has several advantages. However, the distributed capacitance in foil winding has increased compared with copper wire windings. Different connection ways between the winding layers lead to different potential, and then form the different equivalent capacitance [3]. Fig. 1 depicts the simplified mathematical models of single segmented winding and multi-segmented winding. The analytic expression of equivalent distribution capacitance of single segmented winding is: $C_{single}=(n-1)C_1/n^2=(n-1)\varepsilon\ S/n^2d$ the distribution capacitance of segmented winding is analytical calculated is: $C_{multi}=(n-1)C_1/n^2q^2=(n-1)\varepsilon\ S/n^2dq^2$ where ε is the dielectric constant of the winding interlayer insulation medium; *S* is the average area of the winding, d is the winding layer spacing, and C_1 is the static capacitance of the two layer winding with an equivalent area of *S*. it can be seen that the distribution capacitance of the copper foil winding can be effectively reduced by increasing the number of winding layers and the number of segments. *B. Analysis of the high frequency effects* With the increase of frequency, the influence on the current distribution in copper foil produced by the magnetic field is more and more apparent. Mathematical model of magnetic field intensity of copper foil winding is shown in Fig.2. (a). Combined the Bessel equation of internal magnetic field strength *H* and the boundary conditions, the approximate relation between the AC resistance and the DC resistance under the influence of skin effect and proximity effect can been obtained. Then the relation between the number of winding layers and the thickness of wire is shown in Fig. 2 (b), from which can obtain the optimum thickness of winding under arbitrary frequency. The proximity effect is caused by leakage at the end of copper foil winding. Therefore, how to control the leakage magnetic field distribution along the axial direction of the winding and reduce the radial component of the leakage flux at the end of winding is the key to restrain the proximity effect. In this paper, the method of installing annular ferromagnetic plate at the end of segmented copper foil winding and between two segments winding to restrain the proximity effect is proposed. The comparison of the current distribution in segmented winding with and without the annular ferromagnetic plate is shown in Fig. 2 (c), in which the black portion is the ferromagnetic material. It can be seen that the radial component of the leakage magnetic field is effectively controlled when the annular ferromagnetic plate is arranged, and the current distribution in the copper foil winding is more uniform. In conclusion, a segmented winding with copper foil is designed based on the excitation structure as shown in Fig2. (d). III. Conclusion This paper presents a segmented winding with copper foil, which can reduce the influence of high frequency and distribution capacitance. An equivalent model for the AC resistance of the foil winding is established, which determined the optimum thickness of copper foil under different excitation frequency by analyzing the skin effect in excitation winding. The method of installing annular ferromagnetic plate to restrain the proximity effect is proposed, which plays a key role in the establishment of high frequency rotating magnetic field.

"d^0 ferromagnetism" challenged our conventional understanding on the origin of magnetism, and triggered a heated debate [1-3]. In order to explore the magnetism in magnesium oxide (MgO) without doping [4], we have studied the electronic structure and magnetic properties of pristine MgO (001) surface using first principle calculations. The perfect MgO (001) surface is a nonmagnetic insulator with a band gap of about 3.6 eV in our calculations, see Fig.1 (a). The calculated results reveal that isolated oxygen (O) vacancy (V_O) can not introduce the local magnetic moment in the system, see Fig.1 (c). While isolated magnesium (Mg) vacancy (V_{Mg}) can produce a magnetic moment of about 1.67 μ_B. The magnetic moment mainly results from *p*-orbitals of oxygen atoms adjacent to the V_{Mg}, see Fig. 1 (b) and (d). The 3*s* electrons of Mg and the 2*p* electrons of O form molecular orbitals (MO), and when the neutral Mg atom is taken from the surface, it will introduce two holes in the MO. The holes will be arranged spin-parallel in the orbital because of Hund's coupling rules and the on-site Coulomb repulsion energy U_{pp} between the holes. And the spin-down panel is crossing the Fermi level, showing that the structure with one V_{Mg} will have half-metallic properties. We also calculated three types of antiferromagnetic (AFM) state of the surface with one V_{Mg}. The results show that the ferromagnetic state is most stable. In the supercell, the studies of magnetic coupling show that the two V_{Mg}'s on the surface are not always coupled ferromagnetically at different distances. And the system will be in a spin singlet state (S = 0) when the distance is 2.98 or 8.42 Å between two V_{Mg}'s, while the two V_{Mg}'s are coupled ferromagnetically at the distance of 4.21, 5.96, or 6.66 Å, see Fig. 2. As the distance between two V_{Mg}'s increases, the system will change from semiconductor state to half-metallic state, and finally to metal state. In summary, we can conclude that V_{Mg} may introduce the magnetism in MgO (001) surface. Our results are significant for d^0 ferromagnetism of MgO.

HP-02. About softening of phonon modes in Heusler alloys.

V. Buchelnikov[1,2], O. Miroshkina[1,3] and A. Zayak[4]

1. Condensed Matter Physics, Chelyabinsk State University, Chelyabinsk, Russian Federation; 2. National University of Science and Technology "MIS&S", Moscow, Russian Federation; 3. Institute of Radioengineering and Electronics of RAS, Moscow, Russian Federation; 4. Department of Physics & Astronomy, Bowling Green State University, Bowling Green, OH, United States

It is well known that Heusler alloys have a number of the unique properties such as shape memory effect, effects of superelasticity and superplasticity, giant magnetocaloric effect, giant magnetoresistance and magnetostrain, etc. Above properties are associated with martensitic transformations [1-5]. In recent years, much attention has been given to precursor effects where acoustic anomalies, phonon dispersion curves, and diffuse elastic scattering in the parent phase indicate the eventual martensitic structure [6-8]. Experimentally, the phonon dispersion curves can be measured by the means of neutron scattering [9]. Beams of neutrons scattered by matter turn out to have very suitable properties for phonon experiments. It is known from experimental studies that the softening of the mode occurs in the [110] direction. This mode is believed to be responsible for the premartensitic transition: as long as there are imaginary (negative) values of the TA_2 mode frequency, there is a premartensitic transition in this region. According to the results of the theoretical investigation presented in Ref. [10], TA_2 phonon immediately softens starting from q=0. However, the experimental data [9, 11] show that instability of TA_2 phonon takes place in the narrow range of wave-vectors. Previous theoretical investigations give a rather vague picture. According to them, there is a very wide range of instabilities. Thus, it would be interesting to speculate on the way of clarifying the region of instabilities. In this regard, we consider the effect of supercell elongation and chemical disorder on the phonon spectra of Ni_2MnGa and Ni_2MnAl Heusler alloys. Our assumption is that elongation of supercell will lead to the reduction of the range of instabilities. In the furtherance of this goal, Vienna *ab initio* simulation package (VASP) and PHONON software were used [12-15]. With the help of VASP minimizing the total energy of the crystal with respect to the electronic part, lattice constants and atomic positions and calculation of the Hellmann-Feynman forces were carried out. Then using obtained results the phonon dispersion curves were calculated with the help of PHONON. We considered several types of supercell elongations: they are $1\times n\times 1$, where n=4, 5, 6, 7 and 8. The supercell was created by merging n primitive cells along the $[110]_c$ direction of the cubic Heusler structure, which is the $[010]_t$ direction of the tetragonal cell. The phonon-dispersion curves in the $[110]_c$ direction calculated for the Ni_2MnAl compound are presented in Fig. 1. Authors of paper [16] considered the similar type of elongation, and their results are in agreements with ours and the experimental [17]. However, we disagree with authors in their statement, that theory does not predict softening. It predicts but in other types of supercell elongation. As already mentioned, we assumed, that elongation of supercell will lead to the reduction of the range of instabilities. However, our assumption was confirmed only partially. It is seen, that region of instabilities is really narrowing, but at the same time, instability at Γ-point arises. We can conclude that in the case of too long cells (elongation $1\times 7\times 1$ and $1\times 8\times 1$) considerable noise appears in the calculation of forces. They kill the small forces that act at big distances in the supercell. Thus, the mostly optimal elongations are $1\times 5\times 1$ and $1\times 6\times 1$. The phonon-dispersion curves in the $[110]_c$ direction calculated for Ni_2MnGa compound are presented in Fig. 2. It is seen from this figure that transverse acoustic mode TA_2 gets completely softened going well down to negative frequencies in all cases. The results presented in [8] show that instability begins with 0. However, our calculations demonstrate that only wave distortions in a certain wavelength range will be unstable. The experiment does not predict complete softening of the phonon. We tried to explain this by assuming that this may be due to the influence of native disorder. Investigation of the effect of the disorder was conducted using 40 atoms supercell (elongation of supercell $1\times 5\times 1$). The stoichiometric composition with introduced various degrees of site disorder, quantified by the number of random atom-pairs switches (from 1 to 10 pairs), was considered. The TA_2 mode frequency was calculated for ordered and all case of disordered structures. This analysis was done by the same procedure of considering a particular phonon as a harmonic oscillator. The phonon was picked at the wave vector [0.33, 0.33, 0.00], which corresponds to the imaginary frequency of this mode. The TA_2 mode frequency in studying system demonstrates the tendency to "hardening" in case of the disordered structure. Thus, the experimentally studied real samples may be disordered. In this work, we have demonstrated that the supercell elongation influence on the softening of the TA_2 phonon modes of Ni_2MnGa and Ni_2MnAl Heusler alloys. The optimal elongations of supercells are $1\times 5\times 1$ and $1\times 6\times 1$. The investigation showed that the hardening of the unstable phonon is directly correlated with the level of introduced disorder of Ni_2MnGa alloy. Based on our results, the experimentally studied real samples of Ni_2MnGa may be disordered.

HP-03. Investigation of magnetic and structural properties of $FeRh_{1-x}Pt_x$ (x = 0.5 - 1) alloys by first principles method.

O. Pavlukhina[1], V. Sokolovskiy[1], V. Buchelnikov[1] and M.A. Zagrebin[1]
1. Chelyabinsk State University, Chelyabinsk, Russian Federation

Fe-Rh-based alloys have attracted a lot of attention because of their possible application in magnetic cooling, thermally assisted magnetic recording and spintronic devices [1-4]. Magnetic cooling attracts the attention of scientists around the world. The magnetocaloric effect reaches the maximal value at the temperatures of magnetic or magnetostructural phase transitions. Fe-Rh alloys exhibit a metamagnetic phase transition (AFM-FM). The metamagnetic phase transition in Fe-Rh succeeds also the large change in magnetization, which is responsible for a giant magnetocaloric effect upon variation of a magnetic field. For $Fe_{49}Rh_{51}$, Nikitin et al. [5] reported for the first time the giant MCE about -13 K at magnetic field change of 2 T using a direct method of measurements. The similar values of MCE for the same composition were successfully repeated in Refs. [2, 3]. It well known, that the magnetic order in FeRh compounds depends strongly on the concentration. Therefore, it is important to study the effect of adding a third element on the magnetic and structural properties of the material. A. Jezierski et. al. [4] study the influence of dopants Co, Pd, Ru and Pl on the magnetic moment and the density of states at the Fermi energy in FeRh alloys. The article says that a significant change of the magnetic moment and the density of states at the Fermi level during the substitution metals. In our previous work we investigated $FeRh_{1-x}Pt_x$ (x = 0, 0.125, 0.25, 0.375) [6]. In this work, we present theoretical investigations of the structural and magnetic properties $FeRh_{1-x}Pt_x$ (x = 0.5, 0.625, 0.75, 0,875, 1) alloys. In this work, the structural and magnetic properties of Pt-doped Fe-Rh alloys are investigated by using the density functional theory calculations as implemented in the Vienna *Ab initio* Simulation (VASP) package. The ab initio calculations have been carried out by using the 16-atom supercell approach with different initial spin configurations. The generalized gradient approximation for the exchange correlation functional in the formulation of Perdew, Burke and Ernzerhof (PBE) was taken into calculations. The performed calculations were semirelativistic and the spin polarization was taken into account for all the cases. In the calculations the automatically generated uniform grid of k-point as in Monkhorst-Pack grids was taken into account. The k-points in the Brillouin zone for self-consistent field cycles were generated with 12^3 meshes for the lattice relaxation calculations and tetragonal distortion. The energy calculations were performed for the Pm3m supercell ($FeRh_{1-x}Pt_x$). In detail, original cell has atomic coordinates of (0; 0; 0); (1/2; 0; 0); (1/2; 1/2; 1/2) for Rh atoms and those of (1/4; 1/4; 1/4); (3/4; 3/4; 3/4) for Fe atoms in the supercell. Calculations were carried out for ferromagnetic, paramagnetic and three kinds of antiferromagnetic states. In the present work we calculated the total energies for different spin configurations as functions of the lattice parameter. The equilibrium lattice parameters a = 3.020 for $FeRh_{1-x}Pt_x$ (x = 0.5) up to 3.059 for $FeRh_{1-x}Pt_x$ (x = 1). It can be concluded that the addition of Pt atoms leads to an increase in the lattice equilibrium parameter due to the larger atomic radius of Pt compared to the lower Rh value. The calculation of the total energy for the tetragonal distortion of the cubic structure along the *z* axis is performed in this works. To accomplish this, we fixed the volume of a supercell as $V_0 = a_0^3 \approx a^2c$. In the case of $FeRh_{1-x}Pt_x$ (x=0.5, 0.625, 0.75, 0,875) the antiferromagnetic configuration solution is favorable for martensite states. For the parent FePt compound, the ferromagnetic spin configuration is energetically favorable compared to other configurations. Our calculations have shown that the substitution of Pt for Rh results in an appearance of stable body-centered tetragonal state. While the cubic phase becomes unstable. It is important to note that the similar trend is observed experimentally by Yuasa et al. [7]. This work was supported by RSF-Russian Science Foundation No. 17-72-20022\17.

MnAl, as a prospective candidate of magnetic electrode materials for MgO-based magnetic tunnel junctions, possesses several advantages including the spin polarized Δ_1 band, relatively low Gilbert damping factor, and large perpendicular magnetic anisotropy (PMA). Here, we have performed a thorough first-principles studies of magnetocrystalline anisotropy and spin-dependent quantum transport properties of MnAl/MgO/MnAl(001) -magnetic tunnel junctions (MTJs) for both Mn- and Al-terminated structures. The anisotropy energy density of bulk and interface contribution is determined and thickness dependence of PMA is estimated by considering the shape anisotropy for both terminations. It is found that the bulk anisotropy density is 17.39 Merg/cm^3, while the interfacial anisotropy contribution is evaluated to be 0.12 erg/cm^2 and 0.44 erg/cm^2 for Mn- and Al-terminated structures, respectively. The large anisotropy can be attributed to d_{yz} and dz^2 orbits. Orbital-resolved analysis indicates that the Mn-O bond in the interface is inimical to PMA and Al-terminated interfacial structure (or Al insertion) can serve as a possible solution. Therefore, the formation of a Mn-O bond on the interface of MnAl/MgO is shown to be detrimental for the improvement of perpendicular anisotropy. On the other hand, giant TMR ratios for both terminated MTJs under zero bias are predicted. A giant zero-bias tunneling magnetoresistance ratio can be maintained over 2000% even for a bias up to 0.6 V for Mn-terminated MTJs. The in-plane spin transfer torque for Mn-terminated MTJs increases linearly with a bias up to 0.6 V due to the large net spin-polarized current. Our studies give insight into the PMA and spin-dependent transport mechanism of MnAl/MgO/MnAl(001) MTJs and provide some guidelines for the design of spin-transfer torque magnetic random access memory (STT-MRAM) devices.

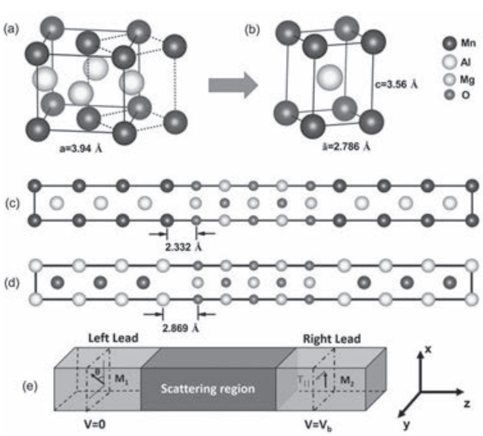

Fig. 1. (a) Crystal structure of L1$_0$ MnAl and (b) reduced tetragonal B$_2$ structure. The optimized atomic structures for (c) Mn-termination and (d) Al-termination. The transport direction is along the z-axis and the MTJ is periodic along the x- and y-directions. Interfacial distances are marked. (e) Schematic sketch of the MTJ structure for in-plane spin-transfer torque T$_\parallel$ calculation. Finite bias V$_b$ is applied on the right electrode. The magnetization direction of left electrode M$_1$ lies in the x – y plane, while that of right electrode M$_2$ points to the x-axis. θ is the angle between M$_1$ and M$_2$.

I.INTRODUCTION To enhance the accuracy of iron loss prediction in high frequency electric machines using superconductive windings, the stacked structure of iron cores needs to be taken into account due to the high proportion of eddy current loss in the iron loss. Thus, the modeling method of the stacked structure of iron cores combining the 3D solid core analysis with the 1D steel plate analysis [1] is improved to include the excess loss in this paper. The iron loss is calculated using the flux and eddy current density obtained from the improved method of magnetic field analysis. In the analysis, the domain wall bowing due to pinning is taken into account by introducing an initial bowing flux [4]. Then, to figure out the change of the resulted iron loss by using the improved method, the method is applied to a single-phase reactor. Finally, the results by using the previous and improved methods are compared in detail. II. METHOD OF LOSS CALCULATION A.Method of Magnetic Field Analysis In the proposed model as shown in Fig. 1, the laminated structure and the eddy currents Jepar are directly considered in the 1D steel plate analysis. The parallel flux density in each element of the 3D solid core is imposed to the 1D steel plate model as boundary condition. 1) 1D Steel Plate Analysis With Domain Wall Bowing Due to Pinning The main cause of excess loss, which is considered to be the domain wall bowing [2] [3]. To take into account the wall bowing by pinning, the 1D nonlinear eddy current finite element analysis is performed applying an initial bowing flux Bp (0, Bpy, 0) distributed along the sheet thickness direction. The fundamental equation is $-\partial(\nu^*(\partial A/\partial z-B_p))/\partial z+\sigma^*\partial A/\partial t=0$ (1) where ν^* and $\sigma^*$are the real reluctivity and conductivity of the steel plate, respectively. Bp is the flux distributed along the sheet thickness in the analyzed model. 2)3D Solid Core Analysis [1] The 3D nonlinear eddy current finite element analysis is applied to calculate the electromagnetic field distribution in the solid core model. The fundamental equations are: $\mathrm{rot}(\nu\,\mathrm{rot}A)+\sigma(\partial A/\partial t+\mathrm{grad}\Phi)=J_0$ (2) $\mathrm{div}(-\sigma(\partial A/\partial t+\mathrm{grad}\Phi))=0$ (3) where A andΦ are the magnetic vector potential and the electrical scalar potential, respectively. Jo is the exciting current vector. ν is the equivalent permeability obtained as mentioned above and $\sigma$is conductivity. B. Method of Loss Density Calculation The hysteresis loss Whys is calculated using the equation as follows. $W_{hys}=K_{hys,Bmax}f$ (4) where Kh,Bmax is the hysteresis coefficients varying with the amplitude of the flux density Bmax in each element. Bmax is obtained by using the parallel and perpendicular flux densities Bpar and Bper obtained from the 1D steel plate analysis and 3D solid core analysis like (4). The eddy current losses We is calculated by using the eddy current densities Jepar and Jeper obtained from the 1D steel plate analysis and the 3D solid core analysis directly. W(ie) $e=\sum\{(\sum(|Je^{(i,j,ie)}{}_{par}+Je^{(j,ie)}{}_{per}/F|\hat{}2)*l^{(i)}/\sigma^*)/(\sum l^{(i)})\}/N_s$ (5) where Ns is the total time step, Ne is the total element number of the 1D analysis, Je is the eddy current density, F is the space factor of the steel plate,σ^* is the conductivity of the steel plate,and l is the length of each element in the 1D analysis. III. ANALYSIS OF A SIMPLE ONE-PHASE REACTOR A.Analyzed model and conditions The simple single-phase reactor constructed by stacked iron cores and coil is analyzed. The cores with gaps are stacked by non-oriented steel plates (thickness 0.35 mm, 35A440) in the z direction, and the space factor F is 0.95. The current with the amplitude of 5×105 A/m2 and frequency of 500 Hz is imposed inside the coil. B.Results The classified iron losses of the reactor with and without Bp are shown in Fig. 2. With Bp, the hysteresis loss is increased due to the increase of the total flux. The increase of total flux is due to the decrease of the magnetic intensity in the air in the 1D steel plate, which makes the equivalent permeability in the parallel direction increase according to (2). The eddy current loss generated by the parallel flux is increased due to the increase of eddy current generated by the parallel flux. The eddy current loss generated by the perpendicular flux is decreased due to the decrease of eddy current generated by the perpendicular flux. And the total iron loss shows about 8% increase finally. IV.CONCLUSIONS 3D-1D combined model of stacked iron cores is analyzed to optimize the accuracy of calculated core loss using the electromagnetic field distribution results. The increase of iron loss shows the applicability of the proposed method at present. In the future, the method will be improved considering the dependence of the Bp on the applied magnetic field and will be verified by experiments.

The perpendicular magnetic tunnel junction (p-MTJ) is the basis for spin transfer torque magnetoresistive devices that have the properties of high-density nonvolatile memory, high thermal stability, and low critical current. The common approach for generating large perpendicular magnetic anisotropy (PMA) for a free layer is to use heavy metal (HM) elements or capping with a HM multilayer. However, adding a noble metal element increases the magnetic damping constant due to its large spin-orbital coupling, and thus can be detrimental to low critical switching current. The spin-orbital coupling strength in 3d ferromagnetic metals (FM) and their oxides is usually 2~3 times smaller than that of HMs or HM multilayer materials. Therefore a light element p-MTJ that can achieve PMA is more desirable. How to enhance the PMA in light element heterojunctions is a pressing problem for the next-generation magnetic memory. Using first-principles calculations, we investigated the effect of compressive and tensile strain on the perpendicular magnetic anisotropy of light element heterostructures of Co films, Co/graphene, and Co/BN. We found that the perpendicular magnetic anisotropy of Co/graphene is greatly enhanced compared to the Co films, while that of Co/BN is reduced compared to the Co films. A compressive strain increases the distance between the interface Co atom and graphene or BN, diminishing their effect. When the interlayer distance reaches ~4 Å, the MAE of Co/Gr and Co/BN heterostructures are nearly the same as that of a Co multilayer. In addition, tensile strain can further enhance perpendicular magnetic anisotropy of Co/graphene and Co/BN heterojunctions by 48.5% and 80.8%, respectively. A density of state analysis, combined with layer and orbital magnetic anisotropy contributions obtained from a second-order perturbation theory, reveals that the tensile strain effect arises from the increase of the hybridization between same spin dxy and $dx^2–y^2$ states of the surface Co film. Our results suggest that strain engineering is an effective approach to enhance the perpendicular magnetic anisotropy of light element heterostructures.

Silicene is an emerging 2D material with advantages of the high carrier mobility, compatibility with silicon-based semiconductor industry [1], and the tunable gap by vertical electrical field due to the buckling structure [2]. In this work, we report a first-principles investigation on the spin injection system, which consists of Fe(111)/silicene stack as the spin injector and pure silicene as the spin channel. An extremely high spin injection efficiency (SIE) close to 100% is achieved. The partial density of states of Fe layers in Fe(111)/silicene stack shows that spin-down states dominate above the Fermi level, resulting in a negligible spin-up current and high SIE. The transmission spectra have been investigated to analyze the spin-resolved properties. The spin injection system based on silicene is promising for the efficient silicon-based spintronics devices such as switching transistors.

Key Laboratory of Magnetic Materials and Devices, Ningbo Institute of Material Technology and Engineering, Chinese Academy of Sciences, Ningbo, China

We report first-principles investigations on magnetocrystalline anisotropy energy (MCAE) oscillation as a function of capping layer thickness in Heusler alloy Co_2FeAl/Ta heterostructure. Substantial oscillation is observed in the structure with FeAl-interface. According to k-space and wave function analysis, this oscillation is mainly attributed to the Fermi-energy-vicinal majority-spin quantum well states (QWS) which are confined between Co_2FeAl/Ta interface and Ta/vacuum surface. The vanishing of QWS in the structure with Co-interface can be explained by the smooth potential transition at the interface. These findings clarify that MCAE in Co_2FeAl/Ta is not a local property of the interface and that the quantum well effect plays a dominant role in MCAE oscillation of the heterostructure. This work presents the possibility of tuning MCAE by QWS in capping layers, and paves the way for artificially controlling magnetic anisotropy energy in magnetic tunnel junctions.

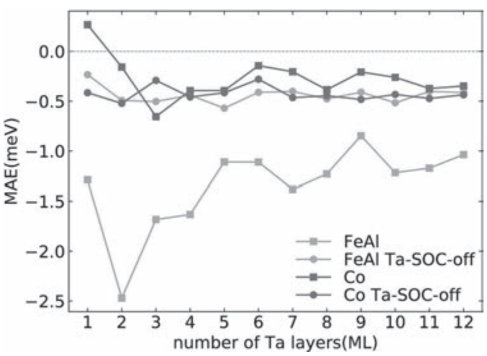

Fig. 1. MCAE oscillation with respect to Ta monolayers (ML) number. Cyan color for FeAl-interface structure, red for Co-interface structure. Circle mark for MCAE calculation with SOC of Ta switched off while spin orbit coupling (SOC) of CFA still included, square mark for normal MCAE calculation. A strong oscillation of MCAE can be observed in FeAl-CFA/Ta structure relative to the thickness of capping layer Ta. For the FeAl-CFA/Ta structure, by suppressing the SOC of Ta while still keeping the SOC of CFA, oscillation of the MCAE relative to Ta layer thickness disappears. This indicates that the electron states in Ta play the determinant role in the MCAE oscillation of CFA/Ta system.

HP-09. Theory of non-collinear interactions beyond Heisenberg exchange; applications to bcc Fe.

S. Attila[1], D. Thonig[1], P.F. Bessarab[2], Y. Kvashnin[1], D. Rodrigues[1], M. Pereiro[1], L. Nordstrom[1], A. Bergman[1], A. Klautau[3], O. Eriksson[1] and R. Cardias[1]

We show for a simple non-collinear configuration of the atomistic spins (in particular, where one spin is rotated by a finite angle in a ferromagnetic background) that the pairwise energy variation computed in terms of multiple scattering formalism cannot be fully mapped onto a bilinear Heisen- berg spin model even in the lack of spin-orbit coupling. The non-Heisenberg terms induced by the spin-polarized host appear in leading orders in the expansion of the infinitesimal angle variations. However, an Eg-T2g symmetry analysis based on the orbital decomposition of the exchange param- eters in bcc Fe leads to the conclusion that the nearest neighbor exchange parameters related to the T2g orbitals are essentially Heisenberg-like: they do not depend on the spin configuration, and can in this case be mapped onto a Heisenberg spin model even in extreme non-collinear cases.

Theory of noncollinear interactions beyond Heisenberg exchange: Applications to bcc Fe A. Szilva, D. Thonig, P. F. Bessarab, Y. O. Kvashnin, D. C. M. Rodrigues, R. Cardias, M. Pereiro, L. Nordström, A. Bergman, A. B. Klautau, and O. Eriksson Phys. Rev. B 96, 144413 – Published 10 October 2017

Miheev Institute of Metal Physics of Ural Branch of Russian Academy of Sciences, Str. S. Kovalevskoy, Ekaterinburg, Russian Federation; 4. Nebraska Center for Materials and Nanoscience and Department of Physics and Astronomy, University of Nebraska-Lincoln, Lincoln, NE, United States

Tetragonal FePd is an interesting magnetic material [1-3] whose formation involves several ordered and disordered phases. Experiment shows that the A1 to $L1_0$ structural transformation in FePd is a complex transformation of the cascade type, which proceeds via intermediate low-symmetry phases, namely the disordered tetragonal phase A6 (I4/mmm), the modified $L1_0$ phase(P4/mmm), the hexagonal ordered phase Fe_2Pd (P3m1), and, probably, the orthorhombic (Cmmm) and the cubic ordered $L1_2$ (Pm-3m) phases [4-5]. We present *ab initio* calculations to understand the experimentally observed situation in FePd. The density-functional calculations employ the generalized gradient approximation (GGA) for exchange and correlations. The calculations are based on the projector augmented wave (PAW) method implemented in the Vienna Ab-Initio Simulation Package (VASP). For the electronic wave functions, an energy cutoff of 500 eV has been taken. We have performed the calculations for ordered, deformed $L1_0$, and two chemically disordered structures. The well known ordered structures for Fe-Pd system are FePd ($L1_0$) and $FePd_3$ ($L1_2$) [4-5]. In addition, we have considered the experimentally observed, hexagonal Fe_2Pd (CdI_2-type), and orthorhombic Fe_3Pd_5 (Pt_5Ga_3-type) structures where order is yet to be established. For simplicity, we have considered only ordered form of these two structures. Furthermore, we have considered deformationsof the $L1_0$ structure, namely pseudocubic structures ($a = b = c$) and structures with c/a<1. For the chemically disordered structures, we took the face-centered cubic A1 structure and a tetragonally distorted 2 x 2 x 2 supercell of $L1_2$ where c/a = 0.974. The disorder was created by substituting one Pd by one Fe in $FePd_3$ ($L1_2$) to form the 50-50 composition for FePd alloy. Figure 1 shows the unit cells for all calculations. We have optimized the experimentally obtained lattice parameters for our calculations. Table 1 shows the optimized lattice parameters and formation energy of all the ordered and disordered phases. The formation-energy calculations, which use ground-state density-functional theory (T= 0) confirms that two ordered phases, Fig. 1(a) and (b) and two chemically disordered phases, (e) and (f), are the stable phases. The other ordered phases, namely(c) and (d) and two deformed versions of $L1_0$ namely the pseudocubic and $L1_0$ with c/a <1 are also likely to be formed in the multiphase Fe-Pd sample as they have very low positive formation energies. In conclusion, we have performed *ab initio* calculations of several ordered and disordered phases of FePd alloys and calculated formation energy and the magnetic moments of Fe and Pd atoms in the alloy systems. The calculated negative formation energies are consistent with the experimentally observed phases. This work was partially supported by the Indian-Russian collaborative project (RFBR No. 17-52-45097 and INT/RUS/RFBR/P-267).

1. Harbin Institute of Technology, Harbin, China

1.INTRODUCTION The losses always occur when PMSM is running. As the losses generate heat, they also determine the machine cooling requirements and efficiency. Therefore, a good knowledge of the losses dissipated in a PMSM is usually required before the machine application stage. To measure the losses of the machine, the output power and input power are usually measured in traditional loss testing methods. The losses can be obtained by subtracting the output power from the input power. Some loss test methods have been mentioned in literature to make the measurement accurately. The latest edition of IEEE standards for the identification of permanent magnet machines includes many test methods [1]. A novel test measuring system and test method to measure the iron loss of stator assembly have been introduced in [2]. A method for measuring magnet losses in the surface mounted PMSM has been presented in [3]. However, in these methods, the machine needs to be connected with a mechanical load. Therefore many loss estimation methods have been investigated. The most accurate reported methods to calculate the iron losses of the PMSM are based on defining the flux density as a function of time with the finite element analysis (FEA) [4]-[7]. Compared with the analytical calculation, the calculation of the machine would usually be more time consuming with the FEA method [8] [9]. Therefore, some fast-calculating analytical methods are developed, although the accuracy of the iron loss prediction is degraded [10]-[13]. In loss estimation methods, the saturation of the machine is mainly dependent on the material property. Even some manufacturing errors occurring in the manufacturing process can not be considered in the estimation. Considering the drawbacks of estimation methods and the traditional testing methods, an indirect testing method for the losses of multi-unit PMSM without any mechanical load is proposed in [15]. In this method, the losses of the machine can be obtained by the particular control strategy and the measurement instead of connecting to the mechanical load. The influence factors of the testing method proposed in [14] will be analyzed and discussed in this paper. 2. The indirect loss testing strategy A. Loss Testing Method According to the relation with the speed, the losses in the machine can be defined as two parts: the speed-dependent losses and the speed-independent losses. The speed-dependent losses mainly include iron losses, stray losses, and mechanical losses. Usually the speed-independent losses are exactly the copper losses. That is to say, instead of testing the speed-dependent losses in the load situation, the losses can be obtained by testing the losses in the no-load situation with the magnetic flux density and the electrical frequency are the same as those in the load situation. The magnetic flux density can not be measured directly in the normal running situation. It can be estimated by calculating the magnet flux linkage. B. Test for the magnet flux linkage Considering that the magnet flux linkage at the load test may be different from that at the no-load test because of the different saturation degrees, the magnet flux linkage produced only by PMs at the load test is estimated with the magnet flux linkage obtained at the no-load test and the inductance in the *d*-axis which can show the saturation in this direction. 3. The influence factors on the indirect test A. Pole-slot Combination To analyze the losses tested by the proposed loss testing method in different pole-slot combination configurations, three PMSM models are established with finite element method. They are the model with 32-pole and 36-slot (fractional–slot concentrated winding configuration), the model with 16-pole and 36-slot (fractional–slot distributed winding configuration), and the model with 8-pole and 36-slot (integral–slot distributed winding configuration). The flux linkage of the winding and magnetic flux density distribution of the three PMSM models are calculated. The calculated iron losses of the three configurations are also listed. B. Saturation Status To analyze the losses tested by the proposed loss testing method in different saturation status, the indirect-testing losses are calculated in the overload operating situation. All PMSM models are overload operating. The flux linkage of the winding and magnetic flux density of the armature teeth of the three PMSM models are calculated in the overload operating situation. C. Harmonic Content According the influence of the pole-slot combination and saturation status on the test error of the proposed method, the harmonic content of the magnetic flux density of the armature teeth is the main influence factor of the test error. To analyze the test error influenced by harmonic, different pole shapes are considered. D. Frequency The effect of the frequency will be analyzed to discuss the application of the proposed method. 4. Result and discussion To validate the proposed loss testing method for multi-unit PMSM, a four-unit PMSM prototype with 32 poles and 36 slots was tested with the proposed method. The direct-testing bench and the indirect-testing bench is shown in Fig. 1.The comparison of the indirect loss test and the direct loss test are shown in Fig.2. 5. Conclusion In this paper, the influence factors of the indirect loss testing method for multi-unit PMSM are analyzed, the applied area of this testing method is discussed.

1. School of Electrical Engineering and Automation, Harbin Institute of Technology, Harbin, China

I. INTRODUCTION Nowadays vibration and noise performance has become an increasingly important consideration for permanent magnet synchronous machines (PMSMs) to meet the industry market's requirement. For PMSMs with low vibration and noise levels, careful analysis and optimization of electromagnetic (EM) force harmonics, i.e., the excitation sources, are essential at the design stage. Among the EM forces, unbalanced magnetic force (UMF) is the most undesirable because it induces significant vibration and noise, and also largely reduces the bearing life. There are numerous factors contributing to UMF for PMSMs in the design and manufacturing processes, among which diametrically asymmetric windings and static or rotating rotor eccentricities are popular topics on account of the UMF's detrimental effect in the last decades. Most recently, a sort of minimum asymmetries from manufacturing imperfections and tolerances have been reported about their effect on UMF or vibration and noise performance in PMSMs [1, 2]. In spite of the tiny variations in structure, the adverse influence is evident. Different from previous contributions, this paper concentratedly discloses the UMF caused by five deliberately introduced asymmetric designs and the resulting degenerated vibration performance in PMSMs. These asymmetric designs are all meant to reduce cogging torque or torque ripple to enable a smoother operation and mitigate relevant vibration components, although the vibration performances have seldom been inspected by experiments [3-7]. Original intention was to cut down tangential excitation sources with the methods, however, at the expanse of probably introducing extra UMF, which the authors paid less attention. In this paper, a further in-depth analysis and numerical verification of the asymmetric designs are carried out with the help of five machines at first. Then the work continues with the characteristics of asymmetric magnetic field and resultant UMF. Lastly experiments are performed on a prototype machine with symmetric and asymmetric designs to verify the degenerated vibration performance. II. ANALYSIS OF ASYMMETRIC DESIGNS The five asymmetric designs can be classified as rotor modifying methods and stator modifying methods. The former include PM shift to reduce cogging torque [6] and torque ripple [3], and asymmetric flux barriers to improve torque ripple behavior [7], while the latter refer to slot-opening shift [4] and teeth pairing to mitigate cogging torque [5]. In view of the effectiveness of these methods, machines with different configurations have been designed for each method. They are successively with 8 /12 (M1), 6/36 (M2), 4 /36 (M3), 8 /12 (M4) and 8/18 (M5) pole/slot combinations. The first three, for rotor modifying methods, are shown in Fig. 1. Essentially these methods are all based on the foundation that critical harmonics induced by symmetric units in the machines can be canceled by slightly modifying at least half units to differ from others. The mentioned critical harmonics can refer to torque ripples themselves or reluctance harmonics or air-gap permeance variations. Confirmed by numerical simulation, three out of the four pole-pairs are respectively shifted by -3.75°, 3.75°and 7.5°mech. angle for M1, and two of the three pole-pairs are shifted by 3.33°and 6.66°for M2. Meanwhile three outer flux-barrier-pairs in M3 are shifted by 2.5°, 5°and 7.5°, and the inner pairs are positioned 12.5°away from the corresponding outer ones. In consequence, as depicted in Fig. 1, fine reduction of 94.5% has been done for the cogging torque of M1, and 81.1% and 82.4% for the torque ripple of M2 and M3. More in-depth analysis described by formulas will be presented in the full paper including the descriptions about stator modifying methods. III. CHARACTERISTICS OF ASYMMETRIC MAGNETIC FIELD AND UMF Fig. 1 shows the flux lines of symmetric and asymmetric designs for M1~3. For symmetric designs, the circumferential cycles of flux line indicate the spatial periodicity of local magnetic stress in fact, since both radial and tangential stress are independent on the polarity of magnetic field. Hence the smallest non-zero spatial order of local force harmonics are respectively 4, 6 and 4 for M1~3. A symmetric design guarantees an ideal zero UMF because no force component with spatial order 1 exists. Unfortunately, the asymmetric designs alter the flux line distributions. Due to the shifts in the rotor, the periodicity in magnetic field is broken. A direct brake happens in the rotor, for which rotating symmetry doesn't exist anymore, and further does in the whole machine. The anisotropic rotor rotates in the machine like a magnetized PM sweeps around the inner surface of the stator. Then UMF comes into being. The UMF ripple in the rotor frame is the iNs-th and further becomes the ($iNs\pm1$)-th when transformed into the stator frame. UMF waveforms in time domain are depicted in Fig. 1. The amplitude is high enough to answer for strong vibrations. IV. EXPERIMENTAL EVALUATION A prototype of M1 with two rotor designs was manufactured, as shown in Fig. 2. Cogging torque and EMF were tested and found to agree well with the numerical simulation. Acceleration at four points on the system was measured. It can be seen high vibration components corresponding to the UMF arise for both the points on the frame and the support for the asymmetric design. This indicates a degenerated vibration performance.

Permanent magnet assistant synchronous reluctance motor (PMA-SynRM) has strong durability and generates reluctance torque without the copper loss of the rotor unlike the induction machine; thus, recently the super-premium (IE4) efficiency PMA-SynRM is being mass-produced. In recent research, for IE4 efficiency PMA-SynRM design, in order to save manufacturing costs while retaining the basis of induction motors (IMs) stator and winding structure, the rotor structure of the PMA-SynRM alone conducted a lot of analysis. Such as optimal design SynRM rotor barriers shape [1], [2]. Barriers angle [3], Barriers number [4] and permanent magnet position [5]. In order to maximize the saliency ratio of PMA-SynRM, recently, the axially laminated anisotropic (ALA)-type SynRM [6] has even been studied, even used 3-D printer to increase the saliency ratio of the SynRM rotor structure [7]. However, we found that the main loss of industrial PMA-SynRM is the copper loss of the stator, therefore, for a fixed PMA-SynRM rotor, the corresponding PMA-SynRM stator design is also very important. So that in this paper, in order to optimal design the PMA-SynRM for meet ultra-premium efficiency (IE5), reduce slots saturation and minimize torque pulsations, we used three steps to optimal design the stator of PMA-SynRM, in the first step, we choose the different winding method for a 4 poles, 3.7kW PMA-SynRM, and is the same diameter of stator and axial length as the premium efficiency (IE3) frame, which is shown in the Fig.1. The stator slots number and winding methods not only consider by the value of the winding coefficient but also the same need to consider the rotor poles, as well as the number of barriers per pole, we can find from Fig 2. [8], for different positions of the rotor, the magnetic flux transfer at different locations will affect the d-q axis inductance, and the result will be calculated by Eq. (1) After determining the winding method and number of turns, in the second step, the yoke width and tooth width around the stator will be optimization by using the response surface methods (RSM). For this step, the optimal design model considers the magnetic saturation in the iron parts of the stator, this saturation results from the actual B–H characteristic of the core. Meanwhile, both core loss and copper loss could be reduced for optimal design model to meet IE5 efficiency. To minimize torque ripple, according to the tendency, the height of the shoes should be over 3.75 mm which was shown in Fig. 3 and the parameter design with the new model (Fig.4)was performed to solve the problems with the harmonic wave. There are many parameters like the height of the shoes, the slot opening. Etc. The parameter design was repeated to make these parameters satisfy the required output and minimum loss characteristics of the first optimal model and only reduce the torque ripple of PMA-SynRM. Through the analysis results by the (finite element method) FEM, it shows that the loss and torque ripple of the final model are significantly reduced. When compared with those of the initial model and an IE3 efficiency IM. At last, in full paper, the experiment result will be discussed.

HQ-04. A Novel Doubly Salient Flux Modulation PM Machine with Halbach Magnets.

K. Xie[1], D. Li[1], *R. Qu*[1], Y. Gao[1] and Y. Pan[1]
1. Huazhong University of Science & Technology, Wuhan, China

I. INTRODUCTION With the advent of high performance permanent magnet materials, many novel PM machine topologies have been developed for various applications. Apart from the "rotor-PM" machines, such as surface mounted, inset and interior PM machines, the "stator-PM" machines [1] such as flux switching (FS-), flux reversal (FS-) and doubly salient (DS-) PM machines have attracted much attention in recent years. With the merit of high torque density, the PM vernier (PMV) machine [2], as a kind of "rotor-PM" machine, has been discussed extensively. Since the PMV machine and magnetic geared machine share the same operation principle [3], they can be classified into the flux modulation machines [4], and the FSPM, DSPM, FRPM and transverse flux PM machines are also included. Based on the flux modulation effect, machines with magnets in both stator and rotor have been the research hotspot recently [5]-[6]. In this paper, a novel flux modulation PM machine with Halbach magnets in both stator and rotor is proposed. It's shown that the torque density of the machine is 49.7 kNm/m^3, more than 1.6 times as that of PMV machines, when the heat loading is 1704 A^2/cm.mm^2. II. STRUCTURE AND OPERATION PRINCIPLE The configuration of the proposed flux modulation PM machine is presented in Fig. 1, while the operation principle is also illustrated briefly. It's seen that the doubly salient structure is preferred, and the Halbach array magnets is employed in both stator and rotor slot opening. Therefore, the proposed machine can be taken as the integration of a "stator-PM" machine and a "rotor-PM" machine, as shown in Fig. 1. Moreover, the operation principles of the "stator-PM" machine part and "rotor-PM" machine part are both based on the flux modulation effect. Then, the winding pole pairs is calculated as the difference between the stator slot number and rotor slot number. For the "stator-PM" machine part, the PM magnetomotive force (MMF) pole pair number is equal to the stator slots, while the PM MMF pole pair number is equal to the rotor slots for the "rotor-PM" machine part. The pole pair number of airgap permeance for the two machines are also different which results in the same winding pole pairs. With Halbach magnets employed, the self-shielding and flux focusing effect is utilized, and the expanded views of the flux lines of the three machines is also shown in Fig. 1 to reveal the integration effect of the proposed machine. III. ELECTROMAGNETIC PERFORMANCES The electromagnetic performances of the proposed flux modulation PM machine are shown in Fig. 2. The main parameters is given in Table I. It's clear that there is one pole pair magnetic flux in the stator of the three machines, while the flux lines and flux density distribution of the proposed machine, the stator-PM machine part and the rotor-PM machine part are similar. As for the proposed machine, the flux density is more uniformly distributed in the iron core, while the tooth tips gets a little saturated. Further, the torque performance of the proposed flux modulation machine, the stator-PM machine part, the rotor-PM machine part and the sum of the stator-PM and rotor-PM part are compared. It's shown that the back-EMF amplitude of the rotor-PM machine part is about 7% higher than that of the stator-PM machine part, while the average torque is 6% higher. Since the structure of the proposed machine can be regarded as the integration of the two machine parts, it's shown that the back-EMF and output torque of the proposed machine is about 15% lower than that of the algebraic addition of the two machine parts due to the saturation. Compared with the two machines part, the torque ripple of proposed machine is decreased to 2.91%. It should be noted that when the heat loading is 1704 A^2/cm.mm^2, the average torque of the proposed machine is 42.1 Nm, and the corresponding torque density is 49.7 kNm/m^3, and the power factor is 0.66. When the electric loading is decreased to 200 A/cm, the output torque is 32.1 Nm and the corresponding torque density is 37.9 kNm/m^3, and the power factor is 0.8. IV. CONCLUSION In this paper, a novel flux modulation PM machine with high torque density and lower torque ripple is proposed. The doubly salient structure is preferred and Halbach array magnets are employed in both stator and rotor slot opening. The proposed machine can be taken as the integration of a stator-PM and a rotor-PM machine. It's shown that the torque density of the proposed machine can be 49.7 kNm/m^3, and the power factor can be 0.8 with decreased electric loading. More detailed analysis will be given in the full paper.

HQ-05. Analysis and Optimization of Cogging Torque in Yokeless and Segmented Armature Axial-Flux Permanent-Magnet Machine with Soft Magnetic Composite Core.

L. Xu[1] and Y. Xu[1]
1. School of Electrical Engineering, Shandong University, Jinan, China

Abstract Yokeless and segmented armature (YASA) axial-flux permanent-magnet machine has high power density and efficiency, which is suitable for in-wheel or near-wheel direct-drive electric vehicles. This paper investigates the cogging torque of a YASA with soft magnetic composite (SMC) core. Firstly, the structure of SMC-based YASA is introduced. Then, the influence of magnet pole-arc ratio, magnet skewing, stator shoe width ratio and stator shoe shifting on cogging torque is analyzed. Based on which, the cogging torque is optimized by response surface model and genetic algorithm (GA). Finally, the optimization results are verified by 3-D finite-element method (FEM). The results confirm that, based on a certain magnet pole-arc ratio, there exists an optimum combination of magnet skewing angle, stator shoe width ratio and stator shoe shifting angle for the cogging torque minimization, while the main performances of the machine remain nearly invariable. I. Introduction Compared with the conventional axial-flux permanent-magnet machine (AFPM), the yokeless and segmented armature (YASA) axial-flux permanent-magnet machine has no stator yoke, therefore has the advantages of less stator core and short magnetic circuit. The stator core of YASA can be fabricated with soft magnetic composite (SMC) material, which can not only reduce the manufacturing difficulty, but also make full use of magnetic, thermal and mechanical isotropic characteristics of the SMC to further improve the performances of the machine. A number of notable works have been done for the cogging torque analysis of AFPM, among which the methods given in [1]-[3] can be used to reduce the cogging torque of YASA with electrical steel core. However, the cogging torque analysis method will be different for the YASA with SMC core, due to the special characteristics of stator tooth and slot shape, magnetic circuit structure and SMC material. II. Structure of the YASA With SMC Core Fig. 1 shows the structure of the YASA with 10 poles and 12 slots. The stator cores are made of SMC material while the rotors are made of solid magnetic material. To make full use of the isotropic magnetic properties of the SMC material, the stator shoe overhangs the stator tooth along circumferential and radial direction, respectively. As a result, the coil end can lie within the effective magnetic field range of the machine. III. Influence of Design Parameters on Cogging Torque A. Magnet Pole-Arc Ratio Magnet pole-arc ratio affects not only the cogging torque, but also the air-gap flux density [4]. Selecting an appropriate magnet pole-arc ratio can reduce the cogging torque while maintaining the main performances of the machine. Here, the optimal magnet pole-arc ratio is determined by 3-D FEM. Based on which, the influences of other parameters on cogging torque will be analyzed. B. Magnet Skewing In order to reduce the cogging torque of the SMC-based YASA, the fan-shaped magnet skewing approach is used [5]. Variations of cogging torque with respect to the magnet skewing angle are analyzed by 3-D FEM. C. Stator Shoe Width Ratio Different from the YASA made of electrical steel, the width of added stator shoes of the SMC-based YASA can change in a relatively large range, leading to the variation of PM leakage magnetic circuit and air-gap stored PM energy. The influence of stator shoe width ratio on the cogging torque is analyzed by 3-D FEM. D. Stator Shoe Shifting For the SMC-based YASA, the two stator shoes of one stator tooth can be symmetrically shifted by an angle in reverse direction to reduce the cogging torque, and the optimal shifting angle for cogging torque minimization is determined by 3-D FEM. IV. Optimization of the Cogging Torque Based on Response Surface Model and Genetic Algorithm The magnet skewing angle β, stator shoe width ratio α_s and stator shoe shifting angle δ are selected as the design variables, and the cogging torque T_{cog} is selected as the response variable. Based on above analysis, the response surface model can be established, and the β, α_s, δ are optimized by GA. V. Finite-Element Verification The performances for the initial design and optimization are calculated by 3-D FEM, with the comparison result of cogging torque shown in Fig. 2. It can be seen that the cogging torque is reduced to a large extent after optimization, which verifies the effectiveness of the proposed optimal method. The paper was supported by the Key Developing Project of Shandong Province(2017CXGC0906).

1. Harbin Institute of Technology, Harbin, China

I. INTRODUCTION Limited-angle torque motor (LATM) featuring a limited rotation less than 180 degrees has been widely applied in position controlling systems such as servo on-off valves, scan mirror system, and so on [1]. Compared with rotating motors in these limited-motion areas, LATMs have many advantages including higher torque/power ratio, higher reliability, and lower cost, owing to fewer mechanical connection parts and maintain free operations [2-3]. However, cogging torque and partial magnetic saturation problems for conventional slotted LATMs result in a non-uniform torque profile so that the slotted LATMs cannot meet the requirements of precise positioning system. Besides, some published material indicates that magnetic saturation in stator teeth due to armature reaction makes torque profile worse even if the slotted LATM operates on rated load [4]. These features have essential influence on position tracking ability for slotted LATMs. Therefore, for taking fully consideration of these problems, a novel slotted LATM with asymmetrical teeth is proposed to improve the both torque profile and torque density. The proposed LATM with 4 poles/4 slots is prototyped, and related experiments are employed to validate the theoretical design and finite element analysis. II. PROPOSED SLOTTED LATM AND ITS SPECIFICATION The proposed slotted LATM shown in Fig. 1 comprises asymmetrical teeth, instead of the conventional symmetrical teeth. In other words, for the existed slotted LATM, all of teeth shape are same, whereas the teeth shape for the proposed LATM are different. The winding connection for the both LATM are shown in Fig. 2. A single-phase winding is adopted for both LATMs. Moreover, this winding connection shown in Fig. 2(b) is distinct from the former since there are only two coils on the number 1# and 2# of tooth. As a result, the manufacturing process of winding for the proposed LATM is much easier than the conventional one. Worth of mention is that non-wounded tooth can be optimized to arbitrary shape for the sake of enhancing torque performance because its shape is not restricted by the winding process. III. LATM MODELING AND TORQUE CALCULATION For initial design of the LATM, a magnetic equivalent circuit (MEC) that is suitable for the slotted LATM is proposed for the initial design process shown in Fig. 3. The proposed MEC modeling is based on the following simplifications: 1.The magnetomotive force (MMF) drop in the iron parts including stator and rotor is neglected. 2.The end effect is ignored. 3. Linear demagnetization characteristic of the permanent magnet (PM) is utilized. For obtaining the MEC modeling accurately, the reluctance of one whole PM is divided into three parts defined as R_{m1}, R_{m2}, and R_{m3}. Meanwhile, the corresponding reluctance of air gap is done the same process, which is depicted as R_{g1}, R_{g2}, and R_{g3}. It should be noticed in Fig. 3 that the number of nodes is only three in consideration of the structure symmetry. Nodal analysis is carried out to solve the magnetic circuit to obtain the torque equation for initial design of LATM [5]. IV. FINITE ELEMENT ANALYSIS AND EXPERIMENTAL VALIDATION Finite element analysis (FEA) is implemented to validate the accuracy of the proposed MEC model. At the same time, further shape optimization of non-wounded teeth is employed for improve the torque profile for the proposed LATM based on the FE method. The proposed LATM with 4 poles/4 slots is prototyped and shown in Fig. 4. Related experiments investigation and discussion will be carried out in this section.

HQ-08. Design Optimization of Interior Permanent Magnet Synchronous Motor for Electric Compressors of Air-Conditioning Systems Mounted on EVs and HEVs.

S. Cho[1], *J. Choi*[1], H. Shin[2], K. Jung[2] and K. Shin[1]
1. Chungnam National Univ., Daejeon, The Republic of Korea; 2. Hanon systems, Daejeon, The Republic of Korea

This paper presents the design optimization and analysis of an interior-type permanent magnet synchronous motor (IPMSM) for use in the electric compressors of air conditioners applied in electric cars and hybrid vehicles. The IPMSM was chosen because it is suitable for high-speed, high-efficiency and lightweight application in electric compressors. The IPMSM is especially suitable for electric compressors because it has a high torque utilization ratio due to the use of reluctance torque and it can prevent the scattering of magnets [1]. The motor efficiency of electric compressors in automotive applications affects the fuel efficiency and mileage of vehicles, so it is important to improve motor efficiency. Moreover, noise generated by the motor is transmitted to the inside of the vehicle, which can cause discomfort to passengers; therefore, noise reduction design is also important. In particular, it is important to reduce the cogging torque; this noise factor has a significant influence on the noise of the motor [2]. In this study, the main design factors of the motor shape were derived to satisfy the efficiency and cogging torque requirements at the same time, and design optimization was carried out through a two-step design optimization process combining the Taguchi and surface response methods. The optimization process is divided into two stages to reduce the number of analysis steps because the amount of time required for motor analysis increases greatly if optimization is done for various design variables simultaneously. The electromagnetic field analysis for the design of a motor uses the finite-element method (FEM), which requires a long time. Therefore, as an alternative, this paper proposes an effective design optimization process using the two-stage design method. To optimize the design, motor performance characteristics, such as efficiency, cogging torque, and operating range were analyzed using JMAG Designer, a motor electromagnetic analysis tool that employs FEM. Based on the results of the design optimization process, motor prototypes were produced and their performance was measured using a dynamometer and a cogging torque tester. Finally, the validity of the design optimization and analysis was verified by comparing the experimental and analysis results. Figure 1 (a) shows the design optimization parameters and levels for the Taguchi design model. Figure 1 (b) shows analysis process used to obtain the analytical results of the Taguchi design model. Figure 1 (c) shows the optimal selection procedure for optimization using the surface reaction method. Figure 3 (a) shows a comparison of the efficiency test results for each optimization model. As the optimization progressed, the efficiency of the motor improved. Figure 3 (b) compares the analysis and test results for the final model and shows that these two sets of results are similar. Figure 3 (c) presents a comparison of the analysis and test results for cogging torque and shows that these two sets of results are similar. More details of the motor design optimization process and additional analysis results will be presented in the final paper. Test results of the manufactured permanent magnet synchronous motor will also be presented.

HQ-09. Comparison of Modular Spoke-type Permanent-Magnet Machines Using Different Magnets for In-Wheel Traction Applications.

H. Zhang[1] and *W. Hua*[1]
1. School of Electrical Engineering, Southeast University, Nanjing, China

Abstract—The main purposes of this paper consist of two parts: First, topologies of novel modular spoke-type permanent-magnet (MSTPM) machines with two different magnetization modes are introduced, and corresponding analytical modes are built as well. Second, two types of magnet, including bonded and sintered neodymium-iron-boron (NdFeB) magnets, are applied in MSTPM machines with different magnetization modes. Based on analytical model and finite element (FE) method, the comparison between MSTPM machines using different magnets is conducted, with respect to field harmonic, back electromotive force (EMF), electromagnetic torque, and over-load capability. A prototype machine is assembled and tested to verify predictions. I.Introduction Due to high compactness and operation flexibility, in-wheel traction machine is considered as an excellent choice for electric vehicles [1]. In-wheel traction machines always require large torque, high efficiency, and strong fault-tolerant capability, which are very challenging to satisfy simultaneously. Hence, the machine topology is still a hot point in the field of in-wheel traction machines. In [2], authors proposed a novel outer-rotor-permanent-magnet flux-switching machine, which has been renamed as modular spoke-type permanent-magnet (MSTPM) machine in this paper, to alleviate the saturation phenomenon in the stator tooth of flux-switching permanent-magnet (FSPM) machines by moving the "sandwich" structure from stator to rotor, and then to improve the over-load capability. Existing researches have indicated that MSTPM machines have superior over-load capability and higher efficiency than FSPM machines [2], and stronger flux-weakening performance than surface permanent magnet (SPM) machines. Hence, the MSTPM machine is a certain candidate for in-wheel traction applications. For MSTPM machines, special features including even-order harmonics and unbalanced magnetic force, were investigated in [3], and the operation principle was analyzed based on field modulation theory in [4]. In addition, the back-EMF feature is discussed in [5]. However, there is no research carried on the PM materials and magnetization modes in MSTPM machines, which are exactly the purpose of this paper. More details will be given in the full paper. II.Topology, Analysis and Comparison Fig. 1 shows topologies of MSTPM machines with different magnetization modes. The Mode I (MI) is that all magnets are circumferentially magnetized in the same direction. The Mode II (MII) is that each two adjacent magnets are circumferentially magnetized in reversal directions. Correspondingly, two simple PM-MMF-permeance models are built to investigate the influence of magnet on MSTPM machines under different magnetization modes. In Fig. 2, the PM-MMF distributions of two adjacent magnets in MI and MII MSTPM machines are shown, and corresponding the single stator-pitch permeance waveforms are illustrated as well. For two MSTPM machines with the same magnet number, the fundamental field frequency of MI machine is double of that of MII machine, according to the Fourier analysis of PM magneto-motive force (PM-MMF). The PM-MMF f_{pm} can be calculated by formula (1) and (2). The H_c is the magnet coercive force, h_{pm} is the magnet thickness, P_{air} is the airgap permeance, P_{pm} is the magnet permeance, and P_{sup} is the permeance of the nonmagnetic support cell between each two rotor modules. Equations (1) and (2) are suitable for MI and MII MSTPM machines, respectively. More details about the derivations of P_{air}, P_{pm}, and P_{sup} will be given in the full paper. The single stator-pitch permeance Λ_1 and Λ_2 can be calculated by formula (3) and (4). The l_{air} is the airgap length, l_{slot} is the slot length, and μ_0 is the permeability of vacuum. Then the radial flux density distribution is calculated by formula (5). The θ is the mechanical position. Then four MI and MII MSTPM machines, whose key parameters are listed in Table I, are analyzed by PM-MMF-permeance models and FE method, and Fig. 3 shows corresponding field harmonic spectrums. Key parameters of the magnets are shown in Table II as well. According to the analytical and FE results, it can be found that: the MI MSTPM machine using sintered magnet has the highest fundamental field harmonic; machine using sintered magnet have higher fundamental field harmonic than machine using bonded magnet; MII MSTPM machines have more field harmonics than MI MSTPM machines, which will cause more back-EMF harmonics in MII MSTPM machines. Fig. 4 shows phase back-EMF of these four MSTPM machines, and it is found that MII MSTPM machines do have more phase EMF harmonics than MI MSTPM machines, which verifies the analysis above. More details, including the influence of magnet material on field and back-EMF harmonic spectrums, torque capability, etc., will be given in the full paper. Besides, as shown Fig. 5, a prototype MSTPM machine was manufactured and tested to verify analysis, and corresponding experimental results will be shown in the full paper.

HQ-10. Study on the torque ripple reduction design through varying the air-gap magnetic flux density in the SPM motor.

K. Lee[1], J. Lee[1], R. Kim[1], J. Seo[1] and S. Rhyu[1]
1. Korea Electronics Technology Institute, Gyeonggi-do, The Republic of Korea

1. Abstract Surface permanent magnet motor for 22kW compressor was designed. To reduce the torque ripple, new method was applied as well as existing methods. The existing methods are stator skew, magnet shape and magnet per pole ratio. New method is varying the air-gap magnetic flux density. Each method was analyzed for the usefulness of torque ripple reduction. Finally, the model for test was designed based on the analyzed data and the test was performed. 2. INTRODUCTION In this paper, a study was conducted to minimize the torque ripple of a 22KW compressor motor applied to direct coupled compressor system. In the case of a direct coupling type compressor, the motors and the air ends are directly connected without gears, so that the vibration of the motor greatly affects the life and performance of the compressor. For this reason, an initially designed 22kW compressor motor was analyzed for torque ripple reduction according to the stator skew [1] and magnet configuration [2] studied previously, and the influence of the two parameters on the torque ripple was analyzed. In addition, a new method is proposed to reduce the cogging torque and torque ripple by varying the air-gap magnetic flux density to minimize the torque ripple. Finally, the final model to be applied to direct - coupled compressors was derived through each method, and the performance evaluation was completed through experiments. 3. 22KW-CLASS SPM MOTOR FOR COMPRESSOR Figure 1 and Table I show the shape and specifications of the initial model of the 22 kW class compressor motor for torque ripple reduction. Figure 2 shows the torque waveform of 15A unit from 0A to 60A in the initial model. It is confirmed that the average torque increases as the current increases, and the ripple is the same even if the average torque increases. As a result of FFT analysis of each torque waveform, it can be seen in Fig. 3 that the 12th order of the cogging torque is almost the same even if the average torque increases. It is confirmed that the cogging torque has a great influence on the torque ripple when the current is applied. 4. TORQUE RIPPLE REDUCTION METHODS Figures 4 and 5 show the conventional method for cogging torque and torque ripple reduction. In the case of skew, 0.25, 0.5, 0.75, and 1 slot variables were analyzed. Magnets were analyzed with 5, 10, 15 and 20 mm of A variables and 5, 10 and 15 degrees of B variables. The effect of the two shape parameters on cogging torque and torque ripple will be explained in detail in the full page. The performance of each shape parameter is also shown in the full paper. The variables in Figure 6 and Table 2 are new methods to reduce cogging torque and torque ripple. Depending on the air- gap length, the air-gap magnetic flux density changes and the cogging torque also changes. The relationship between the air gap flux density and cogging torque, and the reduction of torque ripple through cogging torque reduction will be described in the full paper. A final model with minimized torque ripple was manufactured and tested. Detailed results will be discussed in the full paper. 5. HQ-11. A Study on the Shape Optimization Design of Permanent Magnet Assist to Improve Output Performance of WFSMG.

S. Lee[1], J. Lee[2], B. Kim[2], D. Lee[2] and D. Kang[2]
1. Electronic and Electricity Engineering, Keimyung University, Daegu, The Republic of Korea; 2. Electrical Energy Engineering, Keimyung University, Daegu, The Republic of Korea

For motor generators used in electric vehicles such as EV and HEV in the automobile industry, rare earth permanent magnets having a high output density are mainly used in order to satisfy high efficiency and performance. However, due to unstable supply of rare earth magnet, high price, and environmental problems, development and research of electric machines have been actively carried out to replace them with non-rare earth magnets such as ferrite or to reduce the use of rare earth magnets. WFSMG(Wounded Field Synchronous Motor Generator) is a typical motor generator that can replace PM machine because it has high power density among the devices that do not use permanent magnet. This is a structure in which a coil is wound around a rotor and current is applied from an external power source to form a field, and the field flux can be directly controlled, so that it can be used in a wide operating range from low speed to high speed. Therefore, it has characteristics suitable for use as a motor generator of a vehicle ISG(Integrated Starter Generator) system. In this paper, a study was made to improve the output performance of 2.4kW WFSMG models for an ISG system for automobile. For the WFSMG basic model, PMA(Permanent Magnet Assist) is used as a method to increase the output density because the efficiency is decreased due to increase of the field side copper loss when the field current is increased to increase the output density. The air gap flux density can be sufficiently increased with only a small amount of magnets compared to the permanent magnet used in the PMSMG(Permanent Magnet Synchronous Motor Generator). As a result, the performance and efficiency of the motor generator are improved. In this paper, the influence of the amount of the auxiliary permanent magnet on the output characteristics is analyzed, and the shape optimization of the auxiliary permanent magnet is performed by checking the magnetic flux density and the magnetic flux direction according to the position and shape of the magnet. In order to analyze the optimal permanent magnet insertion position to concentrate the magnetic flux, the magnet structure, inserted into the rotor slot opening and the magnet V shape was selected, and a model was designed according to the shape and position of the magnet for each structure. Electromagnetic field characteristics were analyzed using FEM(Finite Element Method). In addition, the final model was selected and yield strength analysis was performed to verify the stability of the motor generator when the motor was driven.

HQ-12. Analysis and Optimization of Rotor Deformation in Interior Permanent Magnet Synchronous Motors.

Y. Pei[1], Y. Li[1], *F. Chai*[1] and Y. Yu[1]
1. Harbin Institute of Technology, Harbin, China

I. INTRODUCTION Given its high torque density, high power density and wide speed range, interior permanent magnet synchronous motors (IPMSMs) have been widely applied in the electric vehicle in-wheel motor drive system. The rotor part is the major power component of IPMSMs; thus, its structure design significantly affects the electromagnetic and mechanical performances of IPMSMs. As one of the important problem, the rotor deformation, together with its effect on the electromagnetic performance and electromagnetic vibration, has drawn the attention of many scholars. The rotor deformation can be mainly divided into two types, thermal deformation caused by high temperature and the pole shoe deformation caused by high centrifugal force. The combined effects of these two factors are much more complex. To simplify the analytical process, the rotor deformation in this paper is focused on the centrifugal distortion of pole shoe. II. SIMULATION ANALYSIS The geometrical parameters of the interior rotors, such as the thickness of magnetic bridge, the thickness of magnetic rib, and the angle between two PMs in a V-shaped type rotor, all can affect the centrifugal distortion of pole shoe. Thus, the relationships between pole shoe deformation curves and these factors are discussed through the structural analysis. Two types of the interior rotor are included in the study and the difference between them is whether or not there is a central magnetic bridge. The structural FEM of the rotor under a single pole at the maximum rotating speed is built with ABAQUS, which is the software used for the mechanical FEA. Fig. 1 shows the distribution curves of pole shoe deformations varying with the thickness of bilateral magnetic bridge, the thickness of magnetic rib, the angle θ and the thickness of central magnetic bridge (θ=180°), respectively. It can be concluded that: (1) The distribution of rotor deformation under a single pole is similar to one part of an eccentric circle and the maximum deformation point is located in the center of the pole shoe. (2) As these parameters increased in a certain range, the value of maximum deformation changed linearly. In addition, compared with the thickness of magnetic rib, the thickness of magnetic bridge has a greater effect on the rotor deformation. (3) When θ is small, the distribution curve is relatively flat; but when θ is large, the curve obviously becomes sharp. The larger V-shaped angle causes the larger peak deformation, which is contrary to the trend of mechanical stress on magnetic bridges. (4) When the maximum rotating linear velocity is large, the V-shaped type rotor with a central magnetic bridge should be employed. Due to the central bridge connecting the pole shoe and the rotor yoke, the mechanical stress caused by high centrifugal force can be decentralized and shared by multiple magnetic bridges to reduce pole shoe deformation. III. OPTIMIZATION OF ROTOR STRUCTURE In fact, the air-gap magnetic field has a direct relationship with the pole shoe shape. The rotor deformation can affect the harmonics of radial magnetic force density and torque pulsation, which would result in an increase in the level of electromagnetic vibration. Therefore, the rotor deformation should be optimized and reduced to suppress the additional electromagnetic vibration. In the study, the authors suggest that the maximum rotor deformation caused by high centrifugal force is not higher than 10% of the air-gap length. According to the simulation analysis in Section II, the deformation of V-shaped type rotor can be decreased by increasing the thicknesses of magnetic rib and magnetic bridges. However, doing so also increases the magnetic flux leakage and reduces the electromagnetic performance. As is shown in Figure 2, this paper proposes a novel interior rotor structure, in which the tangential magnetized PMs with the trapezoid shape and the modular rotor core are adopted, to reduce the rotor deformation and improve the electromagnetic performance. The dovetail slot structure plays the role of connecting rotor core and shaft, which has a similar function with the central magnetic bridge in the V-shaped type rotor to reduce rotor deformation. But the difference is that the dovetail slot structure has little influence on the rotor magnetic circuit. Meanwhile, the tangential magnetized PMs with the trapezoid shape combines the advantages of V-shaped type and spoke type rotor. All these can improve the electromagnetic performance. IV. CONCLUSION This paper investigates the effect of the thickness of magnetic bridge, the thickness of magnetic rib, the angle between two PMs of a single pole and the thickness of central bridge on the distribution curves of rotor pole shoe deformations. The thicknesses of magnetic bridges have a greater influence than other parameters. In order to eliminate the magnetic flux leakage and ensure mechanical performance, a novel rotor structure is proposed. The tangential magnetized PMs with the trapezoid shape and the modular rotor core with the dovetail slot structure are combines the advantages of V-shaped type and spoke type rotor, which is verified to reduce rotor deformation and improve the electromagnetic performance.

HQ-13. A Robust Design Optimization Method for Electromagnetic Devices with Interval Uncertainties.

B. Ma[1], J. Zheng[1], G. Lei[1], J. Zhu[1] and Y. Guo[1]
1. University of Technology Sydney, Sydney, NSW, Australia

Abstract—To solve the problem with interval uncertainties for robust optimization of electromagnetic devices, this paper presents a robust optimization approach based on Chebyshev interval method to estimate the extreme values of the constraints and objectives. The numerical results of a case study are reported to validate the proposed methodology. I.Introduction Probability theory-based methods and interval theory-based methods are two main analysis approaches for problems with uncertainties. Many of the current research works are based on the probability theory that models the distributions of the parameters by their probabilistic information [1]. Generally speaking, a large number of samples are needed to build the accurate probability distributions of the uncertain parameters. However, in actual engineering problems, it is difficult to acquire sufficient experimental samples in many cases to obtain the accurate probability distributions for some variables but the lower and upper bounds can be easily obtained such as the early stage of design with less manufacturing experience. Interval model makes it possible to measure bounds of the system outputs with only limited information [2,3]. In this paper, we incorporate the Chebyshev interval method to efficiently approximate the extreme values of the interval functions as well as avoiding the double loop process which means to calculate the minimum or maximum value for a considered function, and propose a new robust method for electronic devices with interval uncertainties. Through the comparison study with deterministic and MC based robust optimization of the BLDC motor, the efficiency and accuracy of the interval method are proved. II.Chebyshev Interval Method Based Robust Optimization A. Robust optimization model with uncertainties The optimization models for problems with interval uncertainties will be built under the worst cases by considering the upper bounds of the objective function and the constraints, so the robust design optimization problem can be formulated as equation (1), where *f(X,Y)* represents the objective function, $g_i(X,Y)$ represents the *i*th constraint, and Y_L and Y_U are the upper bound and lower bound of the interval parameters. The above design optimization problem is usually an unstable min-max problem, which may require high computational costs. A non-intrusive Chebyshev method is introduced to overcome the defects and estimate the bounds of the objective function and constraints. B. Chebyshev interval method For numerical simplicity but without losing any generality, we will assume the interval variable Y_i = [-1,1], *i*=1, 2, ···, *m*. Based on the Chebyshev theory [4], the truncated Chebyshev series with k^{th} order is used to approximate the merit function *C*(*Y*) as equation (2), where $c_{n1n2...nm}$ is the corresponding coefficient, n_i, i=1, 2, ···, m constitutes an index vector. Equation (3) is the multivariate Chebyshev polynomial which is built from the univariate Chebyshev polynomial as equation (4). Least square method (LSM) as expressed in equation (5) is used to calculate the coefficient where *A* represents the sample matrix, *C*(*Y*) is the model output vector at the design points. Based on the characteristics of the trigonometric functions, we can find equation (6). Thus, the maximum value for *C(Y)* can be calculated as equation (7) where the sign function is defined as equation (8). III.Numerical Example To verify the effectiveness of the presented method, a brushless DC wheel motor benchmark [5] is investigated in this work. For the problem considering the interval uncertainties, the design parameters with tolerances are listed in table I. The deterministic mono-objective problem of the benchmark aims to have the best efficiency respecting some technical constraints which can be written as equation (9) where η, M_{tot}, D_{int}, D_{ext}, I_{max}, T_a, and *discr* are the efficiency, total mass of the active parts, inner and outer diameter, highest demagnetisation phase current, temperature of the magnets, and the determinant used for the calculation of the slot height respectively. For the bi-objective case, the second objective of the bi-objective case is to reduce the mass as equation (10). IV.Discussion and Results To verify the effectiveness of the robust interval method, the deterministic and robust optimization with MC method are all conducted for comparison. *A. Mono-objective Case* Table II lists the optimization results of the case, and the main conclusions can be drawn. The same optimization objective has been reached by the Chebyshev interval method and MC method which is smaller than the deterministic optimization. And the optimal design parameters of the Chebyshev method are verified by the MC analysis with desired reliability while the deterministic design offense the constraints about I_{max} and *discr*. *B. Bi-objective Case* Fig. 1 illustrates the Pareto results of the bi-objective case, in which the optimization results of the proposed method align well with the ones of the MC method. The optimization time of the Chebyshev interval method is 779s which is much faster than the MC method 9799s. Compared with the deterministic designs, the Pareto front of robust designs move inside the feasible objective space by enforcing of the desired reliable bounds. V.Conclusion The robust optimization approach based on Chebyshev interval method in this paper shows high efficiency and accuracy for the design problem of electromagnetic devices with interval uncertainties.

This paper contains an analysis of the demagnetization and vibration characteristics of an IPMSG(Interior Permanent Magnet Synchronous generator) type motor-generator for 48V 5kw class ISG and the contents of the optimal design for improvement of output characteristics. Particularly, the effect of fractional slot on the demagnetization and vibration characteristics compared with the concentrated winding is studied. By using this, we intend to draw conclusions through the formula type approach of the demagnetization and vibration characteristics. In this research, analysis was carried out using ANSYS EM and the results were analyzed. Based on the results, the optimization design was performed. According to the operation characteristics of the ISG, the driving area was divided into three areas: motoring 3000rpm, power generation area 4000rpm, and 16500rpm. In general, vehicle electrical equipment is very sensitive to vibration characteristics and ISG is attached to the engine part of the vehicle, so specifications are given to minimize vibration. In addition, the high output ISG has a very high driving current, which causes a risk of irreversible demagnetization. Therefore, in this paper, we confirmed the fractional slot-based winding method and the torque ripple of the conventional concentrated winding method in the entire operation region of the ISG. Based on this torque ripple characteristic, the vibration characteristics were compared and analyzed through mechanical Cosimulation. And by applying various driving current ranges that can generate irreversible demagnetization, we compare demagnetization of fractional slot with demagnetization of concentrated winding for the same rotor structure. In addition, the characteristics of demagnetization and eddy current depends on the lamination type of the inserted magnet in the rotor, so this is mainly compared and analyzed. In this paper, permanent magnet is divided into 3segments and 7segments as a comparison model. We analyze how does the stacking of magnets in the fractional slot winding method affects the eddy current loss reduction. The demagnetization phenomenon of laminated magnets is compared and analyzed by 3D simulation. In order to analyze the effect of the irreversible demagnetization of the laminated magnets on vibration, we used mechanical Cosimulation technique. Modal analysis and harmonic analysis are performed for vibration characteristics analysis and resonance frequency is found. In order to verify the results of this analysis, various types of magnets were made and a comparison test was conducted using various types of magnets. so we are willing to show program analysis data and experimental data.

INTRODUCTION: Design optimization of interior permanent magnet (IPM) machines has received an extensive attention due to the very recent developments in finite element analysis (FEA) based design optimization technique such as computationally efficient finite element analysis (CE-FEA) [1, 2]. These techniques have been used in electromagnetic design optimization of IPM machines from multiple perspectives to improve their performance characteristics under the constant-torque and/or constant-power operating regions [3]. Many IPM machine applications such as wind turbines and servo motors require optimal operation under the constant-torque region, where the electromagnetic behavior is typically evaluated at the maximum torque per ampere (MTPA) trajectory. Therefore, an accurate method to estimate the MTPA trajectory is necessary during the electromagnetic design optimization of the IPM machines. Accurate determination of MTPA trajectory is possible using detailed FEA. However, the detailed FEA significantly increases the computational time of design optimization by several orders even with the recent development in processing power of computational resources. Conventional methods of MTPA trajectory estimation use a classical dq model in the dq reference frame. The combination of the classical dq model and CE-FEA has been presented by [1,2] for the estimation of MTPA point at a rated current. The conventional method is fast as it only requires three FEA runs in the pre-processing stage of the design optimization procedure. However, it fails in accuracy for IPM machines with a high level of magnetic saturation due to the variation of inductances with respect to the stator current. In more recent literature [3], authors have proposed a method to build torque and flux linkage look-up tables for a set of dq-axes current using CE-FEA in the pre-processing stage of a design optimization. The look-up tables can cover a wide range of operating cycle, but with a cost of an increase in computational time as it requires a significant number of FEA runs. This paper overcomes the above mentioned drawbacks by proposing a computational-efficient procedure that estimates the MTPA trajectory with a high accuracy and minimum computational effort. The proposed method provides a tradeoff between the computational time and the accuracy of the estimation by using a discrete search algorithm in a magneto-static FEA. METHODOLOGY: The proposed method creates a mesh grid of the developed torque (T_{dev}) for each population concerning the magnitude of stator current (I) and the current angle (γ) using a minimum number of FEA runs. The current angle, γ, is the angle between current vector and q-axis in the *dq*-plane reference frame. Implementation procedure of the proposed method in a multi-objective optimization algorithm is shown in Fig. 1 (a). After the initialization stage of the optimization algorithm, the discrete-search algorithm has been used to find the MTPA trajectory for each population. To reduce the number of FEA runs and computational time, discrete values are selected for I and γ. For further reduction in computational time, it is assumed that the developed torque is zero when *I* is zero and/or when γ is 90 degrees. By fitting a surface on the obtained mesh grid, the MTPA trajectory can be found. Then, the performance characteristics of all populations can be evaluated on their MTPA trajectories. As can be seen, the proposed method requires only eight single magneto-static FEA runs in the pre-processing stages for two sets of stator current, i.e., the currents at a full load and a half load, which significantly reduces computational time in comparison with detailed FEA. RESULTS AND CONCLUSION: The proposed method is used to optimize three different benchmarks IPM motors using a non-dominated sorting genetic algorithm (NSGA-II) as a multi-objective optimization algorithm. First, an FSCW IPM motor with 18-slot 14-pole combination is chosen as a representative for the family of concentrated windings with a high level of harmonics in the stator magneto-motive force as shown in Fig. 1 (b). Second, a 24-slot 4-pole DW IPM motor with a segmented PMs is considered as an unsaturated IPM motor, which is shown in Fig. 1 (c). Finally, the well-known Toyota Prius IPM motor (Fig. 1 (d)) is chosen to investigate the effectiveness of the proposed method under a high current density and saturated iron cores. Fig. 2 (a) compares the T-γ characteristic curves of the Toyota Prius IPM motor obtained by the conventional method, the proposed method and the transient FEA. As evident, the proposed method is relatively similar to the one obtained from the time-stepped FEA with average torque. The results of the multi-objective optimization algorithm for two objectives (saliency ratio and efficiency) are shown in Fig. 2 (b). It is evident that the method of calculating the MTPA trajectory has a significant effect on Pareto-front designs. This comparison highlights the advantages of using the proposed method i.e. high accuracy and less computational time. The MTPA trajectories obtained by the experimental test are not presented due to space limitations but will be provided in the extended manuscript.

HQ-16. Performance Optimization of an Air-core PMSLM with New Double-layer Windings.

W. Mei[1] and Q. Lu[1]
1. College of Electrical Engineering, Zhejiang University, Hangzhou, China

I. INTRODUCTION The air-core PM synchronous linear motors (APMSLM) are widely used in precision location system such as laser test station and IC manufacturing device. Due to without iron core, they have many merits of the low thrust ripple, rapid response and easy controllability etc. [1], but the thrust density is also decreased. Although the methods of double secondary and Halbach PM Array are normally used to increasing the thrust density [2]-[3], the distributed winding structure is another effective way [4]-[5]. However, its overlapping end structure is complex and difficult to be manufactured. In order to solve this problem, a novel double-layer winding air-core PMSLM (DWAPMSLM) with Halbach array PMs is proposed. The structure is only suitable for odd number coils in the same limited space. It adopts double-layer concentrated winding to act as one-layer distributed winding, which successfully shortens the winding end and saves motor volume. To traditional one-layer concentrated winding, the winding factor is not high considering the space limit, so DWAPMSLM places the windings in two layers to let every phase coil get winding factor as high as possible, and then the thrust density is increased rapidly. Moreover, the thrust density per volume is also increased due to the end space of primary is saved. Therefore, the proposed DWAPMSLM is suitable for long time running precision location system because of high thrust density and low heating power. II. MODEL AND ANALYSIS Fig. 1(a) shows the topology of the novel 6-poles/9-coils DWAPMSLM (Model A). The secondary is consisted of Halbach array PMs and back-iron. Halbach array PMs can provide higher flux density and more sinusoidal magnetic field than normal array PMs. The primary is made of 9 coils in two layers. To evaluate the performance of double-layer winding structure, two normal winding structures, concentrated winding (Fig. 1(b), Model B) and distributed winding (Fig. 1(c), Model C), are listed to do comparative study. In order to keep the same volume and power loss, the two traditional winding motors adopts 7-poles/6-coils to provide as high thrust density as possible under the limit of volume and power loss. In addition, their total number of coil turns per phase is also set same regardless of their different poles and coils number. The parameters of three models are shown in Tab. (a). Fig. 2(a) shows the thrust force curve of the three models at current 1A. The force constants of the three models are 17.52N/A, 16.00N/A, 17.74N/A, and the thrust ripples are 1.27%, 0.68%, 0.64%, respectively. Apparently, at the same current, Model A and Model C can provide higher thrust because they own higher winding factor than Model B. Moreover, the force constant of proposed model A is only 1.2% less than that of the traditional model C. Since the structure of model A is much simpler than model C, the new double-layer winding structure is meaningful in some particular application. Fig. 2(b) and fig.2(c) show the back-EMF and flux linkage of the three models at speed 2.02m/s. Their back-EMF peak values are 24.84V, 23.89V, 24.88V, and the flux linkage peak values are 0.0848Wb, 0.0760Wb, 0.0862Wb. Similar to the thrust density, Model A and Model C perform better than Model B. In addition, the difference between Model A and C can be ignored. Therefore, the proposed Model A has almost same performance as model B, but winding structure is simplified and manufacture cost is lowered. III. CONCLUSION This paper proposes a new DWAPMSLM. Compared with traditional concentrated winding and distributed winding in the same air-cored PMSLM application, this double-layer winding structure can not only provide nearly same thrust density as distributed winding, but also have simple structure as concentrated winding. This DWAPMSLM is strong candidate when APMSLM has odd number of coils.

HR-01. Characteristics of Energy Harvesting in Flywheel Energy Storage System Based on Efficiency Map of Electric Machine.

J. Cho[1], H. Hwang[1], Y. Choo[1], C. Kim[1] and C. Lee[1]
1. Electrical and Computer Engineering, Pusan National University, Pusan, The Republic of Korea

A flywheel energy storage system (FESS) having a bidirectional power converter (BDC) and a synchronous machine stores energy as rotational kinetic energy and uses the stored energy whenever required. An FESS has the advantages of high efficiency, large energy storage density, numerous charge and discharge cycles, and environment-friendly characteristics in comparison with other energy storage units. Its applications vary from uninterruptible power supplies (UPS) to micro grids, wind power plants, vehicle regenerative braking and so on. In the past decade, for the improvement of an FESS, a lot of researches have been done on the issues of bearing, motor/generator design, power system, and control algorithm [1-2]. Among the various element technologies, the discharge control of a flywheel rotor from kinetic energy to electrical energy is the core part of the FESS. In the energy discharging mode, a synchronous machine produces voltage by working as a generator and its BDC supplies constant voltage by acting as a boost converter. In this process, energy efficiency in an FESS and maximum voltage gain in the BDC vary by the power of a load in watts, and as a result, the amount of usable kinetic energy from the flywheel is altered. Voltage gain and energy efficiency in the BDC depending on load resistance have been analyzed in [3], and maximum voltage gain and minimum speed according to the ratio of the generator resistance to load resistance have been well described. However, the reason for change in efficiency with respect to load resistance has not been examined clearly. Energy efficiency in an FESS is directly related to the operation characteristic of a synchronous generator, and thus it is important to analyze the efficiency of the generator according to overall speed range. This paper focuses on the characteristic of energy harvesting in a flywheel energy storage system at three different load points during discharging mode. For experimental verification, the FESS having a permanent magnet synchronous machine (PMSM), a flywheel rotor, and a BDC is manufactured and tested at three different load points as shown in Figs. 1 and 2. The PMSM works as a motor to accelerate the flywheel up to 3,000rpm, and then the synchronous machine is switched over to a generator in order to make DC bus voltage constant at 350 volts. In Fig. 2a, the energy harvesting of the flywheel has been experimented at 490, 980, and 1470 watts in load, and energy efficiency is compared with respect to load power. The deviation of energy efficiency at three load conditions is investigated by analyzing the path of q-axis current on the efficiency map of the PMSM in case of generated energy from the flywheel as given in Fig. 2b. Considering current trajectories under each load condition, it can be seen that q-axis current under the condition of 83.3 ohms is contoured as the synchronous generator is operated at higher efficiency compared to the other two conditions. As a result, the efficiency of the flywheel system according to load during power generation is analyzed in considering the efficiency map of the generator and the length of current locus in second at each load point. Also, the loss of the flywheel will be estimated by separating copper loss and iron loss versus speed and torque. The validity of this study is demonstrated by correlating the efficiency of the flywheel system with the efficiency map of the PMSM given in Fig. 2b.

Abstract: Accurately calculation of temperature can truly judge the output of large capacity turbo generator. The copper and core loss of generator is the major factor to determine generator temperature field. And the resistance of coils, an important variable for calculating copper loss, varies with the windings temperature. It is more obviously that the interactions between the resistance and the temperature of windings in the 1100MW nuclear power generator rotor with axial-radial ventilation form, which is because the rotor windings have high thermal coefficient of imbalance in this ventilation form. Thence, the rotor temperature field is calculated by the finite volume method considering varied rotor surface loss. Based on the first calculation results, the new resistance in the calculated temperature of coils is used to secondly calculate rotor temperature filed until the resistance match with the coils temperature. The results between initial calculation and iterative calculation are comparatively studied, which can provide theoretical guidance for precisely calculating iron core loss and generator temperature field. 1. Introduction With the increase of global electricity consumption and improved safety of nuclear energy technology, installed gross capacity of large nuclear power turbine generator get a rapidly progress. The temperature rise of large scale turbine generator is one of the major issues that limits generator capacity. Some scientists in this filed make some researches. Professor Weili Li analyzed the influence of additional loss on rotor surface heat transfer coefficient and temperature field of hydro-generator [1]. Zuomin Wang make a research in numerical simulation of air flow distribution in turbo generator rotor at different rotation speed and inlet pressure [2]. Based on the related research, taking an 1100MW half-speed nuclear power turbine generator rotor with axial-radial ventilation form as an example, that the each part temperature and the thermal coefficient of imbalance vary with the additional loss in the rotor surface is obtained. 2. Mathematic Model and Calculation Methods 2.1 Boundary Conditions As is shown in figure 1, the windings named number 1 to 4 coil from right to left. $S_{1\sim}$ S_3 is insulating surfaces[3]: $dT/dn=0$ (1) S_4 and S_6 is convention surfaces, the average heat transfer coefficient formula is shown in (3): $-\lambda dT/dn=\alpha(T-T_f)$ (2) $\alpha=28[1+(v_1^2+(v_2/2)^2)^{1/4}]$ (3) The heat transfer coefficient in S_4 is 266 W/m$^2\cdot$K, it in S_6 is 248 W/m$^2\cdot$K. 2.2 Additional Loss Calculation In the calculation model, the heat generated by core is calculated by (4)~(8)[4]-[5]. $Q_{2SH}=Q_{2vk}+Q_{2zk}+Q_{2zo}+Q_{2H}/3$ (4) $Q_{2vk}=\phi(\beta)[AS_1/(K_\delta\delta\times10)]^2\times(D_i^5/p^4)\times(l_2/Z_1^{1/2})\times(f/50)^{1.5}\times10^{-18}$(5) $Q_{2Zk}=\phi(\sigma/t_1)[AS_1/100]^2\times(D_i^3/p^{1.5})\times(l_2/Z_1^{1/2})\times(f/50)^{1.5}\times10^{-12}$(6) $Q_{2ZO}=5.1[B_\delta/100\times(K_{\sigma n}-1)]^2\times(D_i^3/p^{1.5})\times(l_{ef}/Z_1^{1/2})\times(f/50)^{1.5}\times10^{-12}$(7) $Q_{2H}=5.73(D_2^4/p^3)l_2\times(f/50)^{1.5}\times(P_H/P_{HO})\times10^{-15}$(8) The results of Q_{2vk}, Q_{2zk}, Q_{2zo}, Q_{2H} are 4.89×10^{-5}kW,71kW,113.4kW,254.5kW. 2.3 Calculation Methods Fluid and transfer calculation method is used to simulate the rotor temperature field [3]. 3. The Influence of Varied Additional Loss in the Rotor Surface on Rotor Temperature Field Based on the fluid and heat transfer theory, the average computational temperature rise of rotor coil is 36K, while the average experimental temperature rise is 37K [6]. The error is 2.7 % to verify the accuracy of the calculation method. Although the studied generator rotor is hydrogen inner-cooled structure, the rotor surface is one of path for cooling. For exploring the influence of varied additional loss in the rotor surface on rotor temperature field, the research scheme uncounting Q_{2vk}, Q_{2zk}, Q_{2zo} are calculated and named scheme i~iii. The 85%, 115% additional loss are also calculated and named scheme iv~v. The calculated results is shown in figure 2. In figure 2, the calculated results of rotor temperature field in the different additional loss have a big difference. Overall, the temperature rise of rotor each part increases with the additional loss enhancing. The temperature rise of the windings, layer insulation, and slot wedge in the schemes differ less than 0.5K, but the temperature rise of iron core and main insulation biggest differ 7K, which means that the heat generated by windings is mostly brought by ventilation groove. The thermal coefficient of imbalance reach 2.15 in the scheme iii, which makes the main insulation stand more pressure to cause layered or selling faults. From scheme i~v, the hot-spot and average temperature rise vary a linear change with additional loss of core. As also shown in figure 2, the thermal coefficient of imbalance of windings in the original scheme is 1.79, which is much higher than the gap gas pick-up and sub-slot ventilation system. The thermal coefficient of imbalance of core is 1.96 and higher than that of the windings, which means that unequal tooth pitch design can effectively reduce the influence of high harmonic of gap magnetic-density, but it makes the thermal unevenness of core enhance and the hot-spot temperature of core is higher than the coil. 4. Conclusion The heat of the hydrogen inner-cooled rotor coil with axial-radial ventilation form is mostly brought by the ventilation duct. Unequal tooth pitch design can effectively reduce the influence of high harmonic of gap magnetic-density, but it makes the thermal unevenness of core enhance and the hot-spot temperature of core is higher than the coil. The temperature calculation values is much closer with the measured values considering that the resistance vary with windings temperature.

HR-03. Research on an Asymmetric-primary Axis-flux Maglev Generator for the Vertical Axis Wind Turbine.

J. Liu[1]
1. Hohai University, Nanjing, China

Abstract—The floating wind power generation has an good application prospect in the field of the wind power generation on the sea. The direct-drive vertical axis wind turbines(DVAWT) is one of the most important for that. In order to improve the starting performance and output power of DVAWT, an axial-flux maglev generator with asymmetric primary is proposed. The motor is designed as disc type with double primaries and one rotor. Two-sided asymmetric primary is adopted to obtain maglev force, working with the lift force of the wind turbine to improve the starting performance. Hybrid excitation is used to adjust the suspension force and output power in real time for the stable output. The principle of the machine is analyzed and computational analysis and optimization of the forces are carried out. 3-D model is built and verifies the machine. Introduction In the field of wind power generation(WPG), the horizontal axis wind power generation(HAWPG) is common applied to the grid-tied large power system, and for the small WPG system, the vertical axis wind power generation(VAWPG) has special superiorities, such as possible suffering wind from all the directions, stable force, small starting speed, small running speed of the wind turbine and easy to install etc.. For the wind power generation on the sea, the HAWPG is facing the questions of great bulk, needing hard foundation, high installing and maintenance cost and so on. The floating wind power generation has an good application prospect in the field of the wind power generation on the sea. It can be installed in the area of strong wind and uses VAWPG to decrease the cost. Seeing the researches about VAWPG, there are two kinds of lift force type and drag force type. The lift force type has small starting torque but little utilization coefficient of wind energy. The drag force type has the big utilization coefficient of wind energy but poor starting performance. As we known, the generator is the centre part which decides the conversion efficiency of the energy and operating performance of the power system. Based on the advantages of the lift force type of VAWPG and disc motor, an asymmetric-primary axis-flux maglev generator for the vertical axis wind turbine is proposed for the VAWPG. I.Structure The maglev design is applied to improve the starting performance and increase the conversion efficiency of the energy and power density of the VAWPG. The motor has a structure of double primaries and one rotor. Two-sided asymmetric primary is adopted to obtain maglev force, working with the lift force of the wind turbine to improve the starting performance. Hybrid excitation is used to adjust the suspension force and output power in real time for the stable output. The structure of the proposed motor is given by Fig.1. I.reluctance-network model To optimize the design, nonlinear reluctance-network method is used to get the parameterized model for the proposed motor. The laws of the parameters effecting the motor performance are grasped. Then, all the optimized structure-dimensions of the magnetic poles are obtained. The maglev force is also analyzed and solved by the virtual work method. The magnetomotive of the electromagnet is F=NI The magnetomotive of the permanent magnet is $F=H_c h_m$ And the matrix is $R\Phi=F$ I.Results To verify the design and optimize the parameters further, 3-D finite element model (FEM)is built upon the results of nonlinear reluctance-network method. The static and the dynamic state are studied and the results are compared. The output voltages of the proposed motor are shown in Fig.2(a) Following the exciting current changing, the maglev force changes too. There are the changing curves of the maglev force under two values of the exciting current shown in Fig.2(b). From it, we can see that the maglev force of the motor can be controlled by controlling exciting current to control the magnetic field.

HR-04. Modeling and Design of a Efficient Magnetostrictive Energy Harvesting System with Low-Voltage and Low-Power under Low Vibration Excitation.

S. Cao[1], X. Wang[1] and J. Zheng[1]
1. Hebei University of Technology, Tianjin, China

Magnetostrictive (e.g., Terfenol-D, Galfenol) vibration generators are attractive because they can provide higher energy density than electromagnetic generators and have similar levels of output power with piezoelectric generators [1]. However, when the magnetostrictive generators are under a low vibration excitation, they exhibit extremely low voltage of a few hundred millivolts [1]-[4] and low power of a few hundred microwatt [2],[3]. Thus, it is necessary to model and design a efficient magnetostrictive harvesting system, which can track the maximal power, store the energy, and can use such low power to boost such low AC voltage for satisfying the load end requirements (1.8-3.3V DC). Different models of the magnetostrictive generators are presented, including the distributed parameter dynamic coupled models [2],[5], the lumped parameter dynamic uncoupled model [3], finite element uncoupled model [6], finite element coupled model [4], and the distributed parameter equivalent circuit dynamic coupled model [7]. As detailed in [7], the models in [2]-[6] are difficult to analyze the harvesting system with practical energy extraction circuits (EECs) while the distributed parameter equivalent circuit model [7] is more complex. Moreover, the harvesting system with a self-powered EEC [7] only can intermittently supply power to the end load only when the generator produce bigger output voltage >1.2V. In order to boost low AC voltage for persistently satisfying the load requirements (1.8-3.3V DC), researchers [8], [9], [10] presented various EECs of electromagnetic generator to implement self-starting and self-powered operation, but in the circuit design, they tended to simplify the generator as constant voltage. A simple modeling and design for a efficient magnetostrictive harvesting system with low-voltage and low-power under low vibration excitation have not been reported. In this paper, a simple lumped parameter equivalent circuit model of a magnetostrictive generator is derived. Based on the model, the low-voltage and low-power characteristics produced by the generator under low acceleration excitation are firstly calculated and analyzed. Then, a self-starting and self-powered EEC with low-voltage and low-power inputs, which consists of the split-capacitor AC-DC rectifier booster [8], the start-up circuit [8], the low-power linear voltage regulator and comparator, is proposed. In order to ensure that the generator is near the maximum power output and reduce the power consumption, three main differences between the proposed EEC and the EEC [8] are: 1) the feedback PI control module [8] is replaced by a comparator; 2) the changeable duty ratio operation [8] is replaced by the fixed duty ratio operation; 3) the low-power linear voltage regulator is added to stabilize the load output to 3.3 V. Finally, a efficient magnetostrictive harvesting system, which accounts for both generator and practical EEC, is modeled in a circuit simulator LTspice for system-level evaluation and design. The results calculated by LTspice are shown in Fig.1 and Fig.2 under acceleration $a(t)$=a0sin(2π222t). Fig.1 shows the characteristics of the generator under a0=0.7g, 1g, 2g and different resistances RL. In Fig.1(a)-(c), the output voltage u increase monotonically with increasing RL while the load instantaneous power PL(t) does not vary monotonously with RL. When RL=50 kΩ, the equivalent circuit of the generator closes to the open circuit. The open-circuit peak voltages under a0=0.7g and 1g are about 0.8V,1.22V. When RL≈120 Ω, the peak PL(t) under a0= 0.7g is about 1.54 mW=1540μW. As expected, PL(t) is almost 0μW when RL=0, 50 kΩ (the short and open circuits). Also, the load average power PavL is 0.5 times the peak PL(t) because the system is linear. Fig.1(d) shows that the calculated and measured load average power curves have similar shape. These verify the validity of the proposed equivalent circuit model of the generator. Fig.2(a), (b) (c) show the structure, power flow, and simulated results of the harvesting system with the proposed EEC and the EEC [8] under a0= 0.7g and load end resistances 38kΩ. In Fig.2 (a) and (b), the fixed virtual impedance Reff is set around 120Ω by the fixed duty ration to ensure that the generator is near the maximum PavL ≈770μW in Fig.1(d), which is bigger than the total power 690μW consumed by the proposed EEC. The load end voltage VLoad reaches and maintains about 3.3V after 0.42s. the battery output current Ibattery increases from -36μA to -60μA in [0s,0.3s], then decreases from -60μA to 0μA in [0.3s,0.7s], finally, the battery current Ibattery is bigger than 0μA and the battery charging starts. These show that the system has the self-starting and self-powered abilities. Fig. 2 (c) shows that the EEC [8] can stabilize the load end output to 3.3 V after 0.42s, but the battery output current Ibattery is in the range of (-115μA,-180μA) from 0s to 1.0s (i.e. the battery has been in the state of discharge), thus the circuit cannot self-start. These show the proposed system has very strong practicability.

HR-05. Performance Analysis of a Novel Brushless Hybrid Excitation Synchronous Generator.

C. Zhu[1], Y. Yang[1], Y. Zhang[2] and Y. Shen[1]
1. School of Electrical Engineering, Shandong University, Jinan, China;
2. Yijun Motor Technology Development Center, Liaochen, China

I. Introduction With the continuous improvement of performance and cost reduction of permanent magnet materials, permanent magnet synchronous machine (PMSM) becomes the most promising machine in industrial and agricultural productions[1-2].Therefore, due to the nature of the permanent magnet itself, when the load or speed varies, the motor lacks the ability to adjust the magnetic flux to keep the output voltage constant. To improve the flux adjustment ability of PMSM, many solutions have been proposed. Hybrid excitation is one of the main ways [3-5]. The paper discusses a hybrid excitation synchronous generator combining induction excitation and permanent magnet. The topology and operation principle are explained and a finite element model is analyzed. The simulation results show that the machine has more flexible magnetic field adjustment ability than permanent magnet synchronous generator and could operate with much higher power density than ordinary induction excitation alternator. II. Structure and Operation Principle 2.1 Machine structure The structure of the machine is shown in Fig.1(a). There are two sets windings on the stator, which are 4-pole three-phase armature windings (W_a) and 2-pole single phase auxiliary windings (W_e). Radically magnetized permanent magnets are attached on the rotor core surface. The rotor induction windings(W_{r1}-W_{r4}) are placed in the rotor slots, which are independent of each other and connected with diodes respectively. The connection schematic diagrams of above windings are shown in Fig.1(b). 2.2 Operation Principle The air gap magnetic field of the hybrid excitation motor is generated by the permanent magnet PM and the field currents in the rotor induction windings together. Due to rotor field currents are obtained by the induction principle between stator auxiliary windings and rotor induction windings [6-8], it can also be said that the motor magnetic field is generated by permanent magnets and stator auxiliary windings currents (referred to as stator field currents for simplicity) together. Fig.1(c)-(d) shows the magnetic field distributions produced by PM and currents of induction windings, respectively. It is obvious that the two magnetic circuits are parallel connected. III. Simulation The main model structure parameters are listed as following: Outer diameter of stator core : 155 mm; Inner diameter of stator core: 98 mm; Number of stator slots:36; Air gap at PM: 1.2 mm; Air gap at rotor slots: 0.6 mm; Diameter of shaft:38 mm; Number of mian pole-pairs: 2; Length of the core:110 mm; Pole arc coefficient: 0.4; PM thickness: 3.3 mm. 3.1 Rotor induction current Fig.2(a) shows rotor induction current waveforms at stator field currents 1A, 3A, respectively. As can be seen from Fig.2(a), rectifier diodes act as slip rings and the machine becomes brushless excitation. 3.2 Magnetic field distribution of no-load The air gap flux density waveforms of the motor under the different stator field current is shown in Fig.2(b). It is obvious that amplitude of the air gap magnetic density increases with the increase of the stator field current. 3.3 No-load characteristic The no-load characteristic here is defined as the output voltage versus stator field currents under no-load conditions at constant speed. The no-load characteristic reflects the field adjustment ability of the machine. Fig.2(c) shows the line voltage waveforms at different stator field currents at speed 1500rpm. Fig.2(d) is the comparison of no-load characteristic of hybrid excitation and induction excitation at the same speed. It shows clearly that field currents required in hybrid excitation are much less than those in induction excitation at the same output voltage, which means much less excitation loss and higher efficiency. 3.4 Regulation characteristics When the speed and output voltage of the motor are kept constant, stator field currents versus load currents is the regulating characteristic of the generator, which reflects the excitation loss and the demand for the field capacity at the same output. Fig.2(e)is the comparison of regulation characteristic of hybrid excitation and induction excitation at output voltage 400V and speed 1500rpm. It illustrates that single induction excitation requires much larger field current to obtain the same output power compared to hybrid excitation and the hybrid excitation obtains much higher power density than single induction at the same field current. IV. Conclusion In view of simple structure but limited excitation capacity of induction excitation synchronous generator and some difficulties in magnetic field regulation of permanent magnet synchronous generator, a novel hybrid excitation synchronous generator is analyzed in this paper. Due to field currents obtained through induction principle, the machine becomes brushless and the machine reliability is improved greatly. Compared to a single induction excitation generator, the hybrid excitation machine utilizes smaller excitation magnetic potential to adjust the air gap flux density, greatly reduces the excitation loss, improves the machine efficiency. On the other hand, under the same excitation magnetic potential, the hybrid excitation generator has much greater power output than a induction excitation generator.

HR-06. Analysis of the Resonance Characteristics by a Variation of Coil Distance in Magnetic Resonant Wireless Power Transmission.

H. Lee[1] and G. Park[1]
1. Department of Electrical Engineering, Pusan National University, Busan, The Republic of Korea

I. Introduction Magnetic resonant wireless power transmission(MRWPT) is a method that enables high efficiency transmission at a longer distance by using an additional resonance phenomenon in a conventional magnetic inductive wireless power transmission [1]. When the power transmission distance is smaller than a specific value, there is a problem that the output becomes maximum at two divided resonant frequencies instead of the conventional resonant frequency. This phenomenon is called 'frequency splitting (or division)'. There are some papers that observe and predict this phenomenon with the approximate formula of coupling coefficient or S-parameter [2]. However, there is no analysis of the frequency splitting phenomenon from the magnetic point of view on the transmission distance [3], [4]. In this paper, for a magnetic resonant wireless power transmission system with a resonant frequency of 20 kHz, the output equation according to the transmission distance is formulated and verified by experiment as shown in Fig. 1. And the resonance characteristics of the resonance state and the frequency splitting state were analyzed by the circle diagram of the current phasor and the magnetic field observation through the finite element analysis. *Fig. 1 here* II. Formulation And Verification A. Formulation Magnetic resonant wireless power transmission system can be represented by an equivalent circuit including two inductances having a coupling coefficient k. By using this, the transmission side current (I_{in}) and the reception side current (I_{out}) can be expressed by equations with coupling coefficient and frequency as variables. When the two coils are the same size, the coupling coefficient is determined by the coil size and the distance between the coils. Therefore, each current can be expressed by the formulas with the transmission distance and frequency, where the magnitude I_{out} is closely related to the output power. $I_{out}=j\omega r^3\sqrt{L_1L_2(r^2+d^2)^3}V_S/(Z_1Z_2+\omega^2r^6L_1L_2/(r^2+d^2)^3)$ (1) This is shown in Fig. 2 as a color map. When the transmission distance is short, frequency splitting phenomenon occurs in which the maximum output appears at two divided frequencies. It also shows the maximum output at a resonant frequency of 20 kHz at the specific distance, and the output sharply decreases at a further distance. *Fig. 2 here* B. Verification To verify these formulas, a real magnetic resonant wireless power transmission system was constructed and tested under the same conditions. The system can transmit 50W of power at a distance of 400mm. The experimental results are very similar to those predicted by the circuit equation, and the results will be added to the full paper. III. Influence of transmission distance A. Analysis using a circle diagram According to the transmission distance, the magnitude and phase of the transmission/reception current (I_{in}, I_{out}) can be calculated for each of the resonance state and the frequency splitting state, and the circle diagram of each current can be drawn with their phasor diagram. The phasors of I_{in} and I_{out} are formed in the shape of a circle around 0° and 90°, respectively, and the frequency splitting occurs due to the circularity being distorted as the transmission distance decreases. In this case, the maximum output appears when the I_{out} passes 0° and 180°, and two divided resonant frequencies can be estimated by finding the point where the imaginary value of I_{out} becomes zero. $f_{1,2}=\sqrt{[(2L-R_L^2C)\pm\sqrt{(R_L^4C^2-4R_L^2LC+4k^2L^2)}/(2L^2C-2k^2L^2C)]}/2\pi$ (2) B. Magnetic phenomena analysis In order to analyze the reason why maximum output appears at the two divided resonant frequencies, the magnetic flux densities of both low resonant frequency and high resonant frequency are simulated by finite element analysis as shown in Fig. 2 (a) and (b). At low resonant frequencies, the magnetic field passes through the entire transmitting/receiving coil, whereas at high resonant frequency it appears to be opposite to each other. As can be seen from the circle diagram, the phasor of I_{out} rotates around 90°. Since the output becomes maximum when the phasor of I_{out} passes near 0° and 180°, it can be seen that the magnetic field of the receiving coil also has the same (0°) or opposite (180°) direction to the magnetic field of transmitting coil. IV. Conclusion In this paper, the equation of output power was formulated with transmission distance as variables and verified through experiments. In addition, the resonance characteristics according to the transmission distance were analyzed through the circle diagram and finite element analysis. From these results, it is possible to know the influence of the transmission distance and the magnetic cause of the frequency splitting phenomenon in the magnetic resonant wireless power transmission. Furthermore, the optimum design for the target transmission distance will be possible, and it will be able to obtain high output and efficiency stably by calculating an approximation of the divided frequency representing the maximum power in the short-range transmission. In the full paper, circle diagrams of transmission/reception current according to all transmission distances, a detailed formula derivation process, and experimental results for verification will be added.

HR-07. Optimization of Planar Spiral Coils for Uniform Magnetic Field to Wirelessly Power Moving Targets.

Y. Xie[1] and Q. Xu[1]
1. Key Laboratory of Image Processing and Intelligent Control of Education Ministry, Department of Control Science and Engineering, Huazhong University of Science and Technology, Wuhan, China

Abstract Wireless power transfer technology via magnetic coupling has been widely used to provide freely positioning power for cell phones, electric cars and drones. In this paper, the configuration of planar spiral coil is optimized by genetic algorithm to achieve the uniform magnetic field distribution above the transmitter, whereas the magnetic field is simulated by HFSS software. A transmitter coil with the turns of fourteen and the radius of 8 cm is designed for an improved evenness of magnetic field distribution. The uniformity of the axial component of magnetic field distribution is evaluated by a coefficient of variation (COV). The measured COVs of the optimized and regular coils within the plane with a height of 8 mm above the transmitting coil are 0.1858 and 0.3161, respectively. Introduction Wireless power transfer (WPT) uses a varying magnetic field to deliver power across an air gap, to a load without physical contact. WPT systems may be classified into far-field and near-field techniques. In general, far-field transmission is available for the devices with high-power requirements. For the moderate power (a few watts to hundreds of watts) and mid-range distances (0 to a few meters), a near-field wireless power system operating at no more than 100 MHz would be far superior to far-field WPT. It is shown that near-field WPT can achieve higher efficiency with less stringent RF exposure safety limit [1]. The mutual coupling and energy transfer efficiency will deteriorate with the misalignment of the transmitter and receiver coils. On the other hand, the transmitting coil must be large enough to accommodate the devices which charged simultaneously. These pose a challenge, as to ensure stable power delivery to moving targets, the distribution of the z-component of the magnetic field in the plane of the receiving coils must be as uniform as possible [2]. Transmitting coils may be designed to produce such fields. One approach is optimizing the structure of coils for single receiving coil systems. Anew hybrid structure which consists of a coil and a spiral winding is designed for improving the uniform magnetic field distribution [3]. Two kinds of transmitting coil structures have been designed based on the continuous current distributions [4]. Another approach is to use an array of transmitter coils. The most reasonable arrangements of transmitter coils are analyzed and designed [5]. Methodology In this paper, a kind of planar spiral transmitting coil structure has been designed based on the genetic algorithm and the simulation by HFSS software that can generate uniform axial component of magnetic field. The equivalent circuit model of two coils system is analyzed firstly. Then the relationship between the η and the magnetic field strength B can be obtained. Also, the axial component of magnetic field generated by the planar spiral coil can be calculated according to the Biot-Savart Law. These analyses indicate that the width of each turn and the spacing between two adjacent turns of the coil are the primary factors that affect the magnetic field strength. The width and the spacing are chosen as the optimization variables. For the optimization of spacing, a series of single concentric current loops are used instead of a planar spiral coil. The coefficient of variation (COV, the standard deviation divided by the mean) of the z-component of the magnetic field which can calculated by the Biot-Savart Law is chosen as the objective function of genetic algorithm. HFSS and Matlab are combined to optimize coil widths on the base of the results of spacing optimization. The planar spiral coil model is built with HFSS and optimized by Matlab. And the COVs of the S21simulated by the HFSS between the planar spiral transmitting coil and receiving coils built on the testing plane are taken as the objective function. Then the COVs of the regular and optimized coils are compared through simulations. And the optimization results are validated by experiments with the network analyzer ROHDE & SCHRWARZ ZVH8. Results Using the above methods, the optimization process is described as follows: Genetic algorithm toolbox in Matlab is used for the optimization of the spacing between two adjacent turns. On the base of the results of spacing optimization, the width of coils are taken as the optimization variables with the planar spiral model built by HFSS through the HFSS-MATLAB API. The COV of the S21 simulated by the HFSS is calculated and optimized with genetic algorithm until reach terminating condition. And the optimized result is shown in Fig.1 and Fig.2. The COVs of the optimized and regular coil on the plane with a height of 8 mm above the transmitting coil are0.1858 and 0.3161 measured by network analyzer. Conclusion To ensure stable power delivery to moving targets, the magnetic field distribution generated by the transmitting coil must be even. The transmitting coil with the turns of fourteen and the radius of 8 cm is designed through genetic algorithm optimization and simulation by HFSS to enable the uniform distribution of axial component of magnetic field, which is verified by the simulation results. And this research demonstrates the feasibility of using the method in the design of coil structures to improve the uniformity of magnetic field.

HR-08. Demagnetization Characteristics of a Permanent Magnet Embedded Salient Pole Wind Generator.

Y. Guo[1], P. Jin[1], H. Yang[2] and Y. Zhu[1]
1. College of Energy and Electrical Engineering, Hohai University, Nanjing, China; 2. School of Electrical Engineering, Southeast University, Nanjing, China

Offshore wind power has become an important direction in the field of wind electricity generation. The commonly used surface-mounted PM wind generator cannot resist the corrosion due to humidity and salt spray. In order to improve the reliability of wind generator, the interior PM structure is adopted in some wind power generators. An improved flux intensifying PM embedded salient pole wind generator (FI-PMESPWG) is proposed in our previous work. As other PM machines, the FI-PMESPWG also faces the demagnetization problems, especially under short-circuit and high temperature conditions. Some important research works about demagnetization performance of interior PM machines are carried out, for example, the transient magnetic behavior of an interior PM machine during fault conditions is investigated in [1], and the partial demagnetization performance of a 7MW interior PM wind generator is investigated in [2]. But these investigations are focus on the normal interior PM machine, and their conclusions are not suitable for the salient pole ones. Therefore, in this paper, the demagnetization characteristics of FI-PMESPWG are investigated to find out some rules suitable for this kind of machines. Fig.1 shows the configuration of FI-PMESPWG. Its rotor core upper surface is designed to a bias arc for yielding a sinusoidal waveform of air-gap flux density. And in each magnetic pole, two PMs with mirror symmetrical magnetizing directions are embedded. In the salient pole, some non-magnetic material is added to guide the magnetic flux path. The magnetic field in the radial direction is intensified owing to the PM's placement. To modify the angle between the two PM pieces, the magnetic field in the magnetic pole will be changed and the demagnetization performance will varies consequently. So, the magnetic field distributions with different PM and non-magnetic material placements and thickness are all calculated and investigated. The variations of magnetic field distributions with different short-circuit currents and operating temperatures are also analyzed based on finite element method. Fig. 2 shows the partially demagnetized regions of selected magnets under 3-phase symmetrical short-circuit faults under rated speed. The demagnetized area, shown in color contour map, is covered by the nodes with flux density <0.6 T in the magnetization direction. As shown in the picture, different from the normal interior PM machine, the PM region near the bottom of pole shoe has the highest demagnetization. That's because the side frame of the pole shoe has some leakage flux and it changed the magnetic flux path and hence affects the demagnetization performance. The demagnetization in the two PMs are not symmetrical due to the armature reaction. Due to its special structure, FI-PMESPWG has some other different demagnetization characteristics from the normal interior PM machines, which will be analyzed and compared with the normal ones detailed in the full paper. The effect of demagnetization on the electromagnetic parameters will be investigated. Based on the analysis results in this paper, the demagnetization rules of interior PM salient pole machines will be concluded and it can supply an important theoretical basis for design of this kind of machine.

HR-09. Design of a Novel Brushless Electrically-Excited Claw-Pole Generator for Hybrid Electric Vehicles.

X. Zhao[1] and S. Niu[1]
1. Electrical Engineering, The Hong Kong Polytechnic University, Kowloon, Hong Kong

Abstract: This paper presents a new brushless electrically-excited claw-pole generator for vehicle power generation. The propose design uses a toroidal excitation coil to magnetize all the stator poles and then generate effective power by saliency effect of dual rotors. One advantage of this new design is its good excitation ability to minimize the excitation copper loss, thus achieving an acceptable energy conversion efficiency. Besides, the brush and slip rings are eliminated compared conventional rotor-electrically-excited claw-pole generator. The generator structure is introduced, along with no load flux distribution illustrated by 3D finite element analysis. Rotor configurations using interlaced and non-interlaced types are both elaborated. Load characteristic is also predicted by field-circuit coupled analysis, which reveals the proposed brushless topology can achieve a comparable performance against conventional brush solution. I. Introduction Electrically-excited claw-pole generator(EECPG) is a popular solution for on board vehicle power generation due to its field regulation ability. One advantage of EECPG is its good excitation ability since all rotor poles can be magnetized by only one toroidal excitation coil. Therefore, less excitation copper loss is consumed compared to those conventional electrically-excited generators with distributed excitation windings, which makes it more possible to achieve an acceptable energy conversion efficiency even with a relatively small power scale. However, EECPG suffers from the burden of brush and slip rings, which brings out a reliability problem and becomes disadvantageous for modern vehicle power generation. II.Proposed generator This paper proposes a novel brushless electrically-excited claw-pole generator (BEECPG) for the power generation in hybrid electric vehicles (HEV). Fig. 1(a) describes the power train for series-type HEV, in which the proposed BEECPG, as shown in Fig. 1(b), works as an ICE-mounted generator to realize mechanical-to-electric energy conversion. The proposed BEECPG is composed of two symmetrical rotors at double sides, a common stator and two set of windings, namely the armature winding and field winding. Both the stator and rotor consist of U-shaped salient poles. The field winding is sandwiched between two set of back-to-back stator poles, while two sets of armature coils are arranged in close to the left and right rotor, respectively. Advantages of this new generator can be summarized as (1) The excitation winding is located at stator side. Therefore, a brushless configuration is realized. (2) With on PMs used, the cost is reduced and reliability is improved especially for high temperature environment around internal combustion engine. (3) All stator poles are magnetized by one toroidal excitation coil. Therefore, excitation loss is minimized and an acceptable energy conversion efficiency is more possibly to be achieved even with a relatively small power scale. III. 3D magnetic circuit analysis The magnetic field distribution of the proposed BEECPG is illustrated in the Fig. 2 by using 3D finite element analysis. Two rotors share the same rotational movement, and at different positions, the alignment between stator poles and rotor poles at two sides are different, as well as corresponding field distribution. As shown in the Fig. 2(a), at this initial position, one set of stator poles are all aligned with the left rotor poles, while the other one is aligned with the right rotor slots. Therefore, the flux generated by the field excitation will almost all go to the left side and linked with the left armature coil. Correspondingly, at this position, the left coil flux has the maximum value while the right coil has the minimum flux linkage, as shown in the Fig. 2(d), and the cascaded flux has the positive maximum value. When a 1/4 pole pitch movement occurs as shown in the Fig. 2(b), the alignments becomes symmetrical between the stator poles and rotor poles at both sides, hence the field flux will shunt into the double armature coils and the cascaded flux becomes zero. Then, as shown in the Fig. 2(c), when the rotor moves half of the pole pitch, the alignment now is in the contrast with that shown in Fig. 2(a), specifically, one set of the stator poles are aligned with the right rotor poles and the other one is aligned with the left rotor slots, thus the field flux are all linked with the right armature coil and the cascaded flux has the negative maximum value. Therefore, as shown in the Fig. 2(d), with the rotor rotation, both armature coils have bias flux linkage but their variation trends are opposite, and when they are cascaded, a bipolar and symmetrical cascaded flux can be obtained as shown in Fig. 2(d). IV.Conclusion This paper proposes a novel brushless electrically-excited claw-pole generator for the power generation in hybrid electric vehicles. This design owns good excitation ability to minimize the excitation copper loss and thus can achieve an acceptable energy conversion efficiency within a relatively small power scale. The performance of this new topology is comparable to conventional electrically-excited claw-pole generator, while the brush is successfully eliminated.

HR-10. Study of Air-gap Magnetic Field of a Novel Integrated Brushless Excitation Generator.

S. Zhu[1] and C. Li[1]
1. Nanjing University of Aeronautics and Astronautics, Nanjing, China

1. Introduction The electrical brushes of the brush excitation generator causes many problems such as looping, noise, short life and serious heat. The realization of the brushless excitation can solve above-mentioned problems[1-3]. A novel integrated brushless excitation method is proposed in this paper. It is very suitable to realize brushless excitation for the wound rotor generator without changing the original topology. The additional excitation part is integrated in the wound rotor generator to realize brushless excitation. However, the magnetic flux of excitation part is coupled with the original magnetic flux of wound rotor generator. The air-gap magnetic field of the novel generator is studied by the theoretical analysis and Finite Element Analysis to decouple two parts of the magnetic flux and study the influence of the additional magnetic flux of excitation part on the operating characteristics of the novel generator. The operating characteristics are also verified by the experiment. 2. The Structure and Operational Principle of the Novel Integrated Brushless Excitation Generator A novel integrated brushless excitation method is applied in a wound rotor hybrid excitation generator (WRHESG) to form an integrated brushless WRHESG. The topology is as shown in Fig. 1(a). The arrangement of the coils are shown in Fig.2(b). The additional stator excitation windings (W_s) are buried in the stator slots with the armature coils (W_a). The rotor excitation windings (W_F) are mounted in the rotor slots. The rotor armature slots are arranged evenly around the rotor iron core and the rotor armature coils (W_r) are buried in the rotor slots. W_s and W_r are the coils of the excitation part to produce I_F. W_a and W_F are the coils of the power part to produce output power. When the dc excitation current is infected into W_s, the static magnetic field is built in the main air gap and is cut by W_r. The ac excitation current is induced in the W_r and is rectified by rotating rectifier to provide dc excitation current (I_F) in the W_F. The rotating magnetic field is built by the magnetic flux of I_F and permanent magnets to induce the voltage in the W_a. 3. The Decoupling of the Air-gap Magnetic Field of Excitation Part and Power Part The harmonics are added in the air-gap because of the addition of the excitation part. The harmonics of the flux density are studied theoretically firstly. The details will be introduced. The calculation of the flux density of the static excitation part are divided into 2 parts: permeance coefficient and magnetic potential. The product of permeance coefficient and magnetic potential is the flux density produced by I_f. B_f can be induced in the full paper In order to verify the correctness of the theoretical analysis, the distribution of the air-gap flux density produced by excitation part and produced by power density is separated by the frozen permeability method. The permeability of the iron core of the brushless excitation WRHESG is recorded. The magnetic field distribution of the excitation part and power part can be gained by calling the permeability of the iron core of the integrated brushless WRHESG. The results are shown in Fig. 1. Fig.1(c) is the magnetic flux density of the excitation part and Fig.1(d) is the magnetic flux density of the power part. The harmonics can be analysed by Fourier decomposition. It can be gained that the odd harmonics are existed in the magnetic field flux of power part. And, the fractional harmonics are existed in the magnetic field flux of excitation part, which agrees well with the theoretical analysis. The details will be given in the full paper. The air-gap magnetic field of the excitation part is static, which will not induce voltage in W_a. The output voltage of the integrated brushless WRHESG and WRHESG will be compared to demonstrate the correctness of analysis. It is obvious that the magnetic flux of the excitation part is much smaller than that of the power part. Because the resistance of the rotor excitation winding is very small, the armature reaction of the excitation part is very serious. Therefore, the extra saturation can be avoided. 4. Experiment The magnetic field cannot be test directly. However, it can be reflected by the output voltage of the generator. A 1.5kVA prototype is fabricated as shown in Fig. 2(a). The no-load characteristics and load characteristics of the integrated brushless WRHESG and WRHESG are compared. The output voltage waveforms of the integrated brushless WRHESG is shown in Fig. 2(b). It can be concluded that the operating characteristics that the integrated brushless WRHESG and WRHESG are quiet similar. The novel integrated brushless excitation method does not affect the operating characteristics of WRHESG. 5. Conclusion A novel integrated brushless excitation method is proposed in this paper. It is applied in a WRHESG to realize brushless excitation without changing the topology of the WRHESG. The design method for decoupling excitation part and power part is given. The flux density decides the quality of the output power and the operating characteristics of the generator. The air-gap magnetic density and the magnetic field distribution of two parts are gained by frozen permeability method. It can be gained that the extra excitation part does not affect the magnetic field distribution of the WRHESG. Finally, it is demonstrated by the operating characteristics tested by prototype.

HR-12. Research of an Axial Flux Stator Partition Hybrid Excitation Brushless Synchronous Generator.

C. Ye[1,2], Y. Du[1], J. Yang[1], X. Liang[1], F. Xiong[1] and W. Xu[1]
1. School of Electrical and Electronic Engineering, Huazhong University of Science and Technology, Wuhan, China; 2. State Key Laboratory of Advanced Electromagnetic Engineering and Technology, Huazhong University of Science and Technology, Wuhan, China

Abstract- A vehicular generator has stringent requirements on its weight and volume. As a combination of permanent magnet and electric excitation motor, hybrid excitation machine could meet the requirements of vehicular generator, with small size, light weight, adjustable output voltage. In this paper, an axial flux stator partition hybrid excitation brushless synchronous generator (ASHG) is proposed. First, the structure and operation principle of ASHM is illustrated. Afterwards, the shape of the magnetic pole is optimized to obtain the air-gap flux density with low harmonic content. Moreover, the regulation performance of the magnetic field and output voltage are investigated by three dimensional finite element analysis (3D FEA). The result indicates that ASHG has a high performance of adjusting terminal voltage. It can improve the generator efficiency, power density and stability comparing with the conventional vehicular generator. I. Introduction The vehicle generator is used to supply power for small appliances in vehicle. At present, there are two main schemes of vehicle generators. One is the electric excitation synchronous generator (EESG), the other is permanent magnet synchronous generator (PMSG). EESG usually needs slip rings and electric brushes to provide the rotor field current. The terminal voltage of EESG could be flexibly adjusted. While the slip rings and electric brushes would lead to the spark and maintenance problems. PMSG has the merits of simple structure, high efficiency, and so on. But it has poor ability to regulate the output voltage. To combine the advantages of aforementioned generators, a novel axial flux stator partition hybrid excitation brushless synchronous generator (ASHG) is proposed. It can adjust the current in the excitation winding to achieve the regulation of the air gap magnetic field. II. structure The structure of ASHG is shown in Fig. 1. The stator core is made of silicon steel sheet. The rotor contains the rotor core, the permanent magnet and the core pole. The permanent magnet and the iron core are staggered on the upper surface of rotor core. The opposite polarity of the permanent magnet and the core are also staggered, to avoid the magnetic circuit intersection. The construction of the rotor is simple which consists of single solid rotor core and laminated rotor. The back electromotive force (back-EMF) would generate in the armature winding when the rotor rotates. III. Working Principle The working principle of ASHG is illustrated as follows: when DC current is charged in the field winding, the magnetizing flux generated by excitation current would be formed, meanwhile, the flux generated by permanent magnet stay unchanged. The air-gap flux density distribution is the results of their synthesis. And thus the air-gap flux density can be regulated by adjusting the field current. IV. Analysis and simulation In Fig. 2(a), the red permanent magnet generates N pole field, the lower part is the S pole, and the black arrows indicate the magnetic field path. Fig. 2(b) shows the magnetizing flux path of ASHG. It can be seen that the flux path of permanent magnet is the same as the theoretical magnetic circuit. Fig. 2(c) shows the three-phase back electromotive force waveforms of ASHG. It can be found the waveforms are nearly sinusoidal. I. Conclusion This paper presents an axial flux stator partition hybrid excitation brushless synchronous generator. The generator has the abilities of dynamic voltage regulation and self-excitation, thus it can make full use of the motor space and reduce the motor volume and quality. At the same time, the basic theory of the motor is studied. The permanent magnetic circuit and the electric excitation magnetic circuit of the static field are simulated, which verifies the correctness of the motor magnetic circuit design. Depending on the specific application requirements, the main parameters of the motor are designed and are optimized by finite element method. By optimizing the magnetic pole structure based on the function equation, the waveform of low harmonic air gap magnetic flux density and the output voltage are obtained. Finally, we studied the ability to tune the magnetic and voltage regulation output performance of ASHG by numerical simulation.

HR-13. A Novel Interior Permanent Magnet Brushless Doubly-fed Generator with Segmented Reluctance Rotor for Wind Power Application.

J. Zhang[1], Y. Jiang[1], J. Zhao[1] and W. Hua[1]
1. School of Electrical Engineering, Southeast University, Nanjing, China

INTRODUCTION: Variable speed brushless doubly-fed generator (BDFG) has no slip rings and no brushes, and only needs a part-size power converter which is similar as the doubly-fed induction generator in the field of wind power generation. So the BDFG has attracted great attentions and owns many advantages, such as high wind power utilization, high reliability and low maintenance [1]. However, the BDFG also has some disadvantages, such as complicated rotor structure, high harmonic distortions, low power density and low efficiency, which lower the potential applications of the BDFG in wind power application. In order to improve the performance of the BDFG, a new interior permanent magnet (IPM) BDFG with three-segmented reluctance rotor based on field modulation is proposed in this paper. Three-segmented structures for outer rotor are adopted to solve the problems of high cogging torque and asymmetrical electromotive force (EMF) caused by the introduction of the PM rotor and field modulation ring. TOPOLOGY: Stationary field modulation ring is firstly used in coaxial magnetic gear to transmit the torque between two surface permanent magnet (PM) rotors whose rotation speeds and pole numbers are different [2-3]. The structure and field modulation function of field modulation ring are similar to that of the reluctance rotor of the traditional BDFG. So it could be introduced to the BDFG as a reluctance rotor [4]. In addition, the PM inner rotor is adopted to provide the excitation magnetic field of the generator, as shown in Fig. 1. Then the flux density might be improved greatly by using high performance rare-earth permanent magnet which improves the power density and efficiency of the BDFG as a result. Commonly the PMs are surface mounted on the inner rotor where a uniform airgap will be achieved between the inner rotor and outer rotor. However, the existence of field modulation ring will lead to the flux distortion of the airgap. It shows that only about half of the PMs are utilized with the surface PM (SPM) rotor, as shown in Fig. 1(a). If the PMs are inserted into the rotor and then interior PM (IPM) rotor is used, the utilization of the PMs will be improved due to the existence of additional harmonic flux paths, as shown in Fig.1 (b). Fig. 1(b) shows the BDFG with IPM rotor has iron-bridges at the terminal of the PMs which may lead to some leakage flux. However, the IPM rotor will provide stronger exciting magnetic field than SPM rotor, even if their PMs are in the same size. It should be noted that there is only fundamental flux in the SPM rotor, as shown in Fig. 1(a). The introduction of field modulation ring would cause the asymmetric phenomena and high cogging torque. The asymmetric phenomena are caused by the asymmetric magnetic circuit due to the different speeds of reluctance rotor and the synchronous speed. In other words, the variations of the relative position of two rotors will lead to the varying harmonic contents of the excitation magnetic field in outer airgap, and the varying period of the harmonic contents is different from the electric cycle of the grid. In order to solve the problem, the reluctance rotor is evenly divided to three segments along axial direction, and there is a specific angle difference among them along circumferential direction, as shown in Fig. 1(c). By this way, the harmonic components are constant during the variation of the relative position of two rotors. FINITE ELEMENT ANALYSIS: In order to verify the effectiveness of the proposed IPM BFDG, finite element method (FEM) is employed. Considering the three-segmented reluctance rotor is symetrical in axis direction and it is better to decrease the computation time, 2D FEM is used in this paper, where three IPM BDFG models are established separately for the three-segmented reluctance rotor with an initial angle difference of 5 degree each other. Then the result of BDFG with three-segmented reluctance rotor could be obtained by averaging the results of three models. Fig. 2(a) shows the exciting magnetic fields provided by the SPM and IPM. The models of IPM BDFG and SPM BDFG have the same size including the PMs. It can be seen that the IPM rotor could provide more exciting magnetic field. There are asymmetric phenomena and large harmonics in three phase electromotive fore (EMF) of the IPM BDFG, as shown in Fig. 2(b). By adopting three-segmented reluctance rotor, the asymmetric phenomena and harmonics could be effectively reduced, as shown in Fig. 2(c). Meanwhile the cogging torque could be greatly reduced, as shown in Fig. 2(d). CONCLUSIONS: In this paper, a novel IPM BDFG with segmented reluctance rotor is proposed, which may improve the utilization of the PMs and the power density of the generator. Through the theoretical analyses, the solution to asymmetrical phenomena and high cogging torque is put forward, and the effectiveness is verified by FEM.

HR-14. Electromagnetic energy harvester for harvesting energy from low-frequency vibration.

K. Zhang[1], *Y. Su*[1], J. Ding[1] and Z. Zhang[1]
1. School of Mechanical Engineering, Zhengzhou University, Zhengzhou, China

We present an electromagnetic energy harvester with magnetic spring for converting low-frequency human motion into electrical energy. The magnetic spring is formed by magnetic forces between the fixed and moving magnets. Inductive coils are arranged at three special positions to obtain a larger output voltage. The experiment results show that the proposed energy harvesters possess frequency up-conversion behavior. A peak-to-peak voltage of 5.68V was obtained at excitation acceleration of 0.32g and frequency of 6.25Hz. Four LEDs in series were lit up successfully through an oscillation circuit which is connected to the energy harvester prototype. INTRODUCTION Research and investments in vibration energy harvesters [1-3] are currently attracting a great deal of interest because of the rapid development of wireless sensors and MEMS technology. In addition, traditional chemical batteries have a limited lifetime, which cannot power electronic devices for a long time. Meanwhile, soil and water will be polluted if wasted batteries were arbitrarily discarded into the environment. Vibration energy harvester can power electronic devices and wireless sensor nodes while converting ambient vibration energy into electric energy. Human motion is a common source of different kinds of vibrations. Various vibration energy harvesters based on kinetic energy have been developed. Three conversion mechanisms, piezoelectric [4], electrostatic [5] and electromagnetic [6] are often employed into energy harvesters. However, the frequency of vibrations produced by human motion is relatively low, usually below 10Hz, and the amplitude is large. In this case, electromagnetic conversion mechanism is more suitable for harvesting energy from human motion [7, 8]. Most electromagnetic vibration energy harvesters reported in literature mainly include a proof mass on a mechanical spring or a beam [9]. These harvesters cannot achieve a maximum efficiency because the resonance frequency of beam or spring cannot match that of the human motion vibration. In the paper, an electromagnetic energy harvester based on human motion with magnetic spring has been proposed. A magnetic spring, as an alternative [10] to mechanical spring or beam, can effectively decrease the resonance frequency of the harvester and make the harvester work in nonresonance condition. DESIGN OF THE HARVESTER The harvester is composed of a circular NdFeB (type N35) magnet, two cylinder NdFeB magnets, and six circular induction coils (ϕ25×ϕ2×3 mm), as shown in Fig. 1. The three magnets are set with their axes parallel to each other. The circular magnet (ϕ20×ϕ10×10 mm) is placed between the fixed magnet (ϕ10×10 mm) and the moving magnet (ϕ20×10 mm). The poles of the fixed (type N35) and moving magnets (type N52) are arranged in the same direction, which is opposite to that of the central magnet. The identical polarization causes the fixed magnet to repel the moving magnet. The two cylinder magnets are strongly attracted to the surface of the central magnet due to the magnetic attraction between the two cylinder magnets and the central magnet. And the fixed magnet is mounted on the inner side of the shell. In addition, the fixed magnet and the central magnet are joined together to prevent their relative movement. The central magnet, the shell and the cover plate are connected by a nylon bolt. The six ring copper coils with a diameter of 0.3 mm are attached to the inner walls of the shell and the cover plate, respectively. Each coil is of 320 turns. Thus, four coils are located at the end of the trajectory of the moving magnet, and the other two lie at the midpoint of the trajectory of the moving magnet. The gap between the inner walls of the shell and the cover plate is 18mm. EXPERIMENT The prototype of the harvester was excited by hand-shaking vibration, as shown in Fig. 2(a). For increasing the output voltage, six coils are connected in series and the total resistance is 23 Ω. The peak-to-peak voltage can reach 5.68 V with a load of 1kΩ at the excitation frequency of 6.25 Hz and amplitude of 0.32g. Corresponding FFTs of the induced voltage signal and the hand-shaking are shown in Fig. 2(b). According to FFTs, the main frequency of the induced voltage is found to be 40 Hz, which reaches 6.4 times of the main frequency of hand-shaking excitation. This phenomenon proves that the harvester possesses the frequency up-conversion behavior. Subsequently, a self-oscillation circuit was connected to the prototype. The circuit consists of two inductors (100μh), a transistor (S9108) and a resistor (1kΩ). And four commercial red LEDs are connected to the circuit in series as the load. Figure. 2(c) shows the four LEDs was lighting up when the prototype was moderately shaken by hand. As the frequency and acceleration of hand-shaking increases, the brightness of LEDs will be enhanced. CONCLUSIONS In this work, we have proposed an electromagnetic energy harvester for converting human motion energy into electrical energy. The harvester based on nonlinear magnetic-spring configuration that is helpful for responding low-frequency vibration. The frequency domain analysis shows that the harvester has a frequency up-conversion behavior. In the future, coil parameters will be optimized to obtain a greater power output and reduce the dimensions of the harvester for portable application. This work is supported by the National Natural Science Foundation of China under grant no.51475436 and the Henan Province Key Project on Science and Technologies under grant no.152102210042.

HR-15. Parameter Determination of PMSM using Coupled Electromagnetic and Thermal Model Incorporating Current Harmonics.

S. Mukundan[1], H. Dhulipati[1], J. Tjong[1] and N. C. Kar[1]

1. Electrical & Computer Engineering, University of Windsor, Windsor, ON, Canada

Motivation: Permanent magnet synchronous machines (PMSMs) are widely used for electric vehicle (EV) propulsion owing to its high performance capabilities over a wide operating range [1]. With advent in machine structure and inverter topologies, accurate parameter determination incorporating machine non-linearities and effects of time and space harmonics is of paramount significance for high-performance control and analysis. Although classical *dq*-axis modeling is widely incorporated: 1) it fails to incorporate the machine non-linearities such as magnetic saturation, cross-saturation and leakage effects; 2) the spatial harmonic contents caused by machine winding and structural configuration are not considered in inductances and flux linkage; and 3) the effects of operating temperature on parameter variation are neglected [2]; and 4) it requires information from experimental data or complex look-up tables for parameter determination. On the other hand, finite element analysis (FEA) is computationally extensive and modelling of time harmonics becomes complex. Thus, in this paper, a coupled electromagnetic and thermal model incorporating current harmonics for parameter determination is developed and validated for a fractional-slot distributed wound (FSDW) laboratory PMSM. *State-of-the-art*: Authors in [3] have incorporated cross-saturation effects in modeling of PMSM drives and [4] includes magnetic saturation effects for parameter determination. However, these papers fail to include the effects of spatial harmonics. [5] includes the effects of air gap flux harmonics but does not take into account parameter variation due to temperature. Similarly, multi-physics models as illustrated in [6] does not consider modeling of current harmonics. Thus, in this paper, a magnetic equivalent circuit (MEC) coupled with a thermal model for interior PMSM (IPMSM) taking into account current harmonics is developed for parameter determination. *Methodology*: For a 27-slot, 6-pole laboratory FSDW IPMSM as shown in Fig. 1(b) with performance details given by Fig. 1(a), a MEC considering magnetic saturation, cross-saturation and slot leakage effects is modelled as indicated in Fig. 1(c). The input current to determine the effective magneto motive force ($F_{i,k,n}$) at the stator includes harmonic components as shown in (1). Thus, both spatial harmonic (n) and time harmonic (k) components are incorporated during calculation of i-phase machine parameters. The machine phase a is assumed to be aligned to d-axis and hence the calculated machine phase inductances can be easily transformed to the two-axis frame using existing transformation equations. In order to incorporate the effect of operating temperature on the parameters, a thermal model incorporating the materials thermal resistances at each node of the machine as shown in Fig. 1(d), is coupled with the developed MEC. Thus, based on the calculated flux values (Φ) from MEC using nodal analysis and material properties, the effective machine losses (P_{losses}) are calculated. The analytically calculated losses are implemented in the thermal model to estimate the operating temperature (T) as in (2) and the magnetic permeability of the stator, rotor and the permanent magnets (PMs) are updated accordingly to calculate the varied machine parameters. The entire procedure of the proposed methodology is depicted in a flowchart as illustrated in Fig. 2(a). *Results*: The proposed model provides a good compromise between model accuracy when compared to classical *dq*-axis models and computation complexity compared to FEA. Moreover, it can be incorporated for both sinusoidal and non-sinusoidal winding distribution machines; accurate modeling and control including temperature effects; and for structural optimization in case of machine design. Fig. 2(b) depicts the no-load induced emf waveforms at the rated speed of 3,000 rpm for the laboratory IPMSM. It can be seen from the figure that the values obtained from experimental analysis, FEA and the proposed model are in close agreement highlighting the accuracy of the model. The corresponding machine parameters including PM flux linkage and *dq*-axis inductances obtained are indicated in Fig. 2(c). Variation of PM flux linkage and *dq*-axis inductances with operating conditions, current harmonics and temperature can be easily obtained using the proposed model and will be shown in the full paper. The detailed analytical modeling of the equivalent electromagnetic and thermal models and a comprehensive comparative performance analysis of the machine obtained from calculations using the proposed model, FEA and experimental investigations will be presented in the full paper.

HS-01. Electromagnetic Shielding Measurement of Magnetic Absorbing Sheets Using IC-stripline.

H. Park[1]
1. School of Electrical and Electronic Engineering, The University of Suwon, Hwaseong-si, The Republic of Korea

I. INTRODUCTION In modern mobile devices, the clock speed and integration density continually increase. The trend makes electromagnetic noises radiated from high-speed ICs and traces interfere and disturb easily the normal operation of adjacent ICs and components, which is called the intra-system electromagnetic interference (EMI) [1]. Particularly, engineers developing mobile devices are suffering from radio-frequency (RF) interference problem that is RF desensitization problem due to EMI of digital noise to RF antenna within the device. In order to solve EMI/RFI problems in mobile devices, various countermeasure components against EMI are popularly employed. Among the components, conductive and magnetic sheets for shielding and absorbing the electromagnetic noise are most commonly used in modern mobile devices. By covering high-speed ICs and traces with these sheets, electromagnetic noise strength radiated from noise sources can be effectively diminished. Therefore, it is important to accurately measure and evaluate the shielding performance of conductive and magnetic sheets. In order to test and measure the shielding property of planar shielding materials for EMI reduction, the most common way used so far is ASTM D4935-99 [2]. The ASTM method was devised to evaluate the shielding performance of planar materials from 30 MHz to 1 GHz by using a flanged coaxial transmission-line holder. This test method provides a procedure for measuring the electromagnetic (EM) shielding effectiveness (SE) of a planar material due to a plane-wave, far-field EM wave. However, as mentioned above, planar shielding and absorbing sheets used in mobile devices are very close to noise sources such as ICs and traces. In other words, these sheets are aimed for shielding near-field EM wave from the noise sources. As a result, far-field measurement method such as ASTM method is not suitable to evaluate the shielding performance of planar EMI sheets. Therefore, it is necessary to measure and evaluate near-field SE. Unfortunately, there is no standardized method for near-field shielding measurement of planar EMI sheets so far. In this paper, a method for near-field shielding measurement of planar shielding materials, especially magnetic absorbing materials is proposed. Our method is based on the IC-stripline method (IEC 61967-8), which defines a method for measuring the EM radiated emission from an integrated circuit (IC) using an IC-stripline in the frequency range of 150 kHz up to 3 GHz [3]. To be precise, the IC-stripline method is not actually aimed for shielding measurement, but this paper comprehensively examined the applicability of the IC-stripline method to near-field shielding evaluation of magnetic absorbing materials. Fig. 1 shows the geometry of IC-stripline method for shielding measurement of magnetic absorbing materials. As an electromagnetic source, a 50 ohm microstrip line on the printed circuit board is used. A magnetic absorbing sheet with 60×60 mm size is mounted and covered over the microstrip line. An IC-stripline, which can capture separately the electric-field (E) coupling and magnetic-field (H) coupling in near-field region, is located above the magnetic absorbing sheet. II. NUMERICAL RESULTS In the first, we conducted full-wave simulation for shielding analysis of a commercial magnetic absorbing sheet by modeling the test structures of IC-stripline and ASTM coaxial line. Fig. 2 shows simulated shielding effectiveness (SE) of a commercial magnetic absorbing sheet using the IC-stripline method (near-field SE) and ASTM method (far-field SE). SE is defined as the ratio of electric field or magnetic field strength before and after placement of a magnetic absorbing sheet. In the case of near-field, electric-field SE (E-SE) and magnetic-field SE. (H-SE) should be defined separately because the wave impedance (the ratio of electric-field and magnetic-field) is not constant in near-field region. However, for far-field, E-SE and H-SE are identical due to the constant wave impedance (377Ω in free-space). When SE of a commercial magnetic absorbing sheet is measured by the IC-stripline, E-SE is almost zero up to 1 GHz, whereas H-SE is around 7~10 dB. When SE is measured using ASTM method, far-field SE is also almost zero up to 3 GHz. These results indicate that for shielding, the magnetic absorbing sheets are effective only for magnetic near-field but completely ineffective to electric near-field and far-field EM wave. More detailed explanation and experimental validation will be presented in on-site conference and an extended full paper.

This work was supported by the National Natural Science Foundation of China under Grant 2015DFR70060. Abstract: For permanent magnet synchronous motor (PMSM), due to the large rotor rotational centrifugal forces, a sleeve is often used to prevent damage to rotor permanent magnets. However, the sleeve material characteristics have much influence on the PMSM, and therewith, most of rotor eddy-current losses are generated in the sleeve, which could increase the temperature of PMSM. If the rotor heat dissipation condition is poor, high temperature can influence the PMSM performance and even result in thermal demagnetization of the permanent magnets. Thus, a sleeve scheme designed with low eddy-current losses is very necessary. In this paper, taking a 12.5 kW, 2000 rpm PMSM with 0.2mm thickness stainless steel sleeve as an example, the sleeve adopted insulation cylinder material is presented. Then, the 2-D mathematical model of PMSM is established, and the electromagnetic field is calculated by utilizing the time-stepping finite element method under rated load condition. In addition, the variations of the eddy-current losses in different kinds of sleeves are analyzed. The calculation results show the effectiveness of the insulation cylinder in reducing the eddy-current losses in the rotor. The obtained conclusions can provide useful reference for the design and research of PMSM. Introduction The eddy-current losses in permanent magnet will be very obvious to increase rotor temperature of the machine. Thus, it is very important to find some measures to reduce the eddy-current losses in the sleeve and magnets. Some scholars have preliminary work in reducing the eddy-current losses in the rotor. Eddy-current losses in the rotor permanent magnet could be reduced by dividing the rotor permanent magnet [1]. The copper plating between the sleeve and permanent magnets could dramatically decrease the eddy-current losses in magnets [2]–[4], but the eddy- current in the sleeve would not be significantly changed. In this paper, taking a PMSM with 0.2mm stainless steel sleeve as the study object, insulation cylinder material is presented. Using the finite element method, the electromagnetic field is calculated before and after insulation cylinder material under rated load condition. The further research on eddy current distribution, which is one of the key influencing factors in PMSM reliability and working life, is researched based on the theories of electromagnetic field. 1: Parameters and Structure of PMSM Fig.1a shows the prototype PMSM experimental platform and tested results operating at rated speed (2000 r/min) and rated load ($R = 0.32\ \Omega$ and $\cos\phi = 0.79$). The rotor magnetic field was excited by the PM (N33SH), whose remanence (Br) and coercivity (Hc) is 1.1T, 838 kA/m, respectively, and limited working temperature is 150 °C. Meanwhile, the conductivity is 6.25×10^5 S/m, and it is divided into three segments in axial direction. To prevent damage to rotor permanent magnets due to the large rotational centrifugal forces, the sleeves, which are coated outer surface of permanent magnets, adopt stainless steel material and are divided into six segments in axial direction, as shown in Fig.1c. The conductivity and thermal conductivity of stainless steel sleeve is 1.1×10^6 S/m and 59 W/m●K, respectively. Basic parameters of PMSM are listed in Table I. Based on the structure and size of the prototype, the 2-D transient electromagnetic field calculation model was established, as shown in Fig.2. By using the finite-element method, the phase voltage and current of PMSM were calculated, and the value is 212.3V, 25.3A respectively. It can prove that the calculated results are in good agreement with the test data of PMSM. 2: Influence of Sleeve Material on Electrical Field In order to reduce the eddy-current losses in the rotor, the insulation cylinder, which is made of HGW2085 material, is proposed. This material has a very high mechanical strength and good insulation properties, and working temperature is 125 °C. In addition, its conductivity is 0 S/m and relative pemeability is 1. Table II gives the electromagnetic calculation results under rated load condition when the sleeve adopts the stainless steel and insulation cylinder material, respectively. From Table II, it can be seen that, whether the sleeve adopts stainless steel or insulation cylinder, the main magnetic flux and flux provided by permanent magnets are not changed under rated load condition, Accordingly, the stator core loss will not also be changed. One point to take notice of is when the sleeve material adopts insulation cylinder, the eddy-current loss in permanent magnet will increase compared with that of the prototype PMSM. This is because the shielding effect of the insulating cylinder on the harmonic magnetic field in the air gap is relatively weak, it is also shown in Fig.3. And gap flux density fundamental value and main harmonics increase compared with that of adopting stainless steel. However, since the conductivity of insulation cylinder is zero, the total rotor eddy-current losses can be reduced. In additional, the insulation cylinder can prevent the heat produced by stator from transferring to the permanent magnet. Thus, it can protect the permanent magnet from high temperature damage. Conclusion 1 : Main magnetic flux and electromagnetic torque can not be changed with the nonmagnetic sleeve material. 2 : Whether the machine power is large or small, the insulation cylinder will have a positive effect on reducing the rotor losses and improving machine efficiency.

I. INTRODUCTION The linear permanent magnet vernier machine (LPMVM) is the combination of the linear permanent magnet machine and vernier machine, which yields high thrust density at low speed and thus is a preferable solution in the direct-drive linear-motional applications [1]. In order to further improve the thrust density of the LPMVM, many new configurations have been proposed in recent years, such as the double-stator spoke-type LPMVM [2], the LPMVM with Halbach permanent magnet (PM) array [3], the LPMVM with consequent-pole and Halbach PM array [4], the linear stator PM vernier machine [5], and so on. It is worth noted that the flux density of the tooth of the LPMVM is even smaller that of the conventional linear PM (CLPM) machines due to the multi-polar and fewer-teeth structure. In order to improve the flux density and the thrust of the LPMVM, the linear interior permanent magnet vernier machine (LIPMVM) is proposed in this paper, in which the PMs are inserted into the stator core. Due to the improvement of the flux density and additional reluctance thrust, the average thrust of the proposed LIPMVM is significantly higher that of the conventional linear surface PM vernier machines (LSPMVM). II. CONFIGURATIONS AND OPERATION PRINCIPLES A. Configurations Fig. 1 (a) shows the configuration of the existing LSPMVM, in which the PMs are mounted on the surface of the stator. Fig. 1 (b) shows the configuration of the proposed LIPMVM. The V-shape PM arrays are adopted in the LIPMVM so that larger volume of PMs can be inserted into the stator core. The air-gap length of the two machine are kept the same. But the effective air-gap length of the LIPMVM will be much smaller that of the LSPMVM due to the interior PM structure. More detailed parameters are listed in Table I. B. Operation Principles and Analysis Both the LSPMVM and LIPMVM obey the operation principles of the vernier machines [6], so the relationship between the mover slots number Z_m, the PM pole-pair Z_{pm} and armature windings pole-pair P_a can be expressed as: $P_a=|Z_m \pm Z_{pm}|$ (1) The air-gap permeance function of the LPMVM can be expressed as [7]: $\Lambda(x, vt)=\mu_0/(g'+G(x, vt))$ (2), where $g'=g+h_m/\mu_r$ (3), g is the air-gap length and G(x, vt) is the additional air-gap length introduced by slotting. In the LIPMVM, we have g'=g as the PMs are inserted into the stator core. Then, the air-gap flux density can be obtained by: $B_g(x, vt)=F_{pm}(x)*\Lambda(x, vt)$ (4), where $F_{pm}(x)=\sum F_{pmi}\sin(iZ_{pm}x)$ (5). So, according to equation (2), a higher flux density can be obtained in the LIPMVM under the same magnetic motive force (MMF) as the LSPMVM due to the smaller g', and both the back electromotive force (EMF) and average thrust will be improved. Furthermore, due to the saliency of the interior PMs (IPMs) structure, there will be an additional reluctance thrust component in the average thrust of the LIPMVM. III. COMPARISONS Two finite element (FE) models about the LSPMVM and LIPMVM are built to compared with each other. In order to reduce the second harmonics in the thrust, the three-sectional structure [3] is adopted in both LSPMVM and LIPMVM. The three-sectional LIPMVM is shown in Fig.2. The flux distributions in the air-gap and iron core of the two machines, calculated by the FE method, are shown in Fig. 3, from which it can be seen that the flux density in the air-gap and mover tooth are both significantly improved due to the adoption of the IPMs. The comparisons of the flux-linkage, back EMF waveforms are shown in Fig. 4 and Fig. 5. The average thrusts at different current density are shown in Fig. 6. More detailed comparisons between the two machine are listed in Table II. It can be seen that the back EMF and average thrust of the LIPMVM is improved by 34% and 30%, respectively, compared to the LSPMVM. It is worth noted that the PM consumption of the LIPMVM is even lower that of the LSPMVM. This thrust improvement can be explained by the flux-strengthening effect and the additional reluctance thrust in the LIPMVM. IV. CONCLUSION This paper mainly proposed the LIPMVM, whose thrust density is 30% higher that of the conventional LSPMVM at the current density of 5A/mm^2, with lower PM consumption. The operation principles and flux-strengthening effect of the LIPMVM are also introduced in the paper. The FE results verified the superiority of the proposed machine.

I. INTRODUCTION Segmented permanent magnets (PMs) in surface-mounted PM (SPM) motors with large diameter are more widely used than ring PMs due to mechanical robustness and manufacturability. Fig. 1(a) shows the one-sixth model of a conventional SPM motor which has 36 slots and 48 poles in 12 segmented PMs. In this type of SPM motors, the radial gap between segmented PMs plays dominant role to change magnetic reluctance, and generates cogging torque and unbalance magnetic pull (UMP) with slot harmonics [1, 2]. Fig. 1(b) shows the noise waterfall of the conventional motor which has the dominant amplitudes corresponding to the 36th and 72nd harmonics originated from slot number. We investigated the characteristics of cogging torque and UMP due to the radial gap between segmented PMs, and proposed the designs of segmented magnets to reduce magnetically induced vibration and noise of the SPM motor due to segmented PMs. II. MAGNETIC EXCITATION FORCES DUE TO SEGMENTED PMS Torque ripple and UMP are major magnetic excitation forces in PM motors. Torque ripple is originated from cogging torque and commutation torque ripple. Cogging torque is generated from the interaction between PMs and slots and it is one of major sources of torque ripple because it exists regardless of armature current. Main harmonics of cogging torque are the least common multiples (LCM) of number of pole and slot [2]. However, reluctance changes whenever the radial gap between segmented PMs passes the slots which lowers harmonics of cogging torque to slot harmonics. These slot harmonic component of cogging torque can be calculated by summing cogging torque caused by each gap. The cogging torque of motors with segmented PMs, T^{cog} can be expressed as follows: $_{\infty N \infty}$ $T^{cog}=\Sigma T_j^{ring}\sin(jN_{LCM}\omega t+\phi_j)+\Sigma\Sigma T_j^{seg}\sin(jQ(\omega t+\Theta_i)+\Psi_j)$ (1) $^{j\ i\ j}$ where T_j^{ring}, ϕ_j, and T_j^{seg}, ψ_j are the Fourier coefficients and phases of cogging torque with ring type magnets and segmented PMs, respectively. And ω, Q, N_{LCM}, N and θ_i are the rotating speed of motor, number of slot, LCM of numbers of poles and slots, number of segmented PMs and angular position of the *i*-th gap, respectively. In real applications, there exists a static eccentricity in which the rotor rotates around the center of stator and the air-gap is not uniform along the circumferential direction because the stator and rotor centers do not coincide. This static eccentricity generates the UMP, and its main harmonics are pole harmonics [3]. The UMP caused by static eccentricity is affected by frequency component of cogging torque [4]. The x-directional UMP, F_x can be defined as follows: $_\infty$ $F_x=(g\varepsilon_s/(g^2-\varepsilon_s^2))^2\Sigma F_j^r\sin(jN_p\omega t+\Phi_j)$ ^{j} $_{\infty N\infty}$ $-\varepsilon_s/(gR_g)(\Sigma T_j^{ring}\sin(jN_{LCM}\omega t+\phi_j)+\Sigma\Sigma T^j_{seg}\sin(jQ(\omega t+\theta_j)+\psi_j)$ (2) $^{j\ i\ j}$ where g, ε_s, and N_p are the length of air gap, static eccentricity and number of poles. F_j^r and Φ_j are the Fourier coefficient and phase of radial magnetic force. The slot harmonics of UMP are also originated from slot harmonics of cogging torque. III. DESIGNS OF SEGMENTED PM TO REDUCE VBATION AND NOISE OF SPM MOTORS The slot harmonics of the cogging torque and UMP can be reduced by adjusting the number of segments and the number of poles in segmented PMs. We investigated Eq. (1) and (2) to find the possible combination of segmented PM and poles in segmented PM to reduce the amplitudes of the cogging torque and UMP. We proposed two designs of the segmented PMs, PM1 and PM2 as shown in Fig. 1(c) and (d). The numbers of poles in PM1 are changed to 3 and 5 from 4 which is the number of poles in segmented PM of the conventional motor. The numbers of poles in PM2 are changed to 5 and 7. The number of segmented PMs in PM1 is 12 which is identical to conventional motor but the number of segmented PMs in PM2 is 8. The proposed motors with PM1 and PM2 has 48 poles which is same as the conventional motor. We performed the finite element analysis to confirm the analytical results of the reduction of cogging torque and UMP. Fig. 2(a) and (b) show the cogging torque and x-directional UMP generated in the conventional motor, PM1 and PM2. The 36th and 108th harmonic of cogging torque and UMP are reduced by 29.3% in PM1 and 52.9% in PM2, respectively, and the 72nd harmonic of excitation forces does not exist in PM1 and PM2. IV. CONCLUSION We investigated the characteristics of cogging torque and UMP due to the radial gap between segmented PMs, and proposed the possible combination of segmented PM and poles in SPM motors to reduce the amplitudes of the cogging torque and UMP. The characteristics of cogging torque and UMP in the proposed equations and proposed PM designs were verified by finite element analysis. This paper will contribute to reducing magnetically induced vibration and noise of SPM motors with segmented PMs.

I. Introduction Stator DC current excited vernier reluctance machines (DC-VRMs), which have concentrated field and armature windings in stator are developed for applications when low cost and wide speed operation range are required [1]. However, the two sets of windings in the stator increase the insulation area and complicate the manufacturing process. Therefore, DC-VRMs with DC current injected into the armature windings are developed [2], [3], as the torque density can be improved under the constant copper loss. This paper deals with the design and analysis of an improved torque density DC-biased-VRM. A 12-stator slot, 10-rotor-slot machine is firstly designed, then by analyzing the magnetic flux distribution, a novel 6/10 machine with 20% higher torque density is developed. Further, by optimizing the stator/rotor tooth width combination and tooth shape, the torque ripple is reduced. Finally, the prototype of 6/10 machine is built, and the experimental results will be shown later. II. Topology, Parameters, and Flux Distribution The operation principle of DC-biased VRMs can be described briefly as follows: the DC component of the armature coils produces a multipole stationary magneto motive force (MMF), with the permeance modulation effect of the open-slot rotor, rotating exciting fields is generated. Average torque can be produced under the interaction of rotating exciting fields with multipole rotating MMF by three-phase balanced AC component. The currents contain a sinusoidal AC current with a DC current, and can be expressed as Eq. (1). Three phase H-bridge inverter is appropriate for this machine. Fig. 1 (a) shows the topology and winding arrangement of an existing 12/10 machine published in [3]. Fig. 1 (b) shows the flux distribution at the initial rotor position with an excitation in Table I. The FEA results reveals that at any time, the flux lines always don't flow through the teeth surrounded by blue dashed line, Besides, considering all the coils are not wound in these teeth, therefore, these stator teeth are removed, and the resulting topology, 6/10 machine in Fig. 2 (a) is proposed. The slot area increases 29%. Therefore, under the condition of the constant copper loss, the allowable electrical loading becomes higher, so the torque density is improved. The main design parameters is listed in Table I. Fig. 2 (b) shows that the simulated load flux distribution of the 6/10 machine is always almost the same with that of the 12/10 machine. III. Performance Comparison The torque waveforms with the aforesaid current are in Fig. 3. The average torque of the 12/10 and 6/10 machine are 2.88 and 3.41 Nm, nearly 20% higher torque is achieved. Besides, by optimizing the stator/rotor tooth arc, tooth shape, and current shaping, the torque ripple can be further reduced. From the flux distribution, it can be inferred that the iron losses basically remain unchanged, and considering the constant copper loss, the efficiency of the motor will also be greatly improved. To verify the analysis results, a prototype of 6/10 machine is built. The picture of the stator and rotor is shown in Fig. 4. The experimental results will be given later. IV. Conclusion In this paper, a higher torque density, 6/10 vernier reluctance machine with DC-biased current is proposed. The analysis results show that the torque density is 20% higher than that of an existing 12/10 machine. Moreover, the efficiency is also improved.

HS-06. The Vibration Reduction Design and Experimental Validation of Generator for Range Extended Electric Vehicle.

B. Son[1], G. Park[1], H. Jung[2], Y. Kim[3] and S. Jung[1]
1. Sungkyunkwan Univ., Suwon-si, The Republic of Korea; 2. Korea Automotive Technology Institute, Cheonan, The Republic of Korea; 3. Chosun Univ., Gwangju, The Republic of Korea

I. Introduction Range Extended Electric Vehicle (REEV) is one of the hybrid systems for an electric vehicle, which adopts electric power-train including Auxiliary Power Unit (APU). The APU is commonly composed of an engine and electric generator, and assists to charge when the battery is exhausted. The REEV system has been widely employed to an electric vehicle since it guarantees extended driving range with relatively small battery pack and fuel combustion [1], [2]. Meanwhile, REEV system has a spatial constraint due to the additional mounting of APU. The generator, main component of APU, is required to have high power density due to the constraint. However, the design for high power density results in a reaction that increases electromagnetic force, which is the main cause of vibration. Furthermore, the structure of the system is vulnerable to vibration, since the generator is directly connected to the engine in the horizontal direction without additional fixation on the other side. Thus, design considering vibration is required to guarantee the control stability and the ride comfort. This paper demonstrates the vibration reduction design for APU generator based on vibration analysis applied to the electromagnetic force. For the conventional designed model, severe vibration occurred at operating points on every multiple of 1,500rpm. It disturbs stable control on the main operating point at 3,000rpm, which is matched for the optimal efficiency of the system. To complement the problem, diverse methods such as pole-slot combination and dimension modification is considered based on the analysis and applied to the revised model. Consequently, the effectiveness of the revised design is verified through manufacture and experiment. II. Electromagnetic Force & Vibration Analysis A. Electromagnetic Force Analysis Electromagnetic force on the stator core is one of the main vibration sources, which transfers in the radial direction. Thus, electromagnetic force analysis should be preceded. Electromagnetic radial force density can be calculated using Maxwell's stress tensor method based on Finite Element Method (FEM) as follow [3], [4]. $f_r(\theta,t) = 1/2\mu_0(B_r^2(\theta,t)-B_0^2(\theta,t))$ Where B_r and B_t are components of the air gap flux density, μ_0 is the permeability of air, θ is the angular position, and $_t$ is the time. The spatial and temporal distribution of electromagnetic force can be analyzed using Fast Fourier Transformation. B. Vibration Analysis Forced vibration analysis applying the calculated electromagnetic force is conducted based on FEM. The fundamental equations employed in the vibration analysis is as follow [4], [5]. $[m]\{x''\}+[c]\{x'\}+[k]\{x\}=\{F\}$ Where $[m]$, $[c]$ and $[k]$ are mass, damping and stiffness matrices, $\{x''\}$, $\{x'\}$ and $\{x'\}$ is nodal acceleration, velocity and displacement vectors and f is the external force, that is the electromagnetic force. For computational efficiency, mode superposition is employed to solve the above equation [4] and 3D modeling of housing is simplified by removing the minor part. III. Problem Analysis & Revised Design A. Problem Analysis of the Conventional Model For the conventional designed model, the control disturbance due to vibration occurs at operating points on every multiple of 1,500rpm, as shown in Fig.1. It should be rectified since the main operating point is on the 3,000rpm considering optimal efficiency matching of the APU system. The conventional model is designed for 8 poles and 36 slots, which is a fractional number of slots per pole. The THD of Back EMF is 0.5% and torque ripple is 4%, which is well-designed with regard to basic electromagnetic performance. However, the electromagnetic radial force has many harmonic components due to magnetic asymmetry in the same pole-pair. Moreover, the vibration is considerably generated at multiples of 1,500rpm, which is adjacent to the calculated natural frequency. B. Revised Design for Vibration Reduction To complement the above problem, the revised design is implemented based on vibration analysis applied to the electromagnetic force. First, the number of slots is modified from 36 to 48, to make magnetic field symmetric in the same pole-pair. As shown in Fig. 2(a), the multiples of 4^{th} harmonic components of electromagnetic force are reduced dramatically. Furthermore, the dimension of housing is modified to shorten in the axial direction. The dimension is settled to increase outer diameter contrary to the decrease of axial length to maintain the basic performance of generator. As the result, it is identified through vibration analysis that the revised model is more robust to vibration and natural frequency is distant from the main operating point. IV. Experimental Validation The revised model is manufactured and experimented. As shown in Fig. 2(b), torque profile of revised model is considerably improved and control is stabilized at 3,000rpm, compared with the conventional model.

HS-07. Comparative Study of Airgap Field Modulation in Flux Reversal and Vernier Permanent Magnet Machines.

H. Li[1], Y. Liu[1] and Z. Zhu[1]
1. Department of Electronic and Electrical Engineering, The University of Sheffield, Sheffield, United Kingdom

Abstract In this paper, the torque production mechanisms of both flux reversal permanent magnet (FRPM) machines and Vernier PM machines are analyzed based on airgap field modulation. The differences in their working harmonics of either PM magnetomotive force (MMF) or airgap permeance distribution are firstly identified, indicating that the fundamental PM MMF together with all permeance harmonics contribute to the torque production of Vernier machine whereas all PM MMF harmonics but only fundamental permeance in FRPM machine produce the torque. Thanks to the utilized large DC component of airgap permeance, the superior torque density of Vernier machine is revealed and verified by both analytical and finite element analyses (FEA). 1. Introduction With the recently developed theories of airgap field modulation (magnetic gearing effect) in electrical machines, the working principle of many existing machine topologies can be re-recognized now [1, 2]. Among various airgap field modulation-based machines, FRPM and Vernier machines are two typical topologies offering advantage of simple mechanical structure, thus attracting much attention for practical applications [3, 4]. As shown in Fig. 1, FRPM and Vernier machines have many similar features, such as single airgap, surface-mounted PM (SPM) structure and integrated modulation iron poles. For both machines, the PM MMF harmonics (resulted from SPM) interact with the permeance harmonics produced by modulation iron poles, thus producing abundant field harmonics in the airgap. The pole pair number of the fundamental PM field no longer equals to that of the armature field, which differs from the conventional PM machine and directly reflects the magnetic gearing effect [5, 6]. However, for FRPM machine, the PMs are mounted on the inner surface of stator teeth and the rotor consists of several iron poles, producing static PM MMF and rotating permeance harmonics; for Vernier machine, the rotor is of conventional SPM structure and the modulation iron poles are located on the stator, resulting in static permeance and rotating PM MMF harmonics. Up to now, the differences of airgap field modulation and corresponding performance comparison between two machines have never been addressed, and will be the main focus of this paper. 2. Influence of PM Thickness on Average Torque Considering the two machines from the perspective of generator, to induce the back-EMF with constant frequency, only those PM field harmonics of the same variation frequency with the fundamental electrical frequency of the rotating element can be utilized. Therefore, for FRPM machine, all PM MMF harmonics but only fundamental permeance are effective components; for Vernier machine, all permeance harmonics but only fundamental PM MMF are effective components. As the magnitude of permeance harmonics rapidly decreases with harmonic order, e.g. the DC component of the permeance has much higher magnitude than that of the fundamental permeance, the airgap field modulation is much stronger in Vernier machine, which is helpful to improve the torque density. To illustrate the difference of airgap field modulation between two machines, one FRPM machine with 12 stator slots and 10 rotor poles, one Vernier machine with 6 stator slots, 12 modulation iron poles and 20 PM poles are globally optimized under the same stator outer diameter (90mm), stack length (25mm) and copper loss (20W). Fig. 2 shows the influence of PM thickness on average torque of two machines. As can be seen, unlike conventional PM machines, there is an optimal PM thickness for each machine. Although the magnitudes of PM MMF harmonics increase with PM thickness, the PM thickness cannot be too large otherwise it enlarges the equivalent airgap length and impairs the field modulation. More importantly, the optimal PM thickness of the Vernier machine is 2.4mm, which is twice of the FRPM machine. This phenomenon can be explained by the different influence of PM thickness on magnitudes of permeance harmonics. In comparison with DC component, the PM thickness has larger influence on the magnitude of fundamental permeance. Therefore, the PM thickness of Vernier machine is larger than the FRPM machine, resulting in higher PM MMF magnitudes and torque density (101% higher in this case). 3. Conclusion In this paper, FRPM machine and Vernier machine are analyzed and compared based on the unified theory of airgap field modulation. It is found that Vernier machine is more likely to have higher torque density than FRPM machine, thanks to the utilized DC component of airgap permeance. In full paper, the detailed analysis of airgap field modulation, and performance comparison between two machines will be given. In addition, two prototypes are being manufactured, of which the test results will be provided.

I. Introduction Permanent magnet vernier machines (PMVMs) have some distinct advantages of high torque density and low torque ripple at low speed [1]. Due to these advantages, they have been extensively researched and proposed for wind power generation [2] and wave energy conversion [3]. To increase the torque density of a PMVM, a novel dual stator vernier topology was presented recently [4], which possessed higher torque density and higher efficiency compared to a conventional vernier machine. However, PMVM generally have high permanent magnet (PM) pole pairs, which increases the cost of the machine. For simplicity, the recently presented machine will be termed as existing machine in this paper. In this paper, in order to further increase the torque density and decrease the cost of the existing machine, a dual stator consequent pole vernier machine has been proposed. The results show that the proposed machine provides a higher torque density compared to the existing machine. Moreover, the cost of the machine is also low since magnet volume has been decreased. II. Topology and working principle The configuration of existing machine is shown in Fig. 1. In the existing machine, there are two stators and a sandwiched rotor. The outer stator has 12 slots and 3 phase 1 pole pair armature winding. The sandwiched rotor has consequent pole PMs arranged in Halbach array form, which has 13 pole pairs. The inner stator has only 12 pole pairs of surface type PMs. The existing machine is the combination of two machines (I & II) as shown in Fig. 2(a) & (b), respectively. Machine I works as a single stator PM machine, whereas machine II works as a double stator vernier machine, which has been discussed in detail in [4]. The configuration of proposed machine is shown in Fig. 3. There are two stators and a sandwiched rotor similar to existing machine. However, in the inner stator instead of surface type PMs, consequent pole PMs have been used, which reduces the magnet volume of the proposed machine. Moreover, the sandwiched rotor does not have Halbach arrays, contrary to existing machine; which otherwise causes flux leakage in the proposed topology. The proposed machine can also be regarded as the combination of two machines, here called as machine I and machine II. The outer stator, sandwiched rotor and inner stator iron teeth is termed as machine I as shown in Fig. 4(a). Whereas the outer stator, iron teeth in the rotor and complete inner stator is termed as machine II as shown in Fig. 4(b). Contrary to existing machine, in the proposed machine, machine I and machine II are both dual stator vernier machines, which increases the torque density of the machine compared to existing machine. The comparison of outer airgap flux density harmonics is shown in Fig. 5(a). In machine I, the rotor PM magneto motive force (MMF) is modulated by the inner stator teeth. The flux goes from rotor to inner airgap, to inner stator, then to outer airgap and finally induces back electromotive force (EMF) in the outer stator winding and hence the effective airgap length is large. Therefore, the flux modulation effect is weak. However, in machine II, the PM MMF from the inner stator is modulated by the rotor teeth. The flux moves from inner stator to rotor, to outer airgap and finally induces back EMF in the outer stator winding. The effective airgap length is comparatively shorter and flux modulation effect can be regarded as comparatively strong. Therefore, in both machine I and machine II in the proposed machine, flux is modulated to produce a component equal to winding pole pairs in the outer airgap; hence, the machine works as a combination of two vernier machines. III. Performance comparison To verify the superiority of the proposed machine, finite element method (FEM) simulations have been performed to compare both the existing machine and proposed machine. The comparison of torque of both the machines is shown in Fig. 5 (b). It can be seen that the proposed machine produces 44% higher torque compared to existing machine. However, the torque ripple of the proposed machine is a little higher compared to existing machine. The overall performances of both the machines have been compared in Table I. In full paper, the machines will be optimized for reduced torque ripple.

HS-09. A Generalized Method of Electromagnetic Vibration Analysis of Amorphous Alloy Permanent Magnet Synchronous Machines.

S. Wu[1], W. Tong[1], R. Sun[1] and R. Tang[1]
1. Shenyang University of Technology, Shenyang, China

The researches on electromagnetic vibration of electrical machines have been focusing on the vibration caused by radial forces (RFs) as the major cause of electromagnetic vibration[1]. According to the other researches, magnetostriction (MS) is a property of magnetic metal in which the material will exhibit strain in the presence of magnetic field and is recognized as another cause of electromagnetic vibration next to RFs for electric machines[2]. For amorphous alloy materials (AAMs), the MS coefficient is much larger than for the conventional silicon steel (SS) sheet. MS coefficient of conventional SS is 9.2×10^{-6}, and MS coefficient of amorphous alloy (AA) is 26×10^{-6}. Hence, the vibration caused by MS effects in AA electric machines is much larger than conventional SS electric machines. Additionally, amorphous alloy cores (AACs) are manufactured as stacks or winding of AA stripes. The magnetic characteristics of AA are greatly effected by stress, so lamination factor of AACs which are applied to electrical machines is lower than SS cores. Laminated stacks are clamped together, and the forces determined by the clamped state of laminated stacks itself are defined as lamination compression forces (LCFs). Hence, the vibration of AA electric machines caused by LCFs cannot be ignored. This paper presents a new numerical and experimental method of the analysis of electromagnetic vibration of AA PMSMs whose stator cores are made from AAMs. This method can be used to calculate the electromagnetic vibration of AA PMSMs caused by RFs, MS effects and LCFs. Steps of the procedure for the numerical analysis are presented in Fig.1. LCFs are not the driving forces of electromagnetic vibration of AA PMSMs. The vibration caused by LCFs is interpreted in two aspects. On the one hand, LCFs affect the magnetization characteristic of AACs. On the other hand, LCFs affect the elasticity modulus parameters of AACs. The vibration caused by LCFs is simulated by adopting experimental magnetization curves and modified elasticity modulus parameters of AACs. The vibration caused by MS effects is simulated by adopting the experimental MS curve and experimental magnetization curve of AACs. The MS curve of the AAMs were tested by the measurement device. The MS as a function of magnetic flux density for the AAM 2605SA1 is obtained. The magnetization characteristics of the AACs were tested, and the *B-H* curve for AACs is obtained. Experimental modal analysis of AACs is based on hammer impact method. The frequency response functions (FRFs) for the AACs are obtained. The peak in FRFs indicate the natural frequencies. The elasticity modulus parameters are modified by utilizing experimental modal analysis of AACs. Electromagnetic vibration of a 2.1kW radial flux AA PMSM is analyzed using the proposed method. The electromagnetic vibration of the AA PMSM under four different conditions which are (a) only RFs, (b) only MS effects, (c) both RFs and MS effects, (d) RFs, MS effects and LCFs are calculated respectively. The stator core and housing deformations of the AA PMSM are shown in Fig.2. The effects of MS and LCFs on electromagnetic vibration of the AA PMSM are obtained. Finally, the accuracy of the proposed approach is verified by comparing the calculations with experimental results.

HS-10. A Double Stator Flux Reversal PM Machine with Halbach Consequent Pole in Slot Opening.

H. Huang[1], D. Li[1], R. Qu[1] and K. Xie[1]
1. Huazhong University of Science & Technology, Wuhan, China

I. INTRODUCTION As one kind of stator-PM machines, flux reversal machine (FRM) has attached lots of attentions for its robust structure and cost effectively [1]. In regular FRMs, the permanent magnets were normally mounted on the stator teeth, which adds a large magnetic resistance to the magnetic circuit of coil winding. It causes reduction of the fundamental airgap permeance, weakening the working flux density and back-EMF, and restricting the electromotive force ultimately [2]. To increase the torque density of FRM, double stators were employed to utilize the inner space of machines [3-4]. However, this structure introduces additional air-gap and more flux leakage to the magnetic circuit, therefore influencing the utilization of magnets. To reduce the flux leakage between N and S pole and improve the utilization of PM, consequent-pole PM was employed in FRM [5]. Instead of placing the PMs on the stator teeth, a novel FRM with Halbach consequent-pole magnets embedded in the slot opening is proposed in [6]. By moving the surface-mounted PM into the slot opening, the resistance of PMs no longer influences the permeance of coil windings, therefore the back-EMF of machine can be markedly increased. Moreover, the slot area is increased and the flux leakage is limited, hence improving the torque density and power factor. To further increase the torque density of FRM, a novel Halbach consequent pole double-stator flux reversal machine (HCP-DS FRM) is proposed in this digest. In proposed machine, a pole-piece rotor was placed between two identical stators with Halbach consequent-pole magnets in the stator opening. The performance of proposed machine with two configurations was then compared. At last, torque density, power factor and other properties of proposed HCP-DS FRM were compared with a regular 12/17 FRM shown in Fig. 1. II. MACHINE TOPOLOGIES AND OPERATION PRINCIPLES The model of proposed machine is showed in Fig. 2. The so-called Halbach consequent pole includes three magnets with different magnetizing directions. Two tangential magnets were placed besides the main radial magnets in order to guide the flux. The inner and outer stator have the same slot-pole combination and structure. As mentioned in [6], the pole-pairs of rotor Pr equals slot number Zs adds or subtracts the winding pole-pairs Ps, which is 17 in Fig. 2 since 12/10 FSCW were applied in stators. Flux line contour and equivalent circuit model are shown in Fig. 3. As shown in the contour, with the assistance of tangential magnets, all the radial magnets can produce main flux to the stator teeth. Since identical windings are placed in two stators, magnetic circuits surrounding any of slots can produce a fundamental back EMF, therefore the leakage flux is limited. As shown in circuit model, the main magnetic circuit for each stator coil is driven by MMF of PMs on both stators, which improves the utilization of magnets. In conclusion, the magnetic structure of proposed machine creates an effective and synergetic condition to produce a better electromotive performance. III. DIFFERENT CONFIGURATION OF THE STATORS According to the polarity of the main radial PMs, the proposed double stator machine has two configurations N-N and N-S, see Fig. 2 (a) and (b). In N-N configuration, the teeth on two stators face each other, and the two windings have the same initial phase angle. In N-S configuration, the teeth on one stator face the slots of another, and the initial phase angle of two windings differ 75 electric degree. This is because the inner stator differs 15 mechanical degree with outer stator. The line back-EMF and static torque of these two configurations with same parameters are shown in Fig. 4 and Fig. 5. The result shows that N-N configuration with consistent polarity has a better electromagnetic performance, which is probably due to a shorter flux path and higher flux density on the air gaps, as shown in Fig. 6. IV. PERFORMANCE COMPARISON WITH REGULAR FRPM MACHINES The crucial advantage of the proposed FRM is the high torque density owing to an adequate use of the inner area of regular FRPM machines. Moreover, the structure of Halbach consequent-pole provides an optimal magnetic circuit to improve the utilization of magnets. Two FEA models were built to validate the superiority of proposed machine, the parameters and performances of two models are shown in Table I. With similar PM volume and copper loss, the proposed machine reach a 121% higher torque density. Since the radial force is offset between inner and outer stator, the torque ripple of the proposed machine decrease from 11.3% to 3.8%. Moreover, compared to 0.68 in the regular FRPM, the power factor of proposed FRPM machine is 0.85. This improvement derives from the Halbach consequent pole structure which reduces the flux leakage. V. CONCLUSIONS A novel Halbach consequent-pole double-stator FRM was proposed in this digest. By inserting additional stator inside the regular FRPM, the space of the machine is well utilized. The Halbach magnets were embedded into the slot opening, which improves the utilization of PMs and the back-EMF. Two configurations of proposed machine were modeled and compared. The result shows that the N-N configuration has better performance due to a higher flux density. At last, the performances of HCP-DS FRPM machine were compared with a regular flux reversal machine under identical parameters. The proposed machine outstands for 121% higher torque density, 66% lower torque ripple, and 25% higher power factor than regular FRM.

2. Shandong Jiemeng Energy Conservation and Environmental Protection Technology Co., Ltd, Ji'nan, China

I. Introduction Permanent magnet coupler (PMC) acts as a magnetic transmission device, the motivation and torque are transmitted through the interaction between the conductor rotor (CR) and permanent magnet rotor (PMR), the mechanical contact between the motor and load is eliminated. And for the effective suppression of the vibration, high reliability and efficient operation, it has been applied in electric power, petrochemical industry, pumps, blowers, water treatment and other fields [1]-[3]. Many structures of the PMCs had been designed, considering the rotational couplers, configurations as radial and axial magnetic flux represent two possible solutions [4]. For the typical axial flux coupler (i.e., disk type) and radial flux coupler (i.e., cylindrical type), the produced torque was controlled by adjusting the length of air gap or the coupling area between the CR and PMR [5]. However, the magnetic field utilization is lower for disk type, and additional mechanical devices are also needed to adjust the axial relative position between the CR and PMR for both types, the reliability is reduced and the space volume is increased. In [6], a flux adjustable PMC with a movable stator ring, whose slip speed can be adjusted by shifting the movable stator ring along the axial direction, was proposed, and the complicated mechanical devices can be avoided. In this paper, a novel flux adjustable PMC with a double-layer PMR is presented. The magnetic flux is adjusted by circumferentially controlling the relative position of the PMR's two layers, the axial movement is replaced. II. The Structure and Principle The structure of the proposed coupler is shown in Fig.1 (a). The PMR is divided into the inner and outer parts, and the PMs in both parts are respectively staggered arrangement by N- and S- pole which are tangentially magnetized. In addition, the inner part can be controlled to circumferentially rotate to adjust the relative position with the outer part, so the excitation magnetic field is controllable. And then the eddy current intensity, torque and the speed can also get adjustable. III. Magnetic Field and Torque Analysis To analyze the field and torque of each different relative position, the change period of the relative position, from N-N to N-S, is divided into seven steps. The magnetic field distribution and air-gap flux density B_r is shown in Fig.1(b). When the relative position is N-N state (position 1), most flux lines will pass through the air-gap to the copper layer besides few linkage flux and the B_r at this state is also the biggest. As the inner part of the PMR is controlled to the position 4, besides passing through the copper layer, parts of the flux lines link between the inner and outer parts' N- and S- pole. The linkage flux is increased, and the effective flux is decreased. While when the relative position is adjusted to N-S (position 7), almost all the flux lines form loops from N- to S-pole, no longer reaching the copper layer, the air-gap flux density also gets smallest. With the relative movement between CR and PMR, the eddy current is nearly not produced, neither is the torque. In addition, based on the analytical method [7]-[9], the electromagnetic characteristics of the coupling and the calculation of eddy current are also researched, and the results are verified by 2D FEM. IV. The Influences of the Structural Parameters As the torque is transmitted through the interaction of magnetic field, and the air gap magnetic field is mainly superimposed by PM magnetic field and eddy current magnetic field. So the structural parameters, including the thickness and material of the CR which impact the eddy current intensity, and the material and pole numbers of PMs in PMR which impact the excitation field, are analyzed and shown in Fig.2 respectively. The comparison of different thickness of copper layer shows that the maximum torque gets larger as the decrease of the copper thickness because of the deeper penetration of the magnetic field, and the speed corresponding to the maximum torque also gets larger. The comparison of different conductor materials among copper, aluminum, and brass whose conductivities are 0.58×10^8 S/m, 0.38×10^8 S/m, and 0.145×10^8 S/m respectively shows that the speed for obtaining the maximum torque becomes larger as the decrease of the conductivity. When the PM material is changed from N35UH (the residual magnetism is 1.19 T, and the coercive force H_c is 887.5 kA/m) to N40UH (the residual magnetism is 1.275 T, and H_c is 907.5 kA/m), the torques increase by nearly 10%. The torque also increases as the pole numbers increase from 20 to 46, and more again, the torque drops due to the increase of the linkage flux and the decrease of the effective magnetic potential. V. Conclusion This paper has presented a novel flux adjustable PMC with a double-layer PMR. The magnetic field and torque are analyzed by 2D finite element method (FEM), and the analytical method is also used to calculate electromagnetic characteristics and eddy current field. And the influences of the structural parameters are researched based on *T-s* curve, which can provide a reference for structural optimization design of this kind of PMC.

HT-01. Peaked linewidth broadening of ferromagnetic resonance induced by Dzyaloshinskii-Moriya interaction.

J. Oh[1], I. Hong[1] and K. Lee[1]
1. Material Science Department, Korea University, Seoul, The Republic of Korea

Magnetic damping that is parameterized by the Gilbert constant describes the energy dissipation rate of magnetization dynamics and determines the performance of magnetic devices including magnetic random access memories and magnetic sensors. The ferromagnetic resonance (FMR) experiment provides a way to measure the damping constant via the FMR linewidth and is also used to characterize magnetic properties of materials [1]. However, this method is not always straightforward as the measured linewidth includes not only intrinsic damping contribution but also extrinsic contributions originating from inhomogeneity of the sample. Especially, the contribution of two magnon scattering to the linewidth also depends on the frequency, demanding a detailed investigation of the frequency-dependent linewidth of two-magnon scattering origin [2]. Recently there have been much interested in a thin ferromagnetic layer with the Dzyaloshinskii-Moriya interaction (DMI) [3]. Because the DMI energetically favors an orthogonal configuration of two neighboring spins with a fixed rotating sense, the magnon dispersion and its scattering property may be varied significantly to show unique behavior in the FMR linewidth. In this respect, it is important to check whether or not the DMI inhomogeneity contributes to the extrinsic broadening of FMR linewidth through two magnon scattering process [4]. For this, we investigated magnon dispersion and the FMR linewidth of a thin ferromagnetic layer in a quantum mechanical way, taking into account scatterings caused by structural inhomogeneity. From equation of motion for magnetization we first calculate susceptibility of the system as function of magnetic field, and then average the susceptibility over an ensemble of impurities or inhomogeneity. By extracting broadening width of the longitudinal susceptibility as a function of FMR frequency, we provide an analytic expression for the FMR linewidth in terms of system parameters such as the saturation magnetization, exchange stiffness, surface anisotropy, and DMI strength D. Detailed forms of the extrinsic FMR linewidth are derived to consists of the part from the inhomogeneity potential and the part determined purely by the magnon dispersion. The magnitude of the FMR line width is mainly determined by the former while the frequency and magnetic-field dependent behavior is found to be responsible for the latter. In Fig. 1, we show the extrinsic linewidth broadening as a function of resonant frequency for various DMI strengths. Overall amplitudes of the linewidth become larger with an increased DMI strength, whereas, for a given DMI strength, the DMI-limited scattering potential exhibits characteristic behavior of the linewidth as a function of frequency. Namely, with varying the resonance frequency from zero, the linewidth changes slightly in a high frequency range while bumps or peaks are developed in a low frequency range. Furthermore, in a strong DMI case, for example, D = 2.3 mJ/m^2 in the figure, one can see that the linewidth is finite even at zero frequency. The peaks in Fig. 1 are found to originate from complicated behavior of the magnon energy dispersion. At the points where the peaks are developed, very small group velocities of magnon are calculated and, in turn, this gives rise to abundant resonant states (as example, Fig. 2 shows the evolution of resonant states as a function of magnetic fields around the peak). The abundant resonant states provide much possibility into which two magnons are scattered and result in a significant increase of the FMR linewidth. On the other hand, the finite value of the FMR linewidth at a zero magnetic field is unique behavior of the DMI system. This may be not possible if a uniform ferromagnetic system such as free-DMI case is a ground state. However, in the case of strong DMI, a non-collinear spin state like spiral configuration has a lower energy than a ferromagnetic one. Consequently, in the presence of the strong DMI, there are still resonant states even at a zero magnetic field and thus a uniform spin texture excited by microwaves in FMR experiments is still scattered into resonant states mediated by inhomogeneity scattering. Fig. 1. The calculated linewidths for various DMI strengths D as a function of FMR frequency. The external magnetic field is applied with in-plane geometry. Fig. 2. In order to resolve the origin of the peak in Fig. 1, equi-energy lines are plotted in the case of D = 1.5 mJ/m^2 around the external magnetic field (464.4 G) exhibiting the peak. We increase the magnetic field by 2.0 G.

1. Physics, Mahasarakham University, Mahasarakham, Thailand; 2. Physics, Mahasarakham University, Mahasarakham, Thailand; 3. Physics, University of York, York, United Kingdom

The GMR and TMR investigations lead to a significant improvement in the potential applications in data storage technology such as reader in hard disk drives and spintronic devices. The spin torque phenomenon provides a new concept for the development of advance MRAM, nonvolatile logics and readers in hard disk drives. It has opened up the possibility to achieve a smaller reader subsequently leading to increasing in the areal density in the hard disk drives. Therefore, it becomes important to understand physics behind the operation of readers which enables us to design them appropriately. In addition, it has been reported that the read back signal is temperature dependent and degraded from low to high temperature [1, 2]. The computational model of read sensors is generally based on micromagnetic approaches. Although successful, micromagnetics is limited in a number of ways which makes the formalism inappropriate for the investigation of a number of factors which will become increasingly important with further scaling of device dimensions. This work proposes the model of read sensor at atomistic level taking the effect of thermal fluctuation into account to study the spin transport behavior. In order to investigate the spin transport behavior in the reader stack, the atomistic model coupled with the spin accumulation model is employed. The former is used to model the stack of reader and to observe the dynamics of magnetization whereas the latter is proposed to calculate the spin accumulation representing spatial magnetoresistance (MR). The inclusion of temperature affecting spin transport properties of magnetic materials is represented in the spin accumulation model through the spin-dependent resistivity [3] given by, $\rho_{\uparrow,\downarrow} = \rho_{\uparrow,\downarrow(0)} + A_{\uparrow,\downarrow}T^2$ (1) where $\rho_\uparrow$ and $\rho_\downarrow$ are the resistivities of up and down spins respectively, $A_{\uparrow,\downarrow}$ is empirical coefficient obtained from experiment, and T is measured temperature. The spin polarization parameters of conductivity (β) and diffusion (β') which can be expressed in term of spin-dependent resistivity. We consider the trilayer system of Co/Cu/Co which is divided into many thin layers. To investigate temperature dependence of the spin transport behavior, the spin transport parameters at any finite temperature required for spin accumulation calculation is first considered through the spin-dependent resistivity in eq. (1) as illustrated in Fig. 1. It is found that the spin transport parameters such as spin polarization parameters, spin diffusion length and diffusion constant are likely to decrease with increasing temperature due to the effect of thermal fluctuation and we could observe zero spin polarisation of material at critical temperature where ferromagnet becomes paramagnet. These spin transport parameters are then used in the generalized spin accumulation model based on modified Zhang-Levy-Fert approach [4] to consider spatial resistance-area product (RA) as a function of temperature which can be calculated directly from the gradient of spin accumulation (Δm) and the coming spin current (j_m) given by, $RA_i = |\Delta m|\, a^2\, t_F k_B T / |j_m|\, e^2$ (2) where a is the lattice constant of material, t_F is the thickness of thin layer, k_BT is 10 meV and e is the electron charge. The total MR of the structure can be evaluated by summing all spatial resistances, $MR = \sum RA_i$. The resistance-area product of parallel (R_P) and anti-parallel (R_{AP}) states are then determined by injecting spin current at the density of 5×10^{11} A/m^2 into the structure. This eventually leads to the calculation of MR ratio. We found that the spin accumulation at the interface region is rapidly changed due to the difference of spin transport properties at the interface. The RA of the AP state is higher than P state due to a stronger spin-dependent scattering. At high temperature, the resistance is increased due to the enhancement of strong spin scattering with low mobility of electron which leads to decreasing in MR ratio as shown in Fig. (2). Our results show an excellent agreement with experimental measurements [5-8]. The proposed model gives rise to the possibility to develop the readers in next generation with both CPP-GMR and CPP-TMR systems. Also this model will allows us to deeply understand the mechanism in the readers which is significantly beneficial in reader design.

With the shrinking of complementary metal oxide semiconductor (CMOS) technology size, the considerable power consumption on logic and memory circuit system has been becoming an unavoidable bottleneck [1]. Spin transfer torque magnetoresistive memories (STT-MRAMs) are prime candidates for non-volatile memory applications. As the basic storage unit of STT-MRAM, magnetic tunnel junction (MTJ) has been extensively studied [2-4]. For instance, double-barrier MTJ (DMTJ), taking advantages of the enhancement of STT effect, significantly reduces the critical switching current (I_{C0}) and switching duration (τ) [5]. MTJ with two CoFeB free layers (FLs) coupled by Ta layer can effectively improves the thermal stability (ΔE) [6]. In this paper, we proposed an electrical modeling of DMTJ with CoFeB/Ta/CoFeB FLs (see Fig. 1 (a)). Compared with conventional MTJ, the propose DMTJ has superiorities in I_{C0}, τ, and ΔE. It can replace MTJ to reduce the device size, improve the reliability of memory and lower the writing energy consumption. Furthermore, this model integrates the stochastic STT switching behavior, the temperature influence and the variation of the layers' thicknesses, which can deeply affect the reliability of hybrid CMOS/MTJ circuits. Fig. 1 (b) shows the principle block diagram of the integrated physical models. In the following, we explain some key blocks modeled in the Verilog-A code. For DMTJ, STTs generated by both the transmitted and reflected spin polarized electrons add together. This enhancement strongly decreases the I_{C0} and τ, which can be expressed as $I_{C0}=2\alpha\gamma e\times(K_{EFF}\times Volume)/\mu_B g_{DMTJ}$ (1) $\tau=[C+\ln(\pi^2\Delta E/4)]\times(em/4\mu_B g_{DMTJ})\times(I_{write}-I_{C0})^{-1}$ (2) where α is Gilbert damping factor. γ is gyromagnetic ratio. e is elementary charge. K_{EFF} is the effective PMA energy density. Volume is the total volume of the dual FLs. μ_B is Bohr magneton's constant. $C\approx0.577$ is the Euler's constant. M_S is the FL's saturation magnetization. $m=M_S\times Volume$ is the total magnetic moment of FL. g_{DMTJ} represents the spin polarization efficiency factor, which is enhanced in comparison with conventional MTJ, this phenomenon can be described by $g_{MTJ}(\theta)=P/2(1+P^{2}\cos\theta)$ (3) $g_{DMTJ}=g_{MTJ}(\theta)+g_{MTJ}(\pi-\theta)=P/(1-P^4\cos^2\theta)$ (4) where $g_{MTJ}(\theta)$ and $g_{MTJ}(\pi-\theta)$ represent the transmitted and reflected spin polarized efficiency factor of MTJ, respectively. P is the spin polarization percentage of the tunnel current, θ is the initial angle between the magnetization orientation FL's and the top reference layer's. However, the stochastic STT switching, which results from thermal fluctuations of magnetization, leads to the large fluctuations in the switching durations. We discover the real switching time comply with a gamma distribution $\Gamma(k,\theta)$. The shape and scale parameters, respectively, k and θ, are linked to the mean and standard deviation through the relations $E[\tau]=\theta k$ and std $[\tau]=\theta k^{-1/2}$. Besides, the temperature influence should not be ignored. Since the tunnel magnetoresistance (TMR) ratio, M_S, and K_{EFF} will decrease with the increasing of temperature [7], the magnetoresistance and I_{C0} can be influenced. In addition, as the limit of the manufacturing technology, the real value of the MgO-barrier layers and FLs' thicsknesses are not the constants as we expected. They always vary in a somewhat small range, but can lead to relatively significant variations for the resistance and I_{C0}. For instance, the resistance is exponentially related to the thickness of two oxidized barrier layers, small thickness variation can lead to relatively significant impacts on resistance. In this paper we used the normal random statistical functions provided by Verilog-A to generate the true values of these thicknesses. The developed Verilog-A compact model is adopted to investigate the writing performance, temperature influence, resistance distributions and STT stochastic switching behavior. Fig.2 (a) illustrates the comparison of STT switching time of DMTJ with MTJ. DMTJ is proved to switch at a considerable speed with a much lower writing current. Fig. 2 (b) shows the DC simulations of 20nm-DMTJ at low, room and high temperature, respectively. Fig. 2(c) describes the distribution of 10k DMTJ's resistances. Monte Carlo simulations of two completed writing operations of 10 DMTJs are shown in Fig. 2 (d). The amplitude differences of different signals are caused by layers' thicknesses variations, whereas the switching time fluctuations of the same DMTJ during two writing operations describe the stochastic STT switching behaviors. These results prove that our proposed model can be a very useful tool for the performance optimizations and reliability analyses of hybrid CMOS/DMTJ circuits.

HT-04. Role of Defect on Stabilizing Skyrmion in Magnetic Nanostructure.

A. Talapatra[1] and *J. Mohanty*[1]
1. Physics, Indian Institute of Technology, Hyderabad, Hyderabad, India

Introduction: The Dzyaloshinskii-Moriya interaction (DMI) is a microscopic characteristic of interacting spins that occurs in a system, lacking inversion symmetry with a strong spin-orbit coupling. The whirling types of magnetization in a chiral magnet are introduced by the DMI. Magnetic skyrmions are topologically protected physically stable spin configuration, appearing due to DMI. Skyrmions are particle-like magnetic configurations, dimension of which can be scaled down to few nm and are easily moved with spin polarized current. Thus skyrmion has its technological importance to pave the way towards ultra-high density magnetic data storage devices. Magnetic skyrmion lattices were first discovered in bulk non-centrosymmetric systems. In magnetic thin films, the most heavily studied mechanism to stabilize skyrmion is through DMI, originating from the asymmetric heavy metal interface [1]. The pioneering work of Sampaio *et al.* describes stabilization and current induced motion of isolated skyrmion in magnetic nanostructure with perpendicular magnetic anisotropy (PMA) [2]. Iwasaki *et al.* explained current induced motion of skyrmion in constricted geometry with micromagnetic simulation [3]. The recent experimental reports prove the presence of skyrmion in rare-earth transition-metal alloys [4] and their multilayer [5]. Here we are going to explain the stabilization of skyrmion in magnetic nanostructure in presence of magnetic defects. The formation of defect is an unavoidable issue during the process of nano-structuring and hence it plays a very important role to decide the magnetic properties of the system [6]. We will emphasis on the effect of dimension and magnetic anisotropy of defect inside the patterned structure. Moreover, the importance of the initial state and external magnetic field has also been explained for the transformation of isolated skyrmion to skyrmion lattice. Results and Discussions: We performed micromagnetic simulations on the formation of skyrmion using OOMMF code including DMI [7], expressed as: $H_{DM} = - D_{12} (S_1 \times S_2)$ (1) where D_{12} is the DM vector and S_1 and S_2 are atomic spins. The input parameters of the simulations include, exchange stiffness constant (A) = 16 pJ/m, effective anisotropy constant (K_{eff}) = 0.51 MJ/m3, saturation magnetization (M_s) = 1100 kA/m and the damping constant (α) = 0.3. The values describes an ultrathin (0.6 nm) Co film on Pt having a strong perpendicular magnetic anisotropy. The simulations have been performed for 0 Kelvin temperature. With the increasing DM parameter D (in mJ/m^2), transition from single domain state (D =2) to multi domain state (D = 6) via skyrmion configuration (D = 3 to 5) can be observed [2]. The decrease in the energy of the ferromagnetic (FM) state occurs with D due to the lowering of DMI energy by an inward tilt of the spins at the edges. For larger D values, the increasing number of twisted spin pairs is responsible for lowering the total energy and hence diameter of skyrmion (S) increases up to the dimensions, limited by the dimension of the nano dot (d_{dot}). Again, smaller skyrmion can be obtained by decreasing d_{dot} without changing the D value. K_{eff} is another important parameter to control S which can be reduced with increasing K_{eff}. Thus, the interplay between D, d_{dot} and K_{eff} essentially decides the formation of skyrmion and the value of S [2]. The situation becomes further complex in presence of magnetic defect, creation of which is an artefact of nano-structuring methods *viz.,* focused ion-beam or electron beam lithography. Fig. 1 (a) and (c) display the variation of S with the change in defect anisotropy (K_{def}) and defect diameter (d_{def}) respectively, where we assume that the defect is situated exactly at the middle of the nano dot. From Fig. 1(b), it is very clear that S increases almost two times (for d_{dot} = 100 nm) when K_{def} increases from 10% to 90% of K_{eff}, whereas the value of S is limited when d_{dot} = 80 nm. The role of d_{def} can be observed from Fig. 1(d). There exists a threshold d_{def} above which S decreases drastically and this effect is very prominent for larger d_{dot}. These simulations shows the stabilization of skyrmion in presence of magnetic defect from initial skyrmion-like configuration, as discussed in [2]. To study the effect of the initial magnetization, now we have considered nano-dot with same parameters (without defect) with initial random state having uniform vertical magnetization (+ Z direction). The ground state magnetization profiles (0 mT) in Fig. 2 display the presence of skyrmion in ferromagnetic matrix, irrespective of the value of d_{dot}. The stabilization of isolated skyrmion or interacting skyrmion lattice is very important from technological aspect and hence the application of Zeeman field is necessary. Isolated skyrmion can be observed for d_{dot} 80 and 100 nm with magnetic field of 84 and 156 mT respectively. With the increase in d_{dot} to 120 and 140 nm, skyrmion lattice can be observed with double and triple skyrmions respectively, stabilized with relatively higher values of magnetic field. The value of D has been fixed to 5 mJ/m^2 for the simulations displayed in Fig. 2. Thus we successfully explain here the transition from isolated skyrmion to a skyrmion lattice by varying d_{dot} and the magnetic field.

HT-05. Comparison of Computational Speed between Landau-Lifshitz-Gilbert and Hybrid-Monte-Carlo Micromagnetics.

J. Song[1], Z. Zhao[1] and D. Wei[1]
1. School of Materials Science and Engineering, Tsinghua University, Beijing, China

The Landau-Lifshitz-Gilbert (LLG) equation is widely utilized to analyze the magnetic properties in micromagnetics [1]. However, the calculation of micromagnetics with Landau-Lifshitz-Gilbert equations is time-consuming, so the FDM-FFT method was brought up to speed up the simulation in large scale [2]. Recently, we have developed a new micromagnetic method based on the Hybrid Monte Carlo (HMC) algorithm, which can calculate M-H loops and domains at finite temperature below Curie point [3]. Some simulation results have been put forward to confirm the validity of the HMC algorithm [4]-[6]. Furthermore, we also wish to focus on the computational efficiency to compare HMC micromagnetics with traditional LLG micromagnetics. Comparison of computational speed has been made of these two methods in various micromagnetic scales in this work. In LLG or HMC micromagnetics, a regular mesh with cell size $5\times5\times5nm^3$ is utilized. Other important parameters are: anisotropy energy constant $K(0K)=1\times10^5 J/m^3$, saturation magnetization at zero temperature $M_s(0K)=7.98\times10^5 A/m$, exchange constant $A^*=1.0\times10^{-11} J/m$. In LLG micromagnetics, the iterations can go endless unless the spin error $|\Delta|$ (the spin maximum deviation between two simulation steps) is set to be a limited number. To ensure the stability and accuracy, $|\Delta|$ is set as 10^{-6} in LLG algorithm. In HMC micromagnetics, the Monte Carlo time t is not real time. Based on the feature of the leap-frog algorithm used for iteration of the Hamilton equations, in HMC micromagnetics, the spin error $|\Delta|$ stands for the spin deviation of two adjacent trajectories. To compare the computational speed of the LLG and the HMC micromagnetic methods, the spin error $|\Delta|$ in HMC MuMag is also set as 10^{-6}. The M-H loops are same under these two micromagnetic algorithms. Fig. 1 shows the computational time to reach $|\Delta|\sim10^{-6}$ at each external magnetic field (H_{ext}), with 16*8*16 micromagnetic cells. The computational time for Hybrid Monte Carlo MuMag keeps around 59 seconds for different H_{ext}; while for Laudau-Lifshitz-Gilbert MuMag, the simulation time is typically several hundred of seconds and shows a sharp rising near coercivity to about 1904 seconds, which is different from HMC MuMag. In Fig. 2, the computational speed of the two micromagnetic methods is presented. The horizontal axis is $log_2(N_{cell})$, and the vertical axis is the total computation time for a loop in Fig.1 (in seconds). The blue line is the speed of the LLG MuMag. In the Ref. 7, the LLG algorithm has a running time proportional to the number of particles N, which yields $O(Nlog_2N)$ computational time. We have compared the computational time of LLG algorithm with $O(Nlog_2N)$. The triangle-dot line is the computation time vs. $log_2(N_{cell})$, which shows great agreement with $O(Nlog_2N)$ (black line in Fig.2). The red dotted line shows the computation time consumed by the HMC algorithm, which show great coincidence with $O(N)$ in the insert figure. From the comparison, the HMC algorithm has a significant advantage for the computational speed. When the number of micromagnetic cells rise to 32*32*32, LLG algorithm spends 16 times more than HMC algorithm.

The black line follows *$O(Nlog_2N)$*. The insert figure shows the computational time of HMC fit well with red line *$O(N)$*.

HT-06. Realistic micromagnetic model in exchange bias: The parametric study including thermal activation as setting process.

W. Daeng-am[1], P. Chureemart[1], L.J. Atkinson[2], R.W. Chantrell[2] and J. Chureemart[1]
1. Physics, Mahasarakham University, Kantharawichai, Thailand; 2. Physics, University of York, York, United Kingdom

Exchange bias is the interfacial effect arising from the exchange coupling between uncompensated antiferromagnetic (AF) and ferromagnetic (FM) spins after field-cooling process [1] which is crucial aspect of the read sensors in data storage devices [1-2]. In order to depth understand behind the complex effect due to thermal instability of AF layer [3], the advanced micromagnetic model is still required the thermal activation phenomena as setting process into the calculation. The consideration of setting process which is used to set the direction of AF stable grain before start measuring the hysteresis loop [2] is very significant in the exchange bias. In this work, we have proposed the advanced micromagnetic model by using the multi-scale calculations which allows to take the effects of the setting process and the distributions of the anisotropy easy axes in AF layer into account. In order to establish the realistic magnetic bilayers system between FM and AF layers to describe the pinning structure in read sensors due to exchange bias phenomenon, the Voronoi tessellation was employed to generate the specified microstructure. The microstructure of each single grain between FM and AF layers are treated as a columnar stack with the same diameter. Figure 1 shows the typical structure of bilayers system (top view) with periodic grain boundary at 100×100 nm^2 and the visualization of bilayers system with the easy axis distribution at the interface between FM/AF layer. The FM and AF layers will be modelled with the different approaches with integrating the stochastic-Landau-Lifshitz-Gilbert equation and kinetic Monte Carlo approach [4] respectively in order to describe the magnetic properties as soft magnetic and hard magnetic materials depending on the nature of the magnetization reversal process. In order to include the setting process in the calculation, the FM grain is assumed to equilibrate in the field direction for every time step of calculation and the direction of AF grain is also saturated in the field direction at the maximum applied field and the setting temperature (T_{SET}). Then, the AF grains will be cooled down to the experimental temperature to achieve the setting configuration of AF layer for the measurement of H_{EB}. Each kMC time-step is used at 10^{-8} s while time-step of FM is defined with the tiny amount of time at 10^{-13} s in order to investigate its magnetization dynamics. The calculation of FM layers needs to be iterated to equilibrium via LLG method after each kMC time-step stages. Therefore, the calculation of magnetization dynamics with two different timescale techniques can be achieved. The current magnetic material in the pinning read sensors as CoFe/IrMn is used to investigate the effects of physical structure such as thickness and grain size effect on exchange bias field (H_{EB}). The median grain diameter is fixed at 8 nm with a lognormal distribution of = 0.2 [5] and T_{SET} is 600 K [2]. The thickness of CoFe and IrMn layers is fixed at 4 nm and 8 nm respectively. The magnetic parameters bilayers used in this calculation are as follow: T_c = 1300 KM_s = 1800 emu/cc, and K_F = 1.8x10^5 erg/cc for CoFe and T_N = 690 K and K_{AF} = 3 x10^6 erg/cc for IrMn [5]. The exchange interlayer field strength representing the exchange coupling between layers is controlled at 250 Oe. The parametric study on exchange bias is presented in order to establish the intrinsic effect of the microstructure on the thermal stability. We firstly consider the effect of grain volume dependence with the different grain diameter from 4 to 12 nm on H_{EB} which is vital factor for thermal stability. The typical hysteresis loops are shown in fig. 2 a) and the exchange bias is unstable with no loop shift at small diameter (4 nm). The tendency of H_{EB} is also increased with increasing of AF grain volume which is consistent with the experimental work [6] because the large grain volume give rise to the large fraction of thermally stable AF state to pin FM spins. Subsequently, the thickness dependence effect on H_{EB} is also investigated with the system of CoFe(4nm)/IrMn(t) where t is varied from 2 to 12 nm at fixed grain diameter = 8 nm. Fig.2 b) shows the consistent results of the variation of H_{EB} between advanced model and experimental work [6]. It is clear that H_{EB} increases rapidly with the increasing of AF thickness reaching the maximum at 6 nm and then become stable for thicker film. The thin thickness (2 nm) of AF layer presents the thermal instability due to the superparamagnetic behavior. In conclusion, we proposed the advanced micromagnetic model integrate with the setting process to investigate the parametric study on CoFe/IrMn bilayer in magnetic read sensor. The results from advanced model give well agreement with the experimental works and conventional theory of H_{EB}.

HT-07. Micromagnetic Studies of Laser-induced Magnetization Dynamics in FePt-C Films.

J. Miao[1], J. Wang[2], R. Mandal[2], D. Wei[1], Y. Takahashi[2] and K. Hono[2]
1. School of Materials Science and Engineering, Tsinghua University, Beijing, China; 2. Research Center for Magnetic and Spintronic Materials, National Institute for Materials Science (NIMS), Tsukuba, Japan

Laser-induced magnetization switching has been studied extensively for its applications in heat-assisted magnetic recording (HAMR) and all-optical switching (AOS), since Beaurepaire *etal.* found that magnetizations can respond to the femtosecond time scale laser pulse [1]. With the help of heat and assistance of external field or helicity-dependent magneto-optical effect, magnetizations switch in an ultrafast regime of picoseconds [2]. Recently, micromagnetic simulations based on LLB equation have been used to study the magnetization dynamics and switching in FePt films [3, 4]. In this work, the hybrid Monte Carlo (HMC) micromagnetics developed by the authors [5, 6] will be utilized to analyze the laser-induced magnetization switching. In this work, we built a model of FePt-C granular film with Voronoi polycrystalline structure. Some magnetic and structural parameters are derived by experimental measurements [7]. The total simulated area is 32nm×32nm×8nm, divided into a regular mesh of 2.5nm×2.5nm×2nm micromagnetic cells and the number of crystalline grains is 48. At T = 0K, in crystalline grains, the saturation $M_s(0)$ is 1300 emu/cc, the exchange constant A^*_1 is 6.8×10^{-7} erg/cm and the anisotropy energy $K(0)$ is 4.5×10^{7}erg/cm^3; at disorder grain boundary, $M'_s(0)$ is $0.1M_s(0)$, A^*_2 is $0.2A^*_1$ and $K'(0)$is $0.1K(0)$ [7]. In simulation of laser-induced magnetization dynamics, the temperature profile of the laser shooting process is vitally important. In LLB micromagnetics, two-temperature model (2TM) is commonly used to get the profile of the electron temperature, which is then introduced in LLB equation via the spin coupling parameter λ. But some parameters in 2TM model are quite arbitrary. In HMC micromagnetics, we use the time-resolved magneto-optical kerr effect (TR-MOKE) to get the spin temperature profile directly. The time resolved kerr rotation, which is proportional to magnetization, is measured with an external magnetic field 2 T applied in the direction of initial magnetization to ensure that all magnetizations are saturated in one direction. The measurement and simulation results are shown in Fig. 1 and Fig. 2. The measured kerr rotation signal is shown in Fig.1(a). In Fig. 1(a), in the process of ~290fs laser shooting, the kerr rotation decreases rapidly and then recovers slowly, which results from the rapid demagnetization and slower recovery of magnetization. Additionally, with higher laser power, the kerr rotation decreases to a critical minimum point where the magnitude of magnetization gets closely to zero, so that we can get the scaling relationship between the kerr rotation signal and the magnetization. We assume a spin temperature profile in Fig.1(b), and the HMC micromagnetics is performed with $M_s(T)$ determined by the mean field Brillouin function based on the temperature profile $T(t)$ in Fig.1(b) [8]. The simulated averaged M(t) curves fit well with the measurements in Fig.1(a), which in turn convince the correct choice of the spin temperature profile in Fig.1(b). So that HMC micromagnetics can be further utilized to study the laser-induced magnetization dynamics with various external magnetic fields or circularly polarized light.

HT-08. Micromagnetic simulation for the effects of Fe nanowires distribution on the magnetic properties of the $Nd_2Fe_{14}B/\alpha$-Fe nanocomposite magnets.

W. Li[1], L. Zhao[1] and *Z. Liu*[1]
1. South China University of Technology, Guangzhou, China

At present, the development of the exchange coupled nanocomposite magnets faces several challenges. High magnetization is usually accompanied by low coercivity, which is a major barrier for achieving high-energy products in this type of magnets. Fe nanowires are reported to have high coercivity due to its strong shape anisotropy,. Hence, it may be an good approach to enhance the coercivity of $Nd_2Fe_{14}B/\alpha$-Fe nanocomposite magnets by introducing Fe nanowires as the soft phase. In the present work, the effects of Fe nanowire arrays on the magnetic properties of nanocomposite magnets are investigated by micromagnetic simulation. The simulation model is shown in Fig. 1. The nanowires arranged along the Z direction and the demagnetization curves of the Fe nanowires indicate the strong shape anisotropy. The nanowires have a length of 105 nm and a square cross section with the side length of S. The hard magnetic $Nd_2Fe_{14}B$ phase matrix is set as spherical without shape anisotropy. Fig. 1 The simulation model and the demagnetization curve of the Fe nanowires. The effects of different angles (θ= 0°, 30°, 45°, 60°, and 90°) between the long axis (Z axis) of nanowires and the easy axis of the hard phase on the magnetic properties are investigated firstly. The size of the nanowires are set as 150×9×9 nm. The simulated demagnetization curves are shown in Fig. 2. The coercivity increases with the increasing θ from 0° to 90°. When the nanowires are parallel to the easy axis of hard phase (θ=0°), the hysteresis loop is a standard square and the moments reverse uniformly in one stage. The demagnetization curve for θ=90° show a long slope. The moments reverse in two steps, parts of the moments rotate slowly followed by all the moments reversing uniformly in one stage. The distribution of magnetization in the first step shows that the moments of the soft phase rotate to the direction of the nanowire due to the shape anisotropy, as shown in Fig.2 inset, where red color means outward, blue means inward. Since the size of nanowire is smaller than the exchange length, the moments in the soft phase are strongly exchange coupled by hard phase. Since the fully reserved direction (-Z direction) of Fe nanowires is the hard magnetization direction and the moments are blocked, that's why the coercivity of θ=90° is much larger than that of θ=0°. Fig. 2 The demagnetization curves of the models with different θ and the magnetization distribution for θ=90° inset. In addition, the size effects of nanowires with S=9 nm, 18 nm, 27 nm, and 54 nm were also studied in the model of θ=0° and 90°. The simulation results show that the nucleation occurs at a low applied field and the coercivities decrease as increasing the nanowires diameters. For θ=90°, the coercivity is relatively stable with the increasing diameters of nanowires. The reason could be attributed to the fact that when the sizes is larger than the exchange length, the exchange coupling effect becomes insignificant and the dipolar coupling is dominant for θ=90°. As a conclusion, the coercivity of the nanocomposite $Nd_2Fe_{14}B/\alpha$-Fe can be increased by introducing the soft magnetic nanowire arrays with the long axis along the direction other than the easy axis of hard phase and the diameter smaller than the exchange length.

1. High Energy Accelerator Research Organization, Tsukuba, Japan; 2. Waseda University, Tokyo, Japan; 3. National Institute for Materials Science (NIMS), Tsukuba, Japan; 4. Hitachi, Ltd., Tokyo, Japan

The recent rapid progress of computer performance resulted in the enlargement of spatiotemporal scales in numerical simulation for the field of material science. In the field of magnetic materials, micromagnetics and multiscale modeling are promising tools for the discovery of novel magnetic materials with a combination of materials informatics. To realize the discovery of a high-performance magnetic material, it is important to clarify the correlation between magnetic properties and the structures or microtextures in the magnetic materials, and micromagnetics and multiscale modeling play an essential role. However, in the accurate calculation of the magnetization dynamics in the magnet materials, a model size of the simulation should be a few hundred nanometers to several micrometers, which is the scale of microtextures in the real magnetic materials, with a mesh size of several nanometers, which is the scale of exchange-correlation length is needed. It is, therefore, necessary to perform an ultra-large-scale micromagnetic simulation. We have succeeded in developing large-scale micromagnetic simulator with a model exceeding 1 billion cells by using the supercomputer [1-4]. On the other hand, it is rather difficult to perform the ultra-large-scale micromagnetic simulation for searching the novel magnetic materials by using the supercomputer, since the computational time of the supercomputer is limited. Parallel processing with strong scaling has been required for the ultra-large-scale micromagnetic simulation. However, the calculation of magnetostatic fields using Three-dimensional Fast Fourier Transform (3D FFT) is considered to be the most difficult part of the parallel processing. 3D FFT is an efficient algorithm for computing discrete Fourier transform in 3D space operations. 3D FFT requires global communication among processors, which limits efficiency even on a massively parallel supercomputer, and it is considered to be difficult to perform ultra-large-scale 3D FFT on the conventional workstation. This drawback can be overcome through the proposed coarse grain task parallelization. The proposed method uses the OSCAR compiler for exploiting coarse grain task parallelism efficiently to get scalable speed-ups with strong scaling. The OSCAR compiler can analyze data dependence and control dependence among coarse grain tasks, such as subroutines, loops and basic blocks. Moreover, locality optimizations considering the boundary calculations of FDM and a new static scheduler that enables more efficient task schedulings on cc-NUMA servers are presented. We performed the ultra-large-scale micromagnetic simulation for a permanent magnet is based on Landau - Lifshitz - Gilbert (LLG) equation. The simulation was performed on the model for the Nd-Fe-B permanent magnets with a size of 512 nm $\times$ 512 nm $\times$ 512 nm. We use finite difference method with the periodic boundary condition for simulation, and the simulation model was discretized into 2.0 nm $\times$ 2.0 nm $\times$ 2.0 nm cells. Thus, the model has 256 grid points in the x, y, and z-direction, and the total grid points are 16,777,216. The performance evaluation shows 120 times speed-up using 128 cores against the sequential execution on a POWER7 based 128 cores cc-NUMA server Hitachi SR16000 M1, 62.1 times speed-up using 64 cores against the sequential execution on a Xeon E7-8830 based 64 cores cc-NUMA server, and 131 times speed-up using 128 cores against the sequential execution on a Xeon E7-8890 based 128 cores cc-NUMA server. This significant speedup of ultra-large-scale micromagnetic simulation with coarse grain task parallelization enables the exhaustive search of novel magnetic materials.

HT-10. Voltage induced strain-mediated perpendicular magnetization control for in-memory computing device.

Q. Wang[1], C. Liang[1] and G.P. Carman[1]
1. Department of Mechanical and Aerospace Engineering, University of California, Los Angeles, Los Angeles, CA, United States

Magnetic memory has attracted substantial attention due to its promise of high energy efficiency combined with non-volatility. Conventionally, the magnetization is controlled by spin-transfer torque (STT) current but ohmic heating makes the current-based switching mechanisms energy inefficient (100fJ/flip). In contrast, strain-mediated multiferroic composites (i.e. coupled magnetoelastic and piezoelectric thin films) provide ultra-high energy efficiency as high as 100aJ/flip due to negligible induced current during the switching process. In this study, a fully coupled model is used to simulate strain-mediated magnetization control of nanodots with perpendicular magnetic anisotropy (PMA) on a PZT ($Pb_y[Zr_xTi_{1-x}]O_3$) thin film. This model is also used to study Bennet clocking of nanodot arrays. Fig. 1 shows the perpendicular magnetization m_z changing with time for CoFeB and Terfenol-D nanodisks under different applied voltages. The nanodisk diameter is 50 nm and the thickness for CoFeB is 1.6nm while for Terfenol-D it is 2nm. The inset plots in Fig. 1(a) and 1(b) illustrate the temporal strain change observed when applying 2.8V to the CoFeB element and 0.1V to the Terfenol-D element, respectively. For all the cases shown here, the magnetization undergoes 180° precessional switching (from $+z$ to $-z$). By increasing the voltage on either material, the switching (writing) time is decreased. However, beyond threshold voltages (6V for CoFeB, 0.2V for Terfenol-D), further increases in voltage no longer decrease switching times. This is because incoherent switching begins to appear at high voltages due to the relatively larger energies introduced into the system. The shortest switching time for both materials are comparable (0.2~0.3ns) while the energy dissipation is substantially different for the two materials. The minimum voltage required to achieve 180° flipping in CoFeB is 2.8V, which corresponds to an energy dissipation as 29.6fJ per flip. In contrast, the minimum voltage required to flip Terfenol-D is 0.1V, which corresponds to an energy dissipation as 22aJ per flip. While the disparity between these two are large, the strain-mediate control for both materials are considerably more efficient than STT method (100fJ). The above information is used to study Bennett clocking mechanisms for different magnetic material systems (e.g., Ni, CoFeB, Terfenol-D) with PMA. Fig. 2 shows the simulation results of perpendicular Bennett clocking for a four-bit Ni system. All the Ni disks have 50nm diameter and 2nm thickness. Fig. 2(a) shows an illustration of the simulated structure. Four nanodisks are attached on the PZT substrate with 50nm edge-to-edge spacing between the neighboring disks. Each disk is surrounded by a pair of electrodes to apply voltage and generate localized strain. The four disks are initialized as ↑↓↑↓, and the neighboring disks are coupled through dipole-dipole coupling. A voltage pulse with 0.7ns duration is applied to the first disk. Through precessional switching, the first disk is flipped 180° from ↑ to ↓. Then voltage pulses with duration of 2ns are applied to the following disks consecutively. Under the long voltage pulse, the magnetization is brought in-plane, which is a metastable state. Because of dipole-dipole interaction, the chain of the Ni disks tends to form an anti-parallel alignment. Fig. 2(b) shows the temporal change of perpendicular magnetization as well as the voltage pulses applied for each disk. It is shown that the system equilibrates to an anti-parallel state defined by ↓↑↓↑. In other words, every disk undergoes 180° switching and the first memory bit change is transferred throughout the entire memory bit chain. These results show that the magnetic memory and logic can be implemented in the same device using strain-mediated switching and clocking methods, which will be the crucial element for next generation in-memory computing devices.

HT-11. Three-dimensional Domain Calculations by Hybrid Monte Carlo Micromagnetics.

L. Bao[1], M. Dai[2], D. Wei[2,3] and *G. Yun*[1,3]
1. Inner Mongolia Key Lab of Nanoscience and Nanotechnology and School of Physical Science and Technology, Inner Mongolia University, Hohhot, China; 2. Key Laboratory of Advanced Materials, School of Materials Science and Engineering, Tsinghua University, Beijing, China; 3. College of Physics and Electronic Information, Inner Mongolia Normal University, Hohhot, China

The domain structure and the motion of domain wall of ferromagnetic material are first studied by Landau and Lifshitz in 1935 [1], which founded the theory of applied magnetism. Nowadays, for applications such as permanent magnets, 3D domain analysis of bulk magnetic materials becomes an important topic. Tsukahara et.al. applied the Landau-Lifshitz-Gilbert (LLG) equation to analyze the propagation of magnetization reversal of 1024 nm ×1024 nm ×1024 nm permanent magnets [2]. However, three-dimensional domain structure of large-scale magnet has not been studied at finite temperature because the LLG equations cannot take the influence of temperature into consideration. In this work, a new micromagnetic method, Hybrid Monte Carlo (HMC) Micromagnetics developed by Wei et.al., [3] is utilized to calculate the domain structure of cubic magnets up to the size of 1μm with different initial states of *M*. The computational speed of HMC micromagnetics is much faster than LLG micromagnetics, therefore it has the potential to calculate magnetic properties at finite temperature for large sized materials. For HMC micromagnetics in Ref.[3], a conjugate momenta Π_j for M_i is generated through a Gaussian distribution $\exp(-V_c\sum_i \Pi_i^2/2k_BT)$ and the correct Boltzmann distribution of free energy $\exp(-F(\{M_i\})/k_BT)$ is obtained by simulations divided into hundreds of trajectories; and in each trajectory, $\{\Pi_i\}$ and $\{M_i\}$ are iterated through the Hamilton equations, followed by the Monte Carlo judgment at the end of each trajectory to reach equilibrium at temperature *T*. In the simulation, the magnet size is divided into $N_x \times N_x \times N_x$ (N_x=8-256) cubic magnetic cells. The length of each cell is 5nm, which is effective to smooth the diverging stray field according to W. Rave's study [4]. The saturation magnetization M_s(0K) is 798 emu/cc, the exchange constant A^* is 1×10^{-6}erg/cm and the first-order anisotropy energy constant K(0K) is 4×10^5 erg/cm^3. The easy axis is along z direction. The magnetization distribution of the cubic magnet with a side size of 640nm are shown in Fig. 1 with different initial conditions of *M*. Here the periodic boundary conditions are applied on the double sized space ($2N_x \times 2N_x \times 2N_x$) to avoid the miscalculation of demagnetizing fields. There are two sets of initial conditions of *M* shown in Fig. 1. If the initial condition is set as up-down mode (*M*=Ms for x<0 and *M*=-Ms for x>0), the whole cube has one large domain and several small sized side domains, as seen in Fig 1(a) and (c). If the initial condition is set as up-down-up-down mode (M=M_s for -L/2<x≤-L/4 and 0<x≤-L/4 and M=-M_s for -L/4<x≤0 and L/4<x<L/2), four domains appear and the domain structure is more complicated as described in Fig 1(b) and (d). Thus, the final domain structure of large-sized cubic magnet largely depends on the initial state of magnetization, which reveal the nonlinearity of magnetics. If periodic boundary condition is applied at y direction and z direction, Bloch domain wall will appear in this magnet (This simulation is performed on the Supercomputer of Beijing Computing Center). It is not ideal Bloch wall because of the limited total size in x direction. By fitting the wall structure of M_z as formula M_z=tanh(x/a), the average bloch wall width *a* is found to be 15.6 nm. It fits quite well with theoretical value of Bloch wall width, which is 15.8nm according to a=√(A^*/K), demonstrating the accuracy of the calculation of domain structure.

HT-12. Design and Optimization of Skyrmion-based Racetrack Memory by Overcoming Clogging and Annihilation of Skyrmion Signals.

G. Zhao[1]
1. Physics, Sichuan Normal University, Chengdu, China

Magnetic skyrmions are promising building blocks for next generation data storage due to their stability, small size and extremely low currents to drive them[1,2]. Skyrmion-based metalic racetrack memory has potention to replace traditional domain walls to store information as data bits, in which, however, skyrmions can drift from the direction of electron flow due to the Magnus force. In addition, skyrmion-edge effect at the end of the racetrack can cause the clogging of the skyrmions at the end of the racetrack[3]. Here we show that the clogging of skyrmion signals can be avoided by by adding various kinds of notch at the end of the racetrack [3]. On the other hand, by adding high-k materials (materials with high magnetic crystalline anisotropy) at the edges, the skyrmions can be confined in the center region of the metalic racetrack successfully[4,5]. This design can overcome the problems of both clogging and anniliation according to our micromagnetic simulation. As a result, skyrmions can pass the right end of the racetrack efficiently at a very high speed (100 to 300 m/s), whereas the driving current is much smaller in comparison with other racetrck design. This work is supported by Natural Science Foundation of China (51771127, 51571126, 51772004)

I. Introduction Due to the features of high efficiency, high torque, and without using permanent magnets, the synchronous reluctance motors (SynRMs) have become popular in industry. Such advantages are contributed by the design of the rotor barriers and ribs that the flux flow path are arranged as shown in Fig. 1(a). However, the requirements of motors usually are not just high efficiency but some other more operation capabilities such as low vibration and easy start. Unfortunately, as compared with the industrial most commonly used induction motors (IMs), position sensors are additionally required for initiating starting of SynRMs [1][2]. Moreover, the barriers and ribs of SynRMs may increase the risk of structure deformation as rotation. Hence, this paper proposes a novel design of applying the 3D bionic structure in the SynRMs with new flux path design to solve the said problems. Further, the additive manufacturing (3D printing) is adopted to fabricate the complicated prototype of the rotor. II. Model and Experiment Results Figure 1 demonstrates the rotor of the 1 kW line-start SynRMs designed in this paper. A bionic web structure fabricated by 3D printing is distributed in the barriers of the rotor, as shown in Fig. 1(b). With these small ribs, the vibration problem can be solved due to the higher robustness. It is noted that such a structure enhancement would not increase flux leakage because the ribs are too small to allow the flux passing through. In Fig. 1(c), an improved cage structure based on aluminum paste technology is added in the rotor, which could downsize the volume of rotor as compared with IMs. Figure 1(d) shows the cages are capable to provide additional starting ability, and let SynRMs rotate from standstill to synchronous speed 1800 rpm without position sensor (i.e., line-start ability). As indicated in Fig. 2, 3D printing method, selective laser melting (SLM), is involved to selectively heat the powdered magnetic materials to the melting point in this paper. III. Conclusion In this paper, a new line-start SynRM rotor structure is proved and investigated. With the proposed designs of the web structure in the rotor and the improved cage structure, the SynRM rotor is equipped the capability of initiating starting without position sensors and also much lower deformation. A prototype based on 3D printing is fabricated to further verify the feasibility of the design.

I. Introduction Integrated charging applications are promising for reducing the components for both drives and charging in battery electric vehicles (BEVs) and plug-in hybrid electric vehicles (PHEVs) [1-4]. By reconfiguring the armature winding of propulsion machine in BEVs or PHEVs to be an AC side inductor for battery charging, the vehicle cost and weight are reduced and improve the on-board fast charging capability [5]. Owing to the high torque density, high power density and high efficiency, permanent-magnet brushless machines are favorable candidates as propulsion machines for BEVs or PHEVs. Notably, interior permanent magnet machines (IPMMs) are commercially used in Toyota Prius and other HEVs [6, 7], due to features of the high-torque density and wide constant power speed range; Vernier permanent magnet machines (VPMMs) are recently investigated and developed for direct-drive vehicle motors [8, 9]. By using the magnetic gearing effect, the modulated field in the air gap is utilized to realize the low-speed and high-torque operation. The purpose of this paper is to quantitative compare the performances of an IPMM and a VPMM as the traction motors for BEVs or PHEVs during integrated charging operation. In order to make a fair comparison, similar dimensions, torque densities and power densities of both machines are specially designed. In addition, the VPMM adopts a surface-mounted PM structure to study the influence of PM locations for the integrated charging. The pulsating torque characteristics, noise, loss and thermal analysis during charging operation are conducted and studied. Based on the comparison results, design suggestions for EV machines used in integrated charging are concluded. II. Analysis Fig. 1 depicts a circuit topology for integrated charging applications using 3 H-bridge inverters. It consists of a DC/DC converter, 3 H-bridge inverters and 3 terminals for connecting the AC grid [1]. The three-phase winding is adopted an open-winding connection without the neural point. 3 terminals for charging is connected in the middle of each phase. For driving operation, the 3 terminals are disconnected from the AC grid. The power is delivered from the battery to the 3-phase winding via the DC/DC converter and the 3 H-bridge inverters. For battery charging operation, the charging current from the AC grid in each phase is split into two identical but opposite component flowing into the battery via the inverters and DC/DC converter. Since the magnetomotive force (MMF) of each phase produced by the split phase current in each phase is cancelled off, the magnetic decoupling between the stator and rotor can be achieved. Hence, the parasitic torque during the charging operation is eliminated which is much desirable for PM machines because of the existence of the PM magnetic field. In order to numerically analyze the machine performances during the charging operation, the field-circuit-coupled finite element method (FCC-FEM) is applied. Since the charging current is variable accordingly to the state-of-charge (SOC) of the battery. Under different charging currents, the magnetic field strengths produced by the armature winding are different. Therefore, the machine performances under different charging currents are analyzed, as show in Fig. 2. Fig. 2(c) and (b) show the Magnetization vector plots for the IPMM and VPMM, respectively when the charging current is 50 A (rms). It can be found that for the IPMM the magnetization strength in PMs is negligible since PMs are buried in the rotor core, whereas for the VPMM the magnetization strength in PMs is large due to the surface-mounted configuration. Thus, PMs are easily demagnetized for the VPMM since PMs are part of the magnetic circuit for the armature MMF. Fig. 2(c) and (d) illustrates the pulsating torque waveforms for the IPMM and VPMM, respectively under different charging currents. It can be found that the average pulsating torque is nearly zero for both machines. However, for the VPMM, since the actual air-gap is larger than that of IPMM, the amplitudes of the pulsating torque is smaller. Also, due to the salient-pole effect, the pulsating torque for IPMM is not exactly symmetrical and the armature inductance is position dependent which may cause a larger charging current ripple. The pulsating torque modelling, PM demagnetization, noise, loss and thermal analysis will be discussed and elaborated in the full paper. This work was supported in part by a grant from the National Natural Science Foundation of China, China under Grant 51607114 and a grant from Research Council of University of Macau under Grant MYRG2017-00158-FST.

I. Introduction The motional drive systems of large telescope have become larger and heavier which demands high torque production from the electric machines. Permanent magnet (PM) synchronous machines featuring high torque density are attractive candidates for this demanding application and have been successfully applied in drives for some well-known large telescopes such as Very Large Telescope and Gran Telescopio CANARIAS [1]. The torque production of conventional PM machines scales approximately linearly with the PM machine volume which limits PM machine applications in large telescopes. Alternative approaches to solving this problem are to either use a combination of high-speed machine and gearbox or to propose new topologies of PM machine with much higher torque density which are more attractive to use in direct-drive configurations than conventional PM machines. The PM vernier machine (PMVM) has been recognized as a competitive candidate to increase machine's torque density sufficiently to enable direct-drive solutions that eliminate mechanical transmissions and associated mechanical loss [2]. However, the PMVM typically suffers from large amounts of spatial magnetic flux leakage caused by the multi-tooth structure, causing higher losses and reduced torque that degrade the machine's performance considerably. In order to solve the problem, a dual-stator PMVM (DSPMVM) is proposed that can achieve high torque density compared to the conventional PMVM with the same volume of PM material [3]. Since the multi-tooth structure of DSPMVMs cause abundant harmonic components, a conventional open-slot stator with straight teeth has been adopted to provide modulating poles that adjust the airgap flux density while simplifying the machine structure [4]. In order to maximize the DSPMVM's torque density, various types of PM arrangements have been investigated, including spoke-type rotors and machine topologies with magnets placed on both the rotor and stator. The purpose of this paper is to propose novel dual-stator DSPMVM topologies featuring various magnet arrangements to provide excitations on both sides (either stator-stator or stator-rotor). The proposed DSPMVMs can be named using their distinctive features, namely, flux-reversal DSPMVM, dual-excitation DSPMVM, asymmetric stator DSPMVM, and consequent-pole DSPMVM, referred to more simply as Model I, II, III, IV, respectively. The topologies and operating principles of these DSPMVMs are described. The major electromagnetic performance characteristics of these topologies are investigated and compared. II. Machine Topology and Operating Principle The proposed DSPMVM topologies are illustrated in Fig. 1(a), where it can be observed that all of the machines adopt the same conventional configuration with open-slot stator teeth. All of models employ the same inner stator designed with 12 slots and a fractional-slot 10-pole three-phase winding that provides a high winding factor. Model I introduces flux-reversal machine concept into the DSPMVM by mounting adjacent magnets with reversed polarities at the tips of each outer and inner stator tooth to provide magnetic excitation. For Model II, the magnets are mounted at the tips of alternate iron poles for both stators as well as on both the inner and outer radial surfaces of each rotor pole to enhance the flux density in both airgaps. Model III uses the same inner stator and rotor configurations as in Model II, but removes the magnets form outer stator tooth tips. This modification changes the modulation pole number of the outer stator, forcing a change in the number of pole pairs for the outer stator and rotor. Model IV has the simplest structure of the four models, adopting the same inner and outer stators as Model II but without any magnets mounted on the rotor surfaces. The slot-pole combinations of all four models are presented in Table I. The teeth of both the inner and outer stators act as the modulation poles. Based on the "magnetic-gearing effect", the relationship of the numbers of modulation pole-pairs, and the rotor and stator pole-pairs of all of the DSPMVM topologies satisfy the following constraint: $p_r=N_s\pm p_s$ where N_s is the modulation pole-pair number, and p_r and p_s are the pole pair numbers of the rotor and stator, respectively [5]. III. Performance Comparison Fig. 1(b) shows the rated-load field and flux distributions calculated using 2D finite element analysis. For a fair comparison, the stator ampere-turns, stack length, and magnet volume are held constant. Figs. 2(a), 2(b), and 2(c) present comparisons of the electromotive force amplitude (i.e., back-EMF), cogging torque, and average torque waveforms, respectively, for the four topologies at 272.72 r/min. The results show that the magnetic flux density of Model II is the highest compared to the other models due to its magnetic excitation on both stators as well as both rotor radial surfaces. Fig. 2(a) shows that Model II has the highest back-EMF amplitude, but Model I produces the most sinusoidal back-EMF waveform. The cogging torque amplitudes of the four topologies are 0.48Nm, 1.32Nm, 0.76Nm, 1.77Nm, respectively, indicating that the Model I topology generates the lowest cogging torque amplitude because the least-common-multiple of its stator and rotor pole-pair number is the highest among the four topologies. Consistent with its high back-EMF, Model II delivers the highest average torque, 12.75Nm, which is 7.7% higher than that of Model I. However, the torque ripple of Model II is 10.84% higher than that of Model I.

HU-04. A New Double-Winding Vernier Permanent Magnet Wind Power Generator for Hybrid AC/DC Microgrid Application.

Q. Wang[1] and S. Niu[1]
1. Department of Electrical Engineering, The Hong Kong Polytechnic University, Hung Hom, Hong Kong

Abstract: This paper proposes a novel double-winding Vernier permanent magnet (DWVPM) wind power generator for hybrid AC/DC microgrid. The key is to employ two sets of windings, namely AC windings and DC windings in the machine, which serve to produce AC supply and DC supply for microgrid, respectively. The PMs are surface mounted on the rotor, and the stator is designed with open slots. The stator teeth can act as flux modulator due to the permeance difference between the stator teeth and the air. Therefore, the field by PMs can be effectively modulated. Besides the original harmonic used to induce sinusoidal back electromotive force (EMF) in the AC windings and generate AC voltage, another low-order harmonic can be generated, which is used to induce square wave EMF in the DC windings and generate DC voltage through diode-bridge rectifier. Since multi-phase windings can get the square wave EMF more easier, the DC windings are designed with six phases. By using time stepping finite element method (TS-FEM), the electromagnetic performances of the proposed DWVPM wind generator are comprehensively investigated and verified. *Index Terms*—AC/DC microgrid, double-winding, TS-FEM, Vernier machine. I. Introduction With the development of distributed generation systems, the concept of microgrid is becoming increasingly attractive, which has the potential to reduce energy exhaustion and carbon dioxide emissions [1-3]. When the power can be directly supplied by the local microgrid, there is no need to conduct long-distance high voltage transmission, and the energy utilization efficiency can be improved. Among all the renewable generation systems in microgrid, wind power is one of the most commonly used energy sources [4]. Since there are various loads exist in a microgrid, multiple reverse conversions using power electronics technology are necessary in an individual AC or DC microgrid, which reduce the power transmission efficiency and make the microgrid system complicated [5-7]. In this paper, a novel double-winding Vernier permanent magnet (DWVPM) wind power generator is proposed, which can generate AC power and DC power simultaneously therefore suitable for hybrid AC/DC power supply in microgrid. Both AC windings and DC windings are employed on the stator, which are used to generate AC power and DC power, respectively. The configuration, winding connection and design principle of the proposed generator are discussed in detail. Through time stepping finite element method (TS-FEM), the electromagnetic performances of the DWVPM wind generator are studied comprehensively. II. Machine Configuration and Design Principle A. Configuration of the Proposed DWVPM Machine Fig. 1(a) shows the configuration of the proposed machine, which has one rotor and one stator. The rotor is surface mounted with PMs, and the stator is designed with open slots. Since the permeance of the stator teeth and the air is different, the stator teeth can act as flux modulators. Besides the original harmonic excited by the PMs and used to generate sinusoidal EMF in the AC windings, another low-order harmonic can be generated, which is used to generate square wave EMF in the DC windings. The sinusoidal voltage produced in the AC windings is used to provide AC power, and the square wave voltage is used to provide DC power through rectification. The AC windings and DC windings are designed with three phases and six phases, as shown in Fig. 1(b) and Fig. 1(c) respectively. B. Design Principle The design principle of the proposed machine is based on the flux modulating effect. The original pole-pair number of PMs is equal to the pole-pair number of AC windings. The number of stator slots should equals to the sum of AC pole-pair number and DC pole-pair number. III. Performance Analysis In this paper, a machine prototype with 24 stator slots and 11 rotor pole-pairs is designed, the pole-pair numbers of the AC winding and DC winding are 11 and 13, respectively. The electromagnetic performances are investigated using TS-FEM. Fig. 2(a) and (b) show the air-gap flux density distribution and the harmonic spectrum. One can find that besides the original harmonic with 11 pole-pairs, another predominant harmonic with 13 pole-pairs is generated due to the flux modulating effect of the stator teeth. The 11 pole-pair harmonic is used to induce sinusoidal back EMF in the AC windings, and the 13 pole-pair harmonic is used to induce square wave back EMF in the DC windings, as shown in Fig. 2(c) and Fig. 2(d), respectively. One can see that sinusoidal EMF and square wave EMF can be effectively induced in the AC windings and DC windings, which means the proposed wind generator can generate AC power and DC power simultaneously. Therefore the proposed DWVPM wind generator is very suitable for hybrid AC/DC microgrid.

HU-05. Ring-shaped surface-mounted permanent magnet generators with modular stator for small wind turbines – a comparison of topologies.

J.A. Oliveira[1,2], A.F. Flores Filho[1] and *D.G. Dorrell*[3]
1. Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil; 2. Universidade Federal de Mato Grosso, Rondonopolis, Brazil; 3. Howard College Campus, University of KwaZulu-Natal, Durban, South Africa

Introduction The work compares the volume, copper and iron losses of three topologies of modular surface-mounted permanent magnet synchronous generator (SPMSG) for a small wind turbine. They would be connected to the grid by a ac-dc-ac converter. The modular construction reduces the manufacturing complexity since the generator has a ring shape and is installed around the turbine. The use of rare earth (NdFeB) and ferrite permanent magnets is assessed by considering the armature modules. The proposed topologies are evaluated with reference to the permanent magnet type and pole number in order to identify the arrangement that produces the lowest loss. Results show the use of ferrite permanent magnetics can achieve that. Wind turbines in urban areas are submitted to low speed and turbulent wind and that requires larger diameter turbines and direct drive – this means many magnetic poles are required. To increase the energy throughput of the topologies studied here, the SPMSG is designed for use in a wind turbine diffuser [1] that can raise the turbine output power. The rotor of the SPMSG is mounted around the blades of the turbine in a ring form [2]. The SPMSG rating is 1 kW. The inner rotor radius is the same as the turbine, i.e. 765 mm. The rectified output voltage is 30 V at 135 rpm. These parameters were obtained based on the design of the turbine and its operation conditions. The converter is suitable for grid connection. The modular stator simplifies the manufacturing of larger diameter machines with no diffuser [3][4], and this concept is extended to small turbines here. The modules are shown in Fig. 1. Each one is different in terms of winding and copper volume. The air-gap and its magnetic flux density are constant. Since the rotor is a large diameter ring, it is desirable to reduce its weight. Also, the pole number, the rate of change of stator flux linkage and iron losses all increase with the turbine diameter. By considering the magnetic circuit, the radial length of the rotor back-iron, module slots and yoke, permanent magnets, and copper volume are determined for an armature with an axial length of 20 mm. Using the volume and characteristics of the copper and laminated iron, the losses are estimated for the three modules employing either ferrite or NdFeB permanent magnets. Analysis The dimensions of the SPMSG are calculated using the magnetic equivalent circuit with reference to the air-gap dimensions and current density described in [5], and in this case the references values are 2 mm and 2 A/mm^2, respectively. The magnet volume is calculated to achieve the maximum energy product operating point of the permanent magnets in order to reduce the rotor weight. The number of turns in each module is determined by the minimum voltage required by the converter that corresponds to the minimum operation speed. The radial length of the back iron rotor is calculated considering the point of maximum permeability of the iron and the flux density of the permanent magnets. The design of the modules considers the high pole number, which increases the losses in the laminated stator iron, so that the operating point of the stator iron is set to a lower figure than the maximum flux density to decrease these losses. The laminated stator iron magnetic characterization was done for different frequencies to allow for a range of turbine speeds. Results The permanent magnet dimensions give the maximum energy product operating point and the magnet flux density is almost constant, so that the back-iron radial length is a function of pole pitch. Fig. 2a shows that the back-iron weight decreases as the pole number increases since the per-pole magnetic flux is proportional to the size of the permanent magnet. The NdFeB volume is lower than the ferrite volume since the energy product of the former is higher. It is harder to manufacture NdFeB magnets if they become too thin, e.g. below 0.5 mm. The rotor weight calculations show that a high pole number configuration is the most appropriate choice. However, Fig. 2b shows that the pole number reduction decreases the total stator iron losses because the flux frequency also decreases. Besides, Fig. 2b shows the copper losses are much smaller than stator iron losses. These results refer to the starting speed of the turbine for Module 3. The behaviour of the stator iron losses and copper losses of the other two modules are similar to the Module 3, but for Module 1 copper losses are larger than for Modules 2 and 3 because more turns are required in order to compensate for the lower magnet flux linkage. NdFeB magnets lead to lower copper losses because the higher energy product reduces the required copper volume. However, this increases the stator iron volume and iron losses. Conclusions The results show that high pole number increases the losses in the stator iron. The results also indicate that copper losses are much lower than the losses in stator iron due to the low power of the wind turbine and high pole numbers that increase the frequencies of the stator flux linkage. NdFeB magnets gives lower copper losses, but the stator losses are larger and rotor weight are increased making it difficult the start the turbine. Modules 2 and 3 with ferrite magnets are lighter and have lower stator iron losses compared with NdFeB magnets.

HU-06. A novel doubly fed wind energy power split system with partial-scale converter and control strategy.

X. Liu[1], M. Li[1] and *S. Huang*[1]
1. Electrical and Information Engineering College, Hunan University, Changsha, China

1.Introduction normally, renewable energy resource is clean, inexhaustible, low maintenance and running costs. Wind energy is considered as an option to solve the environmental issues, due to it is widespread throughout the world. Until now, single rotor wind power generator is widely used in practice. The DFIG system and direct-drive synchronous generator (DDSG) system are currently the mainstream machine for wind turbine [1]. The main merit of the DFIG system is in no need of PM material and only need about 30% converter capacity, hence the whole system is lower cost. However, the additional gearbox, the slip ring and brushes inevitably lead to maintenance problems and low reliability. To the opposite, the DDSG system is famous for high efficiency, low mechanical loss and low maintenance cost. The gearbox can be canceled in high number of poles of PMSG. But, the DDSG system has to be equipped with correspondingly full-scale converter [2]. The existing low speed high torque direct-drive machine is bulky size and large material consumption. To overcome above problems, magnetic gear is introduced into the wind generator as the power split [3]. In [3], the wind turbine system was based on planetary gearbox, which power split to a synchronous generator and a servo PMSM. The system structure and control strategy are complex compared to traditional system. In addition, planetary gearbox is a mechanical device which has inevitable mechanical problems such as frictional loss, high maintenance and audible noise. A novel brushless doubly fed power split system is proposed to substitute for the planetary gearbox in this paper. The extracted wind energy is divided into two parts by the magnetic-field-modulated blushless double rotors machine (MFM-BDRM). The major part of the power directly flows to the power grid through the generator. A small proportion power of the rest is delivered to the back-back converter. For a given wind speed, a MPPT (maximum power point tracking) control strategy is designed to extract the maximum wind energy by controlling the converter. This system has high torque density, high-reliability and low-cost characteristic. 2.System configuration and working principle A. BDF-PST system The proposed BDF-PST system is shown in Fig. 1. The main components of the wind turbine consist of a wind blade, a one-level gearbox, a MFM-BDRM machine, a syngenerator and a back-back converter. The most important part is MFM-BDRM machine, which makes the wind energy flow to the generator or the converter. As we can see, the outer rotor is connected to the wind blade by a gearbox, which the variable speed range of power generation is about 900 rmp to 1500 rmp. Besides, the power grid is directly linked with the syngenerator which is driven by the inner rotor. The converter is the core unit that controls the whole wind turbine, it takes the 20% proportion of the machine capacity. At the same time, a MPPT control strategy is designed for the BDF-PTS system. It ensures the maximum limit utilization rate of wind energy. B. Machine structure and working principle The MFM-BDRM machine consists of one stator and two rotors in [4]. The structure of the machine is shown in Fig. 1(a). The outer rotor is composed of the 21 pieces of modulating ring. The inner rotor has the pole pair of 17 PMs and the stator windings with the pole pair of 4. Assuming the pole-pair number of the stator winding and PM rotor are p and n, The number of the magnetic blocks is q. The relation of the electromagnetic torque of stator (Ts), modulating ring rotor (Tm), and PM rotor (TPM) is proportional of the pole pair. 4.Control strategy and FEM results analysis The BDF-PST system control strategy based on the MPPT is shown in Fig. 2. Using a converter change the windings current frequency and amplitude, the outer rotor speed follows the change of wind speed, the generator will operate at constant speed. Two encoders are installed to observe the inner and outer rotors' position and speed. For the given wind speed, the maximum performance coefficient will select the pitch angle from the look-up table to get the maximum power reference. First, the generator operates the rated speed. Then, closing the grid connection switch, the control strategy turns to a three closed-loop based on the field oriented control (FOC) to acquire the output power from the windings. In the FEM analysis, the amplitude of the back-EMFs at 1500 rmp is 25V and the harmonic spectra is 2.38%. The ripple in back-EMF is mainly because the slot effect. At the rated situation, the speed of the outer rotor and the inner rotor is 1500 r/min, the frequency of syngenerator in the windings is 50 Hz, which is same to the power grid. At the same time, the relationship of the rotors torque and the windings current, power factor, machine efficiency is studied in different operation speed.

HU-07. Partitioned Stator Hybrid Excitation Machine with Separated Field Sources and Armature Winding.

Y. Du[1], W. Lu[1], X. Zhu[1], F. Xiao[1] and L. Quan[1]
1. Jiangsu University, Zhenjiang, China

I. INTRODUCTION Hybrid excitation (HE) machines possess outstanding flux regulation capability whilst maintain the merits of PM machines due to the adoption of two excitation sources of permanent magnets (PMs) and wound field (WF) windings simultaneously [1]. In order to achieve the blushless structure, several single stator-HE (SSHE) machines have been proposed based on stator PM machines, such as HE switching flux (HESF) machines and HE doubly salient (HEDS) machines. Nevertheless, the existing SSHE machines suffer from the space conflict among field sources, namely PMs, WF windings and armature windings are all located in the sole stator with limited space, thus leading to a difficulty to take account of both satisfactory flux regulation capability and high torque density. Recently, the concept of partitioned stator (PS) machine has been proposed, in which an outer stator and an inner stator were employed to accommodate armature windings and field sources, respectively, and a rotor with small volume was sandwiched between the two stators [2]. Consequently, the space conflict in SSHE machines can be effectively avoided by employing the PS configuration. More coppers and PMs can be located within the same machine volume due to the sufficient utilization of inner space, and thus, leading to increased torque density and improved flux regulation capability. In this paper, two sub-structures of a new PSHE machine are proposed according to the different pole center lines (PCLs) positions of PM magnetic fields, namely the PS-HEDS structure and the PS-HESF structure. II. STRUCTURES AND OPERATION PRINCIPLE As shown in Fig. 1, the proposed machines are composed of an outer stator and an inner stator with tooth-slot structure, between which a rotor consists of segmented iron pieces is sandwiched. Thus, armature windings and field windings can be placed in the slots of outer stator and inner stator, respectively, which permits the increased electric load and PM volume to improve its power density and flux regulation capability. Moreover, tangentially magnetized NdFeB-PMs with alternatively opposite directions are embedded between the tooth tips of T-shaped inner stator core. By rotating the inner stator over 1/2 pole pitch, two sub-structures can be obtained, as shown in Fig.1(a) and (b), in which the PCLs positions of PM magnetic fields are in line with that of stator teeth and that of stator slots, respectively. In order to describe the operating principle, equivalent magnetic circuit models at the rotor position of peak flux linkage are shown in Fig.1 (c) and (d). It can be found that the magnetic circuits of two machines are very similar. There are two opposite parallel branches of PM magnetic field due to the adoption of T-shaped inner stator structure, and both of them are magnetically parallel to the WF field, thus the irreversible demagnetization risk can be effectively avoided and the resultant flux can be regulated flexibly. III. RESULTS According to the static and transient simulation results, electromagnetic performances of these two machines are analyzed and compared. In Fig.2 (a) and (b), open-circuit flux linkages in coil A1 and A4 are illustrated. It can be observed that the flux linkages in A1 and A4 are both unipolar while the flux linkages of coil A1+A4 are bipolar for PS-HEDS machine. On the other hand, the flux linkages in Fig. 2(b) are both bipolar for PS-HESF machine. Meanwhile, due to the compensation of even order harmonics, flux linkage waveform of coil A1+A4 are sinusoidal though flux linkage waveforms of coil A1 and A4 are nonsinusoidal, which is similar with switching-flux PM machines. In Fig.2(c), efficiency waveforms with different field current are depicted. It can be seen that the highest efficiency points do not occur when the machines are excited by only PMs. Thus, the rated operation points of two machines are defined when field current I=1A to obtain the highest efficiency. Fig. 2 (d) shows the simplified equivalent magnetic circuit of proposed two machines to estimate the thickness of the inner stator yoke preliminarily theoretically, which contributes dramatic influence upon the electromagnetic performances and will be presented in full paper. In Fig.2 (e) and (f), the waveforms of output torque and the flux regulation capability of two machines at different excitations are illustrated, namely with PM only and with excited current I=1A. It can be observed that the output torque of both machines are improved at the rated condition due to the flux-enhancing current and flux-weakening capability are both increased to achieve a wider constant power range because of the novel defined rated operation point. The analysis and more electromagnetic performances will be presented in full paper.

HU-08. Low-Loss Design and Analysis of Magnetic-Field Modulated Brushless Double-Rotor Machine.

J. Bai[1], J. Liu[1], *P. Zheng*[1] and Y. Liu[1]
1. Harbin Institute of Technology, Harbin, China

Owing to the elimination of brushes and slip rings, magnetic-field modulated brushless double-rotor machine (MFM-BDRM) can be a promising candidate for the electrical-continuously variable transmission in hybrid electric vehicles [1]. The MFM-BDRM is composed of stator, MFM rotor and permanent-magnet (PM) rotor, as shown in Fig. 1(a). In traditional MFM-BDRM, however, the problem of large PM loss and stator core loss, caused by its MFM rotor with alternate arrangement of fan-shape magnetic and nonmagnetic blocks, severely restricts the electromagnetic performance of MFM-BDRM. Therefore, a low-loss MFM-BDRM with the sinusoidal permeance characteristic of MFM rotor is proposed and investigated in this paper, as shown in Fig. 1(b). Since fan-shape magnetic and nonmagnetic blocks cause many harmonic permeances in the air gap and further produce large harmonic loss in the PMs and stator core, the ideal sinusoidal permeance model of MFM rotor is first established and investigated by analytical method. It shows that almost all harmonic permeances can be dramatically weakened by the proper design of the shape and size of magnetic and nonmagnetic blocks. The key idea of this paper is to minimize the harmonic permeance of air gap, thereby the harmonic magnetic fields can be restrained. Considering that Tangential leakage flux among magnetic blocks in the analytical method is difficult to be calculated accurately, the influence of key parameters of proposed MFM rotor, like eccentric distance and pole-arc coefficient of magnetic block, minimum length of inner and outer air gap, on the electromagnetic performance of MFM-BDRM is further investigated and optimized by finite element mothed. Finally, to completely evaluate the performance of the proposed MFM-BDRM, a traditional MFM-BDRM with the same size is designed to compare their performances under different operating conditions, like back EMF, output torque, torque ripple, loss, etc. Due to the space limit, the abstract only shows that the electromagnetic performance comparison between traditional MFM-BDRM and proposed MFM-BDRM when the speeds of MFM rotor and PM rotor are 2000 r/min and 1000 r/min and the same current excitation is applied, as listed in Table I. It shows that the proposed MFM-BDRM can have almost the same torque and power output capacity as the traditional one, and the PM loss and stator core loss are reduced by more 55% and 28% than those of the traditional one under no-load condition, and that are reduced by more 34% and 8% than those of the traditional one under load condition.

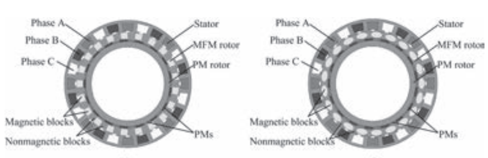

Fig. 1. Structures of MFM-BDRM: (a) Traditional MFM rotor; (b) Proposed MFM rotor

Parameters	Traditional MFM-BDRM	Proposed MFM-BDRM
Outer diameter of the stator	226 mm	226 mm
Axial length	70 mm	70 mm
Pole-pair number of the PM rotor	17	17
Pole-pair number of the stator	4	4
Number of magnetic blocks	21	21
Number of slots	24	24
Amplitude of no-load EMF	110.6 V	109 V
THD of no-load EMF	3.7%	2%
Amplitude of full-load EMF	168.1 V	155 V
THD of full-load EMF	1.9%	1.5%
Torque of MFM rotor	52.4 N·m	51.3 N·m
Torque ripple of MFM rotor	1.7%	1.2%
Torque of the PM rotor	42.2 N·m	41.1 N·m
Torque ripple of PM rotor	1.4%	1.3%
Power factor	0.66	0.7
Stator of no-load core loss	27.9 W	20 W
Magnetic blocks of no-load core loss	13.1 W	9.2 W
PMs of no-load loss	41.4 W	18.5 W
PM rotor of no-load core loss	0.5 W	0.3 W
Stator load core loss	79.6 W	73.3 W
Magnetic blocks of load core loss	16.6 W	12.1 W
PMs of load loss	91.3 W	59.7 W
PM rotor of load core loss	1.8 W	1.6 W
Copper loss	287.5 W	287.5 W
Efficiency	92.7%	93.3%

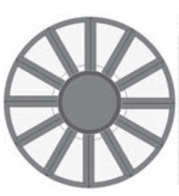
HU-09. Development of a New Stator Module Type Vernier Motor utilizing Amorphous Cut Core.

H. Nakagawa[1], T. Sato[1] and T. Todaka[1]
1. Oita Univ., Oita, Japan

This paper presents a new stator module type vernier motor, which is applicable amorphous magnetic material effectively as a stator core material. The iron loss distribution in the stator module structure made of a Fe-based amorphous material is numerically investigated with the finite element method and compared with those made of oriented electrical steel sheets and non-oriented electrical steel sheets in the laminated core pattern. The results show that the proposed model is useful to improve significantly efficiency of the vernier motor model. Recently, industrial demands are increasing for electric machines with high torque density and high efficiency. Mechanical gears are usually used in order to realize high torque and low speed rotation as a speed reducer in a robot, an electric vehicle, an elevator and so on. However, the mechanical gears have difficulty in high precision control due to backlash and friction. Furthermore, there are mechanical contacts between gear teeth, so that maintenance is necessary. In order to solve these problems, vernier motors that utilize the magnetic gearing effects are getting attention due to their high torque capability and small pulsating torque. The vernier motor is a motor that obtains rotational force through the magnetic flux harmonic component modulated by the geometries of the stator cores. The magnetic flux harmonic component is proportional to the pole number of the rotor magnet and the modulated magnetic field generates the output torque on the rotor. Thus, in the vernier motors, it is important to analyze and design the armature magnetic field and the structure of the stator and rotor cores. The various kinds of vernier motor are still in the research stage, further improvement in efficiency and power factor is required for commercialization and mass production. In order to improve efficiency of the vernier motors, we try to apply the Fe-based amorphous magnetic material to the stator module. The Fe-based amorphous magnetic material has high permeability and low loss, and is extremely excellent as a core material. However, the amorphous magnetic material is difficult to process in the conventional laminated core structure. The proposed stator module type vernier motor is possible to use U-shaped amorphous cut cores annealed in a magnetic field. Thus this model has the following three advantages: the amorphous wound cores are applicable; the harmonic component of the magnetic flux increases in the divided core structure and it leads to improve the torque characteristic; the deterioration of the magnetic properties of the amorphous magnetic material after processing can be prevented by the magnetic annealing. Fig.1 shows the model used in the analysis and its specifications. Because the fifth harmonic is used in the proposed vernier motor model, the number of the pole pairs of the rotor magnets is assumed to be 5. The analyses were conducted under the same conditions, and the stator core material was assumed to be the amorphous magnetic material (2605HB1M), the non-oriented electrical steel sheet (50H470), and the oriented electrical steel sheet (23JG120). Fig. 2 shows comparison of the output power, the iron loss, the copper loss and the efficiency of the each model when the load angle is 90 degrees. As shown in this figure, it is evident that the iron loss is the smallest and the efficiency is the largest in the model utilizing the amorphous magnetic material. Details of the stator module construction and its frequency dependency will be discussed at the presentation and in the full version of paper.



Specifications

HU-10. Optimal Arrangement of Permanent Magnets in a Dual-permanent-magnet-excited Synchronous Motor.

Y. Chen[1] and *W. Fu*[1]
1. Department of Electrical Engineering, The Hong Kong Polytechnic University, Hong Kong, Hong Kong

I. Introduction Permanent magnet (PM) electric machines have wide applications as they can realize large electromagnetic torque transmission without extra external excitation [1]. Most conventional PM synchronous motor have surface-mounted PM arrangement with N pole - S pole - N pole - S pole ... on the rotors. Magnetic gear (MG) can be directly combined with a conventional PM motor which will improve the system torque density significantly. However, it has the disadvantage of requiring two rotating parts and complicated mechanical structure [2]. In [3], a novel magnetic gear motor is presented in which MG is integrated into a conventional outer-rotor PM brushless motor. And it has only one rotary part. It can be called flux-modulated motor. In [4], a dual-PM-excited (DPME) synchronous motor was presented which is designed with PMs on both stator and rotor. The PMs in each slot have the same magnetization polarity. The PMs on the stator facing the air gap side are N poles and the PMs on the rotor facing the air gap side are S poles in consequent-pole-type PM arrangement. In this configuration two set of flux-modulated motor can be realized and the torque density can be improved significantly. In this paper, an optimal PM arrangement in a DPME synchronous motor is proposed which leads the motor has more competitive torque capability and efficiency compared to the conventional counterparts. The sizes of the PM configuration are determined by optimization algorithm. The performances of DPME synchronous motors with different PM arrangements are quantitative compared. II. Proposed Configurations A DPME synchronous motor with conventional PM arrangement (as Model I) is shown in Fig. 1 (a). The stator has 30 slots which carry one set of p_w pole-pair three-phase armature winding. The rotor has 32 salient PM pole-pairs with simple consequent-pole type arrangement of N pole - Fe - N pole - Fe …, as shown in Fig. 2 (a). There are four main parameters of the conventional PM arrangement. A Halback array magnet arrangement is attracted importance since it offers a number of attractive features. This arrangement can transmit a relatively high torque density whose magnet material is fully utilized and it is very appropriate for slotless and brushless machines [5-7]. In this paper, a simplified consequent-pole Halback array type PM arrangement is proposed to replace the consequent-pole type one. A DPME synchronous motor with simplified consequent-pole Halback array type PM arrangement inserted on the rotor (as Model II) is shown in Fig. 1 (b). There are six main parameters of the simplified consequent-pole Halback array type PM arrangement, as shown in Fig. 2 (b). As the spoke type PM arrangement of N pole - Fe - S pole - Fe - N pole - Fe … which has the function of flux focusing can achieve high torque density and less centrifugal forces [8], the consequent-pole PMs in the stator slots can also be replaced by spoke type PMs. Then a new motor configuration (as Model III) can be achieved, as shown in Fig. 1 (c). There are six main parameters of the spoke type PM arrangement, as shown in Fig. 2 (c). III. Optimization In this paper, a multi-objective optimization algorithm is employed to find the optimal sizes of PM arrangement. The objective function in this case is the output torque and the efficiency of the motor. The rotor is rotated at a constant speed and the transient numerical solution is applied. The optimization process is shown in Fig. 3. The simulation is done through the coupling of finite-element motor model and optimization procedure. IV. Performance Comparison The three styles of motor configurations are optimized using a multi-objective optimization algorithm and their magnetic fields are analyzed using time-stepping finite element method (FEM). The electromagnetic torque, torque per volume, torque per PM volume, copper loss regarding winding, core loss, solid loss and corresponding power efficiency of DPME synchronous motors with different PM arrangements are listed in Table I. From Table I, one can find that Model II has 40% higher electromagnetic torque than Model I and Model III has 5.9% higher electromagnetic torque than Model II. The DPME synchronous motor with the optimal PM arrangement has the highest torque and torque per total volume in the three designs. But its torque per PM volume is the lowest. The torque per PM volume of Model II is the highest. The DPME synchronous motor with the optimal PM arrangement has 3.2% higher efficiency compared with the motor with conventional PM arrangement while the total loss of the three motor types are nearly equality.

HU-11. Loss and efficiency of a flux-switching permanent-magnet double-rotor machine with high torque density.

L. Mo[1]
1. Huaiyin Institute of Technology, Huaian, China

I. Introduction Double rotor machine (DRM) used for hybrid electric vehicles (HEVs) can offer multi-operational modes and enables the internal combustion engine (ICE) to operate at optimum efficiency independent of road conditions, thus decreasing the emissions and fuel consumption. To achieve high torque density and little torque ripple, a flux-switching permanent-magnet double-rotor machine (FSPM-DRM) has been proposed (see Fig.1(a)) [1][2]. Besides the high torque density, the FSPM-DRM used for HEV should has high efficiency at different operation mode during wide speed range. So, to verify the machine's performance, it's essential to investigated the FSPM-DRM loss and efficiency accurately, which is also needed for further thermal analysis. Traditionally, the conductor eddy current loss,as a part of copper loss, is usually ignored in loss analysis. While in the FSPM-DRM, for its higher electromagnetic torque density than most doubly salient machine, and its larger slot opening, the conductor eddy current loss in it also increases correspondingly. Besides, the high frequency from 22-pole middle rotor, high slot leakage across the coils from the narrow slots, and various operational modes especially at large load and high-speed operations, make the conductor eddy current loss cannot be ignored for accurate efficiency evaluation. II. Machine topology Fig.1(a) shows the configuration of the FSPM-DR machine, in which two 12/22-pole and three-phase FSPM machines are artfully integrated and thus a compact structure and lower torque ripple can be obtained. It has three basic parts: an outer stator, a middle rotor and an inner rotor. Three parts are separated by two air gaps but coupled magnetically. The proposed FSPM-DR machine can be regarded as an integration of the two machines, namely, the outer machine which are composed of the outer stator and the middle rotor, and the inner machine which are composed of the inner rotor and middle rotor. III. Loss analysis *A. Conductor eddy current loss* In the FSPM-DRM, the copper loss consists of two parts: the DC copper loss and the conductor eddy current loss. Skin effect and proximity effect are the two effects that make the current density distributions in windings non-uniform, and thus produce the conductor eddy current loss. 1) Analytical method As the conductor diameters of the inner and the outer machines are smaller (1.4mm and 1.18mm) than the skin depth at the even 7 times of rated speed (1.51mm), the skin effect loss in FSPM-DRM is negligible. Usually, the current density throughout the slot area is supposed as uniform to simplify the proximity loss calculation. In this paper, to accurately evaluate FSPM-DRM's performance, two kinds of slot shapes in the FSPM-DRM and the variations of the flux densities in the slots with radial and tangential directions are taken into account in the proximity loss calculation. 2) 2D FEA method A 2-D FE model is also used for the prediction of the conductor eddy current loss, where the windings' coils are driven with three phase sinusoidal and balanced current waveforms. Individual winding conductors are represented within the FE model. The current distributions of the inner and the outer slots at certain rotor position are also shown in Fig.1(c). As can be seen, the current densities in those conductors that located near the slot opening regions have the greatest change for both inner and outer slots. And it is the same for the conductors near the tangential center region of the outer slot. In other words, the conductors closest to these regions experience the highest induced conductor eddy current loss, which is helpful for conductor's placement design. *B. Other losses* In this paper, the iron loss of the outer stator, the middle rotor, and the inner rotor, and the PM eddy current loss in the FSPM-DRM are obtained by a 2-D FEA model. Fig.1(d) shows the variations of the iron loss, PM eddy current loss, and the conductor eddy current loss with the q-axis current. It displays that the eddy current loss of armature winding in the FSPM-DRM is smaller than the iron loss at rated load, while it increases much faster with the frequency and current density than the iron loss and PM eddy current loss. The mechanical loss including the bearing and the windage loss is about 2.5% of the rated power. Since the bearing loss cannot be considered in the 2-D FEA, only the windage loss which is approximately 55%~65% of the mechanical loss is assumed in the loss analysis. IV. Efficiency Table I lists the FSPM-DRM's losses and efficiencies at various operation conditions. The inner and the outer machines both exhibit excellent efficiencies in different operation areas and wide speed range, which is favorable for HEV applications [3][4]. V. CONCLUSIONS A prototype machine of the FSPM-DRM was designed and manufactured for the testing facilities (Fig.1(b)). An improved analytical scheme and a 2-D FE simulation model of conductor eddy current loss are presented. There is a relatively good agreement between the two results. The iron losses and PM eddy current losses in different parts at various operational modes are also calculated. From the comparisons of the efficiencies from FEA simulation and experimental verification, we can see the similarities of machine's electromagnetic performances, as well as, the differences, which is helpful for machine design and performance optimization.

Abstract - In this paper, we study the robust torque control of wireless tram with independently rotating wheelsets (IRWs). IRWs require active control of traction torque and lateral restoring torque. In this system, the required torque must have high precision and quick response, and it is necessary to perform robust control under various driving conditions. However, FEA is a numerical analysis that assumes various ideal conditions, it is difficult to consider the actual controller and driving conditions. As a result, there is a difference between the FEA results and the actual experimental results. In this paper, we have studied torque control considering driving condition through motor-inverter co-simulation. The simulation result was verified through dynamo test. 1. Introduction In a conventional Railway vehicles, wheels joined together by a solid axle, requiring only traction torque for driving. In this wheelset, the control is relatively simple, but the snake motion occurs at high speed and the wear between the wheel and the rail largely occurs. This problem can be solved by IRWs [1], but there is a disadvantage that control becomes complicated. In IRWs, lateral restoring torque is additionally required for existing traction torques. At this time, the lateral restoration torque generates the steering force using the difference in the left and right wheel torque. The lateral restoring torque is relatively small compared to the traction torque, but requires a high bandwidth, so the total torque is as shown in Fig.1. In addition, since the wireless tram is driven by a battery, torque control is required stably even if voltage fluctuation occurs due to charging and discharging. 2. torque control method When the current command is calculated in real time, the load of the DSP is increased and it is difficult to consider the driving condition, so that the torque error is large. In this section, we discuss how to configure the offline current table to perform robust torque control in IRWS. In order to perform robust torque control in the driving condition, d-q axis current commands are required in consideration of changes in four variables (speed, required torque, battery voltage, and temperature). Temperature changes affect the magnetic flux value of the permanent magnet. This method requires excessive FEA analysis and experimentation. However, since the linkage flux in the motor contains speed and battery voltage information [2][3], it is possible to simplify it by affecting three variables (linkage flux, required torque, temperature). In addition, if samarium cobalt is used as a permanent magnet, it can be reduced to two variables (linkage flux, required torque) since the magnetic flux change with temperature is small. As a result, it is possible to perform robust torque control considering the train vehicle driving conditions with only two variables. This method can greatly reduce the number of experiments. When the FEA is used in the simulation, the magnetic flux can be directly obtained, so the current command(LUT) of the two variables (linkage flux, required torque) can be easily obtained. In addition, there is an advantage that nonlinear and cross-saturation effects can be considered. However, since it assumes ideal conditions like a sinusoidal current source, it differs from the actual driving conditions and the error increases for this reason. In actual motors, there is influence on carrier frequency and dead time, and magnetic flux is estimated by IPMSM voltage equation. In order to take into account the actual effects, the current command(LUT) was obtained using the motor-inverter co-simulation, and the result was more similar to the actual motor test result D, q axis inductance determine the motor characteristics and affect the control performance. The inductance results using the co-simulation differ from the FEA results in the saturation region. 3. conclusion The simulation result was verified through dynamo test as shown in Fig 2. The results (current command, d-q axis inductance) are compared and the analysis of the results will be discussed in detail in the full paper.

HU-13. Investigation of Flux Modulation Effect on Double-Side-Excited Permanent Magnet Vernier Machine with Various Magnet Topologies.

M. Jiang[1] and *X. Zhu*[1]
1. School of Electrical and Information Engineering, Jiangsu University, Zhenjiang, China

I. Introduction Vernier permanent magnet (VPM) machines, as a member of harmonic machine family with feature of low-speed and large-torque, have attracted increasing concerns and interest. Due to the flux-modulated effect or magnetic gear effect, the VPM machine often possesses an outstanding torque capability, which is considered as one of the promising candidates in direct-drive applications, such as electric vehicles (EVs) and wind power generation [1]. Based on the concept of flux modulation, many studies focus on the exploration and innovation of the topologies of VPM machines in recent years. In [2], a VPM machine with surface-mounted PM rotor topology is proposed and investigated, which verifies that a desirable torque capability is obtained. Yet, the whole machine structure exhibits a bulky size to some extent, which limits its improvement of torque density. To solve this problem, a spoke-type VPM machine is proposed in [3], where an enhanced flux-modulated effect is realized. And the results reveal that an improved torque density is achieved in such machine. It is noted that the serious flux leakage in rotor and relatively low power factor are still the key problems for realizing the development of the machine. Recently, a new type of VPM machine employing two set of PMs is proposed, where the one is located on the stator and the other on the rotor [4]. In such design, the modulated harmonics are produced together by the two set of PMs, offering an improved power factor. However, the PMs in machine stator adopt the form of the Halbach array, and they are located in the stator slot opening. So the requirement of manufacturing and assembly technology is relatively strict, and a relatively serious flux leakage phenomenon still exists in the air-gap. Thus, how to make the most of the flux-modulated effect to design a high performance VPM machine is becoming a hot research orientation and full of full of challenge. In this paper, by incorporating the design concept of dual-PM-excited into the VPM machine, a double-side-excited permanent magnet vernier (DSE-PMV) machine with three various PM topologies is proposed and investigated. By using the unique design of the double-side PM excitation, the modulated working harmonics in the air-gap magnetic field will be abundant and enhanced. It contributes to realizing the design of a high performance VPM machine. II. Motor Topology and Simulation Results Fig.1 shows the whole design concept of the proposed DSE-PMV machine, where three different PM topologies of model I, model II, and model III are presented. It can be seen that the PMs in stator are derived from the external part of rotor PMs, which aims at the full utilization of the PMs. It is noted that the similarity among the three models lies in the same design of the rotor PM topology, which utilize the spoke type PM and tangential magnetization. Meanwhile, the difference among them is the various PM topology designs in stator, consisting of entire PM design with radial magnetization, segment PM design with radial magnetization, segment PM design with tangential magnetization, as shown in Fig. 1 (a), (b) and (c). The specific three topologies of the DSE-PMV machine are illustrated in Fig. 2. Fig.3 depicts the flux distributions of the DSE-PMVs with the three PM topologies. The no-load air-gap flux density curves of the DSE-PMV machine are calculated and compared in Fig. 4. It can be seen that the peak value of the air-gap flux density in Mode III is relatively low but Model I and Model II have a higher peak value. At the same time, the corresponding harmonic spectrum analysis of air-gap flux density is given in Fig. 5. Obviously, the amplitude of the fundamental and high-order harmonic of the Model II is higher than the other two, and the sum of amplitude of the neglected harmonics are comparatively small. It means that the Model II has better flux modulation effect than others. In addition, the back-EMF characteristics of the DSE-PMV machine are presented in Fig. 6. Obviously, from the figure, the back-EMF waveform of the Model II is more sinusoidal than other two models, indicating that it will possess a relatively low cogging torque among the three models. Besides, it can also be observed that the amplitude of Model II is slightly higher than the other two models. It means that a relatively high PM utilization is achieved in the model, which agrees with the analysis results in Fig. 4 and 5. The cogging torque performances of the DSE-PMV machine three PM topologies are also investigated and compared, as depicted in Fig. 7. It can be found that, as expected, the Model II achieves the minimum cogging torque, which is in accordance with the analysis results in Fig. 6. And the amplitude of the cogging toque in Model II reaches 2Nm. In conclusion, the above study results reveal that the DSE-PMV machine with the PM topologies of Model II has better performances, such as higher torque capability and lower cogging torque. More detailed theoretical analysis and experimental results will be given in full paper.

HU-14. Investigation of Dual Stator Spoke Type Vernier Machine for EV Application.

K. Jung-Woo[1] and B. Kwon[1]
1. Electronic Engineering, Hanyang University, Ansan, The Republic of Korea

I. INTRODUCTION Recently, vernier machines have been nominated for EV applications numerously [1-3]. The attractive features of vernier machine for EV applications are a reduction of volume due to the removal of gearbox [4], and high power density owing to magnetic gear effect, also called as vernier effect. However, one of the critical issues for vernier machine on EV application is the low power factor. To enhance power factor of vernier machine, various methods and topologies were suggested continuously [5]. Especially, one stator-spoke type vernier machine was suggested to increase power factor with the use of flux focusing effect. However, it had flux bypass issue that reduced vernier effect [6]. To solve the issue, dual stator spoke type vernier machine (DSSTVM) uses dual stator to permit flux as additional flux path [7]. DSSTVM eventually realized flux focusing effect to boost torque thus high power factor. However, the study of DSSTVM had been limited to the combination of 12 slots and 20 poles [8]. In this paper, the comparative study of different slot/pole combination DSSTVMs with different winding configurations to find a suitable model for the EV application is done. Power density per volume and weight is a critical feature for light weighted EV. Additionally, good flux weakening capability for wide speed range and high efficiency for less energy usage is required for future EV application. Hence, comparisons of different models of DSSTVM with the aspect of back-emf, torque, power density, power factor, loss, and efficiency are done. The top priority of the work was to find the best model for EV application in overall performance and to discover various trade-off relationships for each machine with differences they are given. Finite element method (FEM) analysis is utilized for the overall performance comparison. II. DESIGN OF COMPARISON MODELS Based on 12S20P DSSTVM, 12S22P DSSTVM was designed using the same constraints such as outer diameter, stack length, airgap volume, phase turns, and magnet volume. Both machines utilized spoke type magnet arrangement for flux focusing effect and dual stator to compensate the flux bypass issue, which was aforementioned. Two models 12S20P and 12S22P were wound with two different winding configurations, concentrated winding and distributed winding. Especially, for distributed winding, 12S20P and 12S22P had a different number of slot pitch for one phase coil. Accordingly, the length of each coil was different and thus different copper loss was expected. All the models used two different airgaps, 1.0 mm in the outer airgap, and 0.5 mm in the inner airgap. Also, stator tooth size of both outer and inner stator was same for both 12S20P and 12S22P model. Operating frequency of the machine was different for each model due to different magnet pole numbers. Since the 12S22P model has a higher frequency, it was expected that the 12S22P model will cause more iron loss than the 12S20P model. Additionally, it was predictable to find distributed winding models to have higher power density due to higher back-EMF and higher vernier effect. III. RESULTS AND DISCUSSION The analysis model of FEM Model I - 12S20P and Model II - 12S22P DSSTVM was shown in Fig. 1. Back-emf and output torque FEM analysis results of each model according to different winding configurations were compared in Fig. 2 (a) and (b). As shown in the figure, Model I with distributed winding achieved highest back-EMF and torque. However, it showed large torque ripple due to a relatively less sinusoidal back-EMF waveform. On the other hand, Model II with distributed winding showed extremely low torque ripple with little less torque compared to the Model I. Loss and efficiency of each model were shown in Fig. 2 (c). From Fig. 2 (c), it can be seen that Model II with distributed winding achieved the highest efficiency, higher than Model I with distributed winding, due to its lower copper loss. Each model, Model I - Concentrated, Model I - Distributed, Model II - Concentrated, and Model II - Distributed showed power density of 9.79, 18.05, 8.68, and 16.5 kW/mm^2 at 100 rpm, respectively. All models achieved power factor higher than 0.9. Consequently, Model II - Distributed was the best for EV application in an aspect of torque performance and efficiency at 100 rpm. Additional studies for more combinations of DSSTVM will be done in the full paper. Equations for back-emf, torque, and flux weakening capability of DSSTVM will be used to predict the performance. Then, a thorough comparison of each model will be done with FEM analysis to show the tendency of trade-off relationships and to show which model is the best. Efficiency map of each machine will also be presented in the full paper.

HU-15. Hybrid Rectangular Bar Wave Windings to Minimize Winding Losses of Permanent Magnet Machines for EV/HEVs over a Driving Cycle.

X. Fan[1], D. Li[1], R. Qu[1], C. Wang[1] and J. Li[1]
1. School of Electricity and Electronic Engineering, Huazhong University of Science and Technology, State Key Laboratory of Advanced Electromagnetic Engineering and Technology, Wuhan, China

I. Introduction The utility of thick rectangular wire wave windings in electrical machines for electrical vehicle/hybrid electrical vehicles (EV/HEVs) have gained increasing interest due to its high slot filling factor, short end-winding, good manufacturability and excellent heat dissipation capability, etc. [1]. More EV makers tend to adopt this kind of windings in their new generation EV motors [2] [3]. However, significant eddy current losses may be induced in the thick bars especially at a high speed operation, thus reducing the machine efficiency and may cause winding local overheating. The conductor in a slot suffers from the circumferential flux caused by the armature (blue) and the radial flux caused by the magnet (red), as shown in Fig. 1 (a). The magnitude of radial flux density caused by the magnet and the circumferential flux density caused by the armature along the center line is shown in Fig. 1 (b). It can be seen that the flux density dramatically decreased as the distance to the stator bore increases. This means the conductors in the slot near the slot opening are exposed to a relatively large variable field by magnet and armature and significant AC losses may occur. Some methods have been reported to reduce the AC losses in the existing papers [4]-[6]. Reference [4] shows that the AC losses can be reduced by keeping the conductors away from the slot opening or using the magnetic wedge. Reference [5] and [6] reduce the AC losses by choosing an optimal winding layout and stranding the conductors, respectively. This paper proposes a novel hybrid rectangular bar wave winding consisting of copper bars and aluminum bars to reduce the winding losses. The aluminum bars are located close to the slot opening to suppress the induced AC losses for its high resistivity. It shows that the total winding losses can be reduced with the hybrid winding compared to with the conventional copper winding, especially at high speeds and light loads. Besides, the weight and cost can be also reduced. Further, an optimization method is proposed to minimize the winding losses over a given driving cycle. The areas of the copper and aluminum bars and the distance of conductor to the slot opening are optimized using this method. II. Proposed Hybrid Thick Rectangular Wire Wave Windings A stator winding with four layers of conductor bars in one slot is used to illustrate the concept of the hybrid windings. Fig. 2 shows the stator with conventional copper winding and the hybrid windings. The detail layout of the conductors in the slot is depicted in Fig. 3. It can be seen that the aluminum bars of the hybrid windings are located in the first two layers close to the slot opening. This layout can be beneficial to suppress the eddy current loss induced by the variable field close to the slot opening for the high resistivity of aluminum. Furthermore, the use of aluminum can also reduce the weight and cost of the windings, which is very important for the machines used in EV/HEVs. The defect of the hybrid winding is the possible electrochemical corrosion happened at the joint between the copper bars and aluminum bars. This can be solved by using transition joints or a special welding procedure. III. Comparison with the Conventional Rectangular Bar Wave Windings Two permanent magnet traction motors having the same geometry and parameters except for winding materials are designed to demonstrate the potential superiority of the hybrid winding over the conventional copper windings, as shown in Fig. 4. Each conductor bar of the two windings has the same area. The winding losses with two different speeds and current levels are calculated for the two windings by finite element method (FEM). The results are listed in Table I. It has to be noted that the end-winding losses are also included to consider the low AC effects in the end-winding. It can be seen from Table I that the winding losses can be effectively reduced with the hybrid winding at a high speed and light loads. The current density distribution in the conductors can be also reduced, as shown in Fig.5. Even though the hybrid winding increase the winding loss at a low speed and heavy load, the total losses of the hybrid winding over a driving cycle may be less than that of the conventional winding. Therefore, a comparison of the losses of the two windings according to a given driving cycle is required, which will be reported in the full paper. IV. Minimizing the Winding Losses over a Given Driving Cycle An optimization method is proposed to minimize the winding losses over a given driving cycle. A typical used driving cycle is shown in Fig. 6 (a). The optimization variables are the area ratio of the aluminum bar to the copper bar l_a/l_c and the distance of the conductor to the slot opening D_c (shown in Fig.6 (b)). The detail of the optimization method will be presented in the full paper. V. Conclusion A novel hybrid rectangular bar wave winding consisting of copper bars and aluminum bars is proposed in this paper. The aluminum bars are located close to the slot opening to suppress the AC losses. It shows that the total winding losses can be reduced with the hybrid winding compared to with the conventional copper winding, especially at high speeds and light loads. An optimization method is proposed to minimize the losses of the hybrid winding over a given driving cycle. The areas of the copper and aluminum bars and the distance of conductor to the slot opening are optimized using this method. More results will be reported in the full paper.

HU-16. Reduction of Vibration and Acoustic Noise in Fractional-Slot Concentrated-Windings Permanent-Magnet Machine.

S. Zhu[1], W. Zhao[1], J. Ji[1] and J. Zheng[1]
1. School of Electrical and Information Engineering, Jiangsu University, Zhenjiang, China

Introduction Due to the advantages of high efficiency, high power density, and high fault-tolerant capability, the fractional-slot concentrated-windings permanent-magnet (FSCW-PM) machines have received increased attention. [1]. However, the abundant harmonics in FSCW-PM machines will produce low-order radial electromagnetic force, thus aggravating the vibration and acoustic noise performances [2]. Therefore, many magnetomotive force (MMF) harmonic reduction techniques were proposed [3], but their abilities to reduce the low-order radial electromagnetic force were relatively poor. The purpose of this paper is to analyze the generation mechanism of low-order radial electromagnetic force from different magnetic field components, and a new design will be proposed to reduce the vibration and acoustic noise of FSCW-PM machines. New design Due to the interaction of tooth harmonics and fundamental magnetic field, the lowest order radial electromagnetic force will be generated in FSCW-PM machine, thus resulting in vibration and acoustic noise. Fig. 1 compares the stator structure of two existing and proposed machines. In the proposed unequal tooth stator, the angle of two adjacent opening-slots has been designed to control the MMF amplitude of each harmonic component. It should be noted that the fundamental wave keeps constant with the existing one, so the output performance is unchanged. However, the tooth harmonic is weakened effectively. Results In order to verify the proposed machine, the finite-element method and acoustic boundary-element method are employed to evaluate vibration and noise performances. The MMF and radial electromagnetic force between the existing and proposed machines are compared in Figs. 2 and 3, respectively. The proposed machine can effectively weaken the tooth harmonics and the radial electromagnetic force which plays a significant role in the vibration and acoustic noise of FSCW-PM machines. Fig. 4 compares the vibration spectrum between the existing and proposed machines. It can be seen that the proposed one has 12% lower vibration than the existing one. Finally, the sound power level spectrum of the proposed FSCW-PM machine is given in Fig. 5. Resonance does not occur because of the large difference between the electromagnetic force frequency and the modal frequency.

I. INTRODUCTION Three-dimensional magnetic recording using microwave assisted magnetic recording (MAMR) has been proposed as one of the prospective recording technologies which uses a spin-torque oscillator (STO) as a reading sensor as well as a write-assisting device [1]. In the reading process using an STO, the reproducing waveform is given as temporal dynamics of magnetization [2]. The amplitude of STO oscillation waveform decreases as the STO comes close to the recorded dot of "0", and the amplitude increases again as it leaves from the recorded dot of "0" [3]. The recorded dot "1" few influence on the amplitude. Therefore, we cannot discriminate whether the dead dot or recorded dot of "1". However, the STO which reacts to the recorded dot of "1" can be produced by adjusting the resistance, the direct current, the external magnetic field, and so on [4]. In this research, we propose the envelope demodulation using two temporal magnetization dynamics from dual STO, and evaluate the bit error rate (BER) performance of R/W channel with dual STO by the computer simulation. II. READ/WRITE CHANNEL MODEL Figure 1 shows the temporal magnetization dynamics of the STO for the diameter of dot equals 20 nm and the envelope model obtained by the convolution of the attenuation function [3] using the STO #1 which reacts to recorded dot of "0", where the recorded data pattern is "000111000111" as shown in bottom of Fig.1. In this study, the relative velocity between the medium and the STO, the dot diameter and pitch are 20 m/s, 20 nm and 25 nm, respectively. The dashed and solid lines show the temporal magnetization dynamics and the reproducing envelope model, respectively. The x-axis shows the time normalized by the channel dot pitch interval T_c. As can be seen from Fig. 1, the amplitude of STO oscillation waveform decreases as the STO comes close to the recorded dot "0", on the other hand, as it leaves from the dot of "0", the amplitude increases again. In this research, we assume that the STO #2 reacts to the recorded dot of "1" as the opposite reaction of the STO #1. In the evaluate system, the input data sequence is recorded on the dots composed of perpendicular soft and hard layers antiferromagnetically coupled (AFC) with each other. The AFC structure reduces the net stray field and that is suitable for multi-layered media [5]. The STO #1 and #2 scan on the same recorded dots or the same track. We assumed that the system noise at the reading point for the envelope is the additive white Gaussian noise (AWGN) whose power in the band width equal to the channel dot rate $f_c = 1 / T_c$ is given by σ_s^2. Then, we define the signal-to-noise ratio (SNR) of the saturation envelope level of STO magnetization A and the effective value of system noise σ_s as $\mathrm{SNR}_S = 20 \log_{10} A / \sigma_s$ [dB]. The reproducing envelope sampled by the T_c interval is fed to low-pass filters (LPF) with the cut-off frequency x_h normalized by f_c in order to suppress excessive high frequency noise. The LPF output for STO #2 is subtracted from the output from STO #1, and is fed to the finite impulse response (FIR) filter with N_t taps to be equalized to the partial response class-I (PR1) [6]. The output is decoded by the Viterbi detector. III. SIMULATION RESULTS AND DISCASSION Figure 2 shows the BER performances, where $x_h = 0.5$ and $N_t = 15$. The open square, open triangle and filled circle symbols show the BER performances using the STO #1, STO #2, and the proposed dual STO, respectively. The vertical and horizontal axis show the BER performance and SNR_S. As can be seen from the figure, the BER performance of the proposed system using dual STO shows the better than the single STO systems. The SNR improvement at a BER of 10^{-4} is about 2.7 dB by the effect of averaging the system noise. Furthermore, the system using dual STO can detect dead dots by the lack of signal become possible by using envelopes from dual STO. IV. CONCLUSIONS We proposed the envelope demodulation using two temporal magnetization dynamics from dual STO, and evaluated the BER performance by the computer simulation. The results show that our proposed system provides the SNR improvement of 2.7 dB at a BER of 10^{-4}. Furthermore, it makes the dead dot detection possible. HV-02. Two-dimensional Signal Processing Systems Using CRC-polar Coding and List Decoding for Bit-patterned Magnetic Recording.

H. Saito[1]
1. School of Advanced Engineering, Kogakuin University, Tokyo, Japan

I. INTRODUCTION In this research, a new effective signal processing scheme is proposed for a two-dimensional magnetic recording (TDMR) system using bit-patterned media (BPM). The proposed signal processing scheme uses concatenated cyclic redundancy check polar (CRC-polar) codes [1] as modulation codes and a non-binary low-density parity-check (LDPC) code as an error-correction code (ECC). In decoding process, successive-cancellation list (SCL) decoders [1] are introduced. These SCL decoders are expected to give an error rate performance improvement to the successive cancellation decoder of [2]. In these list decoder, several decoding paths are considered concurrently at each decoding stage. At the end of the decoding process, the most likely path among these survived paths is selected as the single codeword at the decoder output. II. PROPOSED SIGNAL PROCESSING SCHEME FOR TDMR Fig.1 shows the block diagram of the proposed signal processing scheme for a TDMR system using BPM. In Fig.1, $2N$+1track recording is assumed for the TDMR system. In this read/write system, a raw data sequence $\{a_k\}$ is input into a CRC precoder and *parity* (dummy) symbols are inserted in the CRC sequence. These dummy symbols are used to give run length limited (RLL) constraints in the both of cross-track and down-track directions. The (d_1, k_1, d_2, k_2)-RLL constraint sequence outputted from the CRC precoder is the precoded sequence $\{b_{i,k'}\}$ and is recorded on the i-th track. The sequence $\{b_{i,k'}\}$ is transformed into the systematic polar codeword sequence. In polar encoding, systematic encoding with bit-reversal is assumed using a cascade of two non-systematic polar encoder circuits [3]. The $2N$+1 binary polar codeword sequences are input to the systematic 2^{2N+1}-ary LDPC encoder and transformed into a LDPC codeword sequence $\{c_{i,k'}\}$. After LDPC encoding, the interleaver Π takes incoming block of the LDPC codeword sequence and rearranges the sequence in a different temporal order. The arranged sequence is NRZ-recorded on islands made of the discrete double layered perpendicular magnetic medium with a soft under layer. These islands are arranged on a rectangular grid in the surface of recording medium. For the readback TDMR channel, the readback signal of BPM is represented by the 2D Gaussian pulse response given by [4] and the normalized peak amplitude is A_p. In this system, the parallel readback signal sequence $\{r'_{i,k'}\}$ is obtained by combining readback signal sequences from several adjacent tracks. In Fig. 1, $r'_{i,k'} = (r_{i-N,k'},\ldots,r_{i,k'}\ldots,r_{i+N,k'}) + (n_{i-N,k'},\ldots,n_{i,k'},\ldots,n_{i+N,k'})$, where the sequence$\{r_{i,k'}\}$is the readback signal sequence from the i-th track and the noise sequence $\{n_{i,k'}\}$ is added at the reading point. The sequence $\{n_{i,k'}\}$ is additive white Gaussian noise (AWGN) with zero mean and variance. The reproducing waveform corresponding to the recording sequences readback by the reading head is inputted into the equalizer which consists of a 2D low-pass filter (LPF) and the 2D transversal filter (TVF). The equalization is performed so that the overall characteristic between the input of recording head and the output of the equalizer is equal to the aimed 2D generalized partial response (GPR) targets. The equalizer output sequence $\{y'_{i,k'}\}$ is obtained which sums equalizer output sequences from several adjacent tracks. In the equalizing process, tap-gain coefficients in the 2D TVF are evaluated by minimizing the expectation of the mean square error (MSE) $E(\{e_{i,k'}\})$, where the sequence $\{e_{i,k'}\}$is the equalized error sequence between the ideal GPR target output sequence $\{d_{i,k'}\}$ and the sequence $\{y_{i,k'}\}$. The signal-to-noise ratio (SNR) at the reading point is defined as the ratio of A_p and the noise power of AWGN. In decoding process, the equalizer output sequence $\{y'_{i,k'}\}$ is decoded by the 1D log-likelihood ratio (LLR) detector and and the estimated LLR sequence $\{L(c'_{i,k'})\}$ is given as the detector output. The sequence $\{L(c'_{i,k'})\}$ is decoded by the sum-product algorithm in the LDPC decoder. After the recursive decoding process, we know the all $2N$+1 LLRs for each $L(c'_{i,k'})$. The sequence $\{L(c'_{i,k'})\}$ is needed to convert the *channel level likelihood ratio* (CLLR) sequence $\{\Lambda(c'_{i,k'})\}$. The estimated sequence $\{c'_{i,k'}\}$ is given as the detector output. The sequence $\{c'_{i,k'}\}$ is decoded by CRC-aided SCL decoders. After frozen symbols are eliminated, we get the estimated precoded sequence $\{b'_{i,k'}\}$. At the end, the estimated output data sequence $\{a'_k\}$ is obtained after demodulation. The block error rate (BER) performance is evaluated by computer simulation between the sequences $\{a_k\}$ and $\{a'_k\}$. III. ERROR RATE PERFORMANCES Fig. 2 shows the BER performances of the coded generalized partial response systems. In Fig.2, the solid line show the BER performance of the proposed coding scheme with the (0,3,0,3) run-length limited (RLL) constraint using four-track recording. The dashed line shows the performance of the conventional binary LDPC coding scheme [5] with the (0,9) RLL constraint using single-track recording. These coding scheme have the effective transmission rate = 2.6, 0.93, respectively. The recording condition corresponds to the areal density of 4.0 Tb/in^2 given by [4]. As can be seen Fig. 2, the proposed coding scheme using four tracks outperforms that of the conventional coding scheme using a single track by about 6.0 dB of SNR gains at a BER of 10^{-5}. IV. CONCLUSION In this digest, a new signal processing schemes using CRC-polar coding and LDPC coding is proposed for a TDMR system.

HV-03. Performance of Bit-Patterned Media Recording According to Island Patterns.

S. Jeong[1], *J. Kim*[1] and J. Lee[1]
1. Soongsil University, Seoul, The Republic of Korea

To increase a density in hard disk drive, bit patterned media recording (BPMR) is regarded as a promising candidate for the next generation storage system. Reduction of spacing between bit islands is essential to increase the density in BPMR but causes inter-symbol interference (ISI) and inter-track interference (ITI). Islands can be arranged on a rectangular pattern (regular array) or packed in a staggered pattern (hexagonal lattice), depending upon the lithography approach adopted in BPMR. Since the staggered pattern can mitigate the effect of the ITI due to the presence of adjacent tracks, bit error rate (BER) performance of staggered pattern is better than that of rectangular pattern in previous study. In another work of channel modeling for staggered pattern, the staggered pattern with bit-aspect ratios (BAR) =Track Pitch (T_z) / Bit Length (T_x) of 2 performs better than the staggered pattern with BAR of 1. In this paper, we investigate the performance of BPMR island patterns according to the distances of track pitch and bit length, respectively. Fig. 1 presents BER performance of island arrangement according to areal densities of 2 Tb/in^2 and 3 Tb/in^2. When the areal density is 2 Tb/in^2, (T_x = 15.5nm, T_z = 21.0nm) provides best performance. Also, when the areal density is 3 Tb/in^2, (T_x = 13.0nm, T_z = 17.0nm) shows best performance. Fig. 2 illustrates BER performance in accordance with island arrangements. Case (1) represents the arrangement of islands that distributed over a rectangular array at T_x of 18.0nm and T_z of 18.0nm in 2 Tb/in^2 and T_x of 14.5nm and T_z of 14.5nm in 3 Tb/in^2. Case (2) represents the arrangement of islands that distributed over a staggered pattern at T_x of 21.0nm and T_z of 15.5nm in 2 Tb/in^2 and T_x of 17.0nm and T_z of 13.0nm in 3 Tb/in^2. Case (3) represents the arrangement of islands that distributed over a staggered pattern at T_x of 18.0nm and T_z of 18.0nm in 2 Tb/in^2 and T_x of 14.5nm and T_z of 14.5nm in 3 Tb/in^2. Case (4) represents the arrangement of islands that distributed over a staggered pattern at T_x of 15.5nm and T_z of 21.0nm in 2 Tb/in^2 and T_x of 13.0nm and T_z of 17.0nm in 3 Tb/in^2. Since the influence of adjacent tracks of Case (4) is less than that of Case (1), Case (2), and Case (3), i.e., the effect of ITI is reduced, Case (4) shows the best performance in both 2 Tb/in^2 and 3 Tb/in^2.

HV-04. A Rate-5/6 2D Modulation Code for Single-Reader/Two-Track Reading in BPMR Systems.

K. Buahing[1], W. Busyatras[2] and *C. Warisarn*[1]

1. College of Advanced Manufacturing Innovation, King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand; 2. Faculty of Science and Technology, Rajamangala University of Technology Thanyaburi, Pathumthani, Thailand

I. Introduction A reduction in the track width of magnetic recording systems results in a welcome increase in areal density (AD), but also in the unfortunate appearance of extreme inter-track interference (ITI) that can severely deteriorate system performance. The effect of severe ITI may be mitigated through the use of coding schemes [1]. In this paper, therefore, we present a rate-5/6 two-dimensional (2D) modulation code that is designed based on a proposed single-reader/two-track reading (SRTR) technique to cope with this serious problem in staggered bit-patterned media recording (BPMR) systems. We then evaluate the bit-error rate (BER) performance of the proposed system in the presence of media noise, e.g., position and size fluctuation. Our simulation results indicate that, at the same user density (UD), the proposed system is better than an uncoded system by about 1.0 dB at the BER of 10^{-5} and is also superior to a conventional recording system. II. BPMR Channel Model We consider a hexagonal island with a diameter of 12 nm and a bit period of 16.0 and 14.5 nm, which correspond to the ADs of 2.5 and 3.0 Tb/in^2, respectively. The bit islands were arranged as a staggered array and covered with a readhead sensitivity response [2] as shown in Fig. 1. The readback signal is simply obtained from the 2D convolution between the magnetization and the readhead sensitivity response of the reader whose track width covers more than two whole neighboring tracks. The center of the readhead sensitivity function is positioned at the intermediate point between the parallel tracks. Then, the readback signal is further corrupted by electronic noise. To obtain the sample amplitudes, the readback signal is perfectly over-sampled at the sampling period, $0.5T_x$, that is located at the centers of the recorded magnetization. Next, the readback data sequence, r_k is equalized by a 1D equalizer to obtain the data sequence, s_k, and is fed to the 1D Viterbi detector to produce estimated data sequences. Finally, this sequence will be rearranged to become two data sequences, i.e., $x'_{k,l}$ and $x'_{k,l+1}$ before being passed on to the proposed decoder to produce the estimated user bits. III. 2D Modulation Code We first analyzed the peak amplitude of all possible $2^6 = 64$ data patterns in a matrix form of 2×3 bits that were arranged as a staggered array BPMR, where the peak amplitudes of each data pattern were obtained from 2D convolution between their magnetizations without sidetrack data and readhead sensitivity response, as shown in Fig. 1. Since we found that the desired bit peak amplitude will always reverse in the opposite direction when the data bits of each pattern contain many 1's and -1's which easily causes an error during the data recovery process. To avoid this unwanted situation, therefore, this condition will be defined as a criterion for designing a codeword, which can efficiently avoid such destructive data patterns. Since we consider 6 data bits, there will be $2^6 = 64$ possible data patterns composed of: 2 bits in the first column [$x_{k,l}$, $x_{k,l+1}$], 2 bits in the second column [$x_{k+1,l}$, $x_{k+1,l+1}$], and lastly, 2 bits in the third column [$x_{k+2,l}$, $x_{k+2,l+1}$]. We have selected the best 32 data patterns that provide the biggest group from the same data bit. These patterns will then be assigned to become the proposed codewords. Then, we match the 5 input bits, a ≡ [a_k, a_{k+1}, a_{k+2}, a_{k+3}, a_{k+4}] with a 6-bit codeword, x ≡ [$x_{k,l}$, $x_{k,l+1}$; $x_{k+1,l}$, $x_{k+1,l+1}$; $x_{k+2,l}$, $x_{k+2,l+1}$]^T. Moreover, to create more accuracy in the decoding process, we have partially defined a mapping condition to create a codeword so that the first two input bits match the first column of the codeword, the second two input bits match the second column of the codeword, while the remaining one input bit corresponds with the upper track in the third column of the codeword. Unfortunately, 14 patterns that cannot match still remain after using the above conditions; however, these patterns are still among the 32 good patterns. Thus, they can output the appropriate readback signal. IV. Results and Discussion We compare the BER performance between 1) the proposed SRTR system performs together with the proposed 5/6 2D modulation code, 2) the proposed SRTR system [3], and 3) a conventional reading system which uses one reader, reads the data form one track i.e., an input sequence a_k is written onto a single track with random data on sidetracks. For a fair comparison, the staggered BPMR system performance should be compared using the UD. In this paper, the UD is defined as UD = AD×R, where R is a code rate. The signal-to-noise ratio (SNR) is defined as $10\log_{10}(1/\sigma^2)$ in dB, where σ is a standard deviation of AWGN. As shown in Fig. 2, it is clear that the proposed SRTR system that performs together with the proposed 5/6 2D modulation code at the UD of 2.5 Tb/in^2 is better than the uncoded SRTR system by about 1.0 dB at the BER = 10^{-5} and is superior to a conventional reading system. HV-05. Control Scheme for Read/Write Head Positioning in Dual-Stage Magnetic Disk Drive Servo System.

B. Shi[1,2], Y. Meng[1] and C. Jin[1]
1. School of Mechanical and Electrical Engineering, Shandong Jianzhu University, Jinan, China; 2. School of Mechanical Engineering, Hebei University of Technology, Tianjin, China

1.Introduction As we are in an era of information exploding, and more than half of the digital data is stored in magnetic disk drives[1], to increase storage capacity is one of the key issues for developing magnetic disk drives. Therefore, an accurate positioning servomechanism is required to achieve an ultra-high disk density. For a dual-stage actuated (DSA) disk drive servo control system, a large servo bandwidth is desirable to attain ultra-high accuracy in read/write head positioning. A lot of control techniques have been proposed for DSA servo control design, such as the LQG/LTR technique[2], nonlinear PID control strategies[3], tracking differentiator and H_∞ almost disturbance decoupling technique [4], and optimal decoupled disturbance observers approaches[5], composite nonlinear feedback (CNF) technique[6-7], etc. In the present study, we proposed a control scheme for the read/write(R/W) head positioning in dual-stage magnetic disk drive servo system using two controllers for a primary voice coil motor (VCM) actuator and a secondary micro-actuator (MA), respectively. Simulation results of the proposed control scheme are presented and compared with those of a single-stage actuated CNF method and a dual-stage linear feedback control (LFC) technique. 2.Design of the Control Scheme Figure 1 shows the identified model of the primary coarse VCM actuator [10]. The VCM model is simplified into a 4^{th}-order model as shown in the solid line in Fig.1. It is easily noticed that there is a resonant mode at 4240 Hz in the VCM actuator. For the primary VCM controller, a notch filter is designed to weaken the high frequency resonance of the VCM actuator. Furthermore, a lead compensator is designed to prevent the phase lose caused by the filter and to improve the stability of the control servo system. Finally, the VCM controller is designed by the combination of the notch filter and the lead compensator. The model of the secondary MA adopted in the present study is from [11]. The MA controller is designed using a integral resonant control (IRC) compensator [8-9] in series with a notch filter to adequately suppress the higher frequency resonance for the R/W head high-precision positioning. To make sure that the VCM and MA actuators will not be damaged from excessive voltage, the saturation functions are added respectively for the two actuators. Since large and fast motion is performed by the VCM actuator, while small and precise motion is executed by the MA, a switch function is added in the MA control loop to make sure that the MA is activated if the R/W head is within the reachable distance of its target track. 3. Simulation Example As an example, Fig. 2 shows the performance of the proposed control scheme for R/W head positioning in DSA disk drives. For comparison, those of a single-stage actuated CNF approach and a dual-stage LFC approach through simulation for seek length with 1 micron are also shown in Fig. 2. From Fig.2 we can see that: The R/W head positioning DSA system controlled by the scheme proposed in this paper moves the read/write head and settles on the target track within 0.55 ms with almost no overshoot, which is shorter than that, 1.2 ms, needed for the SSA CNF method to move the R/W head to the target position, while the LFC method has a much bigger oscillation. It is shown that the proposed control scheme for R/W head positioning in DSA disk drives is able to track accurately with a shorter settling time for head positioning to guarantee the robustness of the control servo system. 4. Summary A control scheme is proposed for R/W head positioning in dual-stage magnetic disk drive servo system using two controllers of the primary VCM actuator and the secondary MA. For the VCM actuator controller, we combine a notch filter and a lead compensator to eliminate its high frequency resonance and to prevent the phase lose for facilitating large motion. For the MA controller, we use the IRC compensator together with a notch filter to realize quick and precise positioning. The performance of the proposed control scheme is verified through a simulation example. Detailed procedure and process to design the control scheme and the servo system will be presented in the full paper with comprehensive simulation results and discussions to further verify the performance of the proposed control scheme for DSA servo system. *Acknowledgments* This work was supported by the National Natural Science Foundation of China (Grant No. 51275279), and the Tribology Science Fund of State Key Laboratory of Tribology (Grant No. SKLTKF16A01).

1.Introduction In channel coding theory, the performance of error correcting codes (ECCs) approaching the Shannon limit can be achieved through increasing code lengths. Unfortunately, the complexity of ECCs will be increased as the code length increases. Nowadays, the magnetic recording (MR) system takes advantage of powerful ECCs by using 4 Kbytes sector. Among the advanced ECCs, the spatially coupled LDPC (SC-LDPC) codes (also known as a LDPC convolutional code) [1] are shown to have the decoding latency and complexity lower than those of the underlying LDPC block codes (LDPC-BC). Moreover, the SC-LDPC codes with threshold decoding outperform the LDPC-BC codes [2]. Hence, the SC-LDPC codes are the strong candidate for the future MR systems, when the sector size is increased beyond 4 Kbytes. An SC-LDPC decoder can use sliding window decoding [3] whereby the received signals are decoded by sliding window along the bit sequence. The window decoder is called "*uniform window decoding (U-WD),*" when all variable nodes (VNs) within a window are updated. In order to reduce the complexity of window decoding, some researchers proposed the *non-uniform window decoding (N-WD)* [4], which do not update the VNs with no improvement in the bit error rate (BER). This approach provides about 35-50% reduction in complexity compared to U-WD. In this work, we consider the application of SC-LDPC codes in MR systems, whereby SC-LDPC decoder cooperates with BCJR detector to encounter inter-symbol interference (ISI). We propose the dynamic shifting of window decoding (DS-WD) to reduce the complexity of SC-LDPC codes. Herein, the number of shifted bits is defined according to their soft BERs which are estimated at each decoding position. In addition, we modify the N-WD [4] to reinforce our proposed algorithm called "*dynamic-shifting non-uniform window decoding (DS-N-WD).*" The DS-WD and DS-N-WD achieve the complexity reduction of 7% and 25% without any loss in performance compared to the N-WD algorithms. 2.Turbo equalization with SC-LDPC codes A *(J,K)*-SC-LDPC is constructed from a protograph represented by base matrix B [3]. The matrix B contain J and K ones in each column and row, respectively. The protograph is copied N times, and then the edges of each replica are connected among the N replicas to obtain the derived graph represented by parity-check matrix H. In order to explain the coupled codes, we first examine transmitting a sequence of L code blocks v_t, $t = 1,..,L$. An essential feature of the coupled codes are that the consecutive transmitted code blocks are connected. The coupling of consecutive code blocks can be obtained using the edge spreading procedure [3], which must satisfy the condition $B=B_0+B_1+..+B_{m\_cc}$ to maintain the original degree distribution of the protograph. The matrix B_i has n_c rows and n_v columns. To decode SC-LDPC codes in turbo equalization, after the BCJR detector receives the ensemble code blocks y_t from the channel, the detection process is performed corresponding to the designed channel targets. The produced LLR values of the BCJR detector are sent to SC-LDPC decoder with a window size of $W \geq m_{cc}+1$. Each decoding position covers the received code block y_{t+w-1}, $w =1,..,W$ and each code block contains Nn_v VNs. In Fig. 1, we give an example of (3,6)-SC-LDPC decoder of code rate $R = 1/2$ with $W = 4$ and the edge spreading procedure is defined as B= [3 3], where B_0, B_1 and B_2=[1 1]. At each decoding position t, the message passing decoding between the VNs and CNs within a window is performed until the maximum number of decoding iteration I_{LDPC} is reached. Then, the window is shifted to decode the next decoding position $t = t + s_t$, where s_t is denoted as the maximum number of code blocks shifted from the decoding position t. In the standard window decoding, s_t is set to be 1. 3.Reduced-complexity window decoding of SC-LDPC codes One possibility to reduce the window decoding complexity of SC-LDPC codes is to shift the multiple code blocks at the same time when the estimated soft BERs of each block are the same. The soft BER is estimated at the end of decoding process in terms of log(P(w)). Herein, the code block w is shifted when the equation $\alpha_w \log(P(w)) \leq \log(P(w-1))$, $w =2,..,m_{cc}+1$, is satisfied. Thus, we possibly choose s_t from 1 to $m_{cc}+1$. The shifting factor α_w must be chosen by the Monte Carlo simulation. We name the first proposed decoding algorithm as "the DS-WD algorithm." Moreover, we modify the N-WD algorithm to reinforce DS-WD called "the DS-N-WD algorithm." The DS-N-WD can stop updating some VNs in the window. Since the soft BER estimate of each code block depends on the number of shifted code blocks, the update schedules must be investigated corresponding to the number of shifted code blocks s_t. 4.Simulation results We consider the BPMR channels at the areal density of 2 Tb/in^2 [5]. The code rate of (3,21)-SC-LDPC is 6/7. The m_{cc} is set to be 2, therefore, B_0, B_1 and B_2 are [1 1 1 1 1 1 1]. The matrix H is generated using PEG method [6] with L and N =100. The W = 8, I_{LDPC} =30 and I_{Turbo} =3 are selected. The complexities of all decoding methods are compared by computing the average number of VN updates U_{avg}[4] required to decode the total length of coupled codes as shown in Fig. 2. We found that the DS-WD provides 40% and 7% reduction in complexity compared to the U-WD and N-WD, respectively at SNR=4.9*dB* without any loss in performance. The reductions of complexity are up to 53% and 25% when the DS-N-WD is applied.

Introduction In recent years, shingled magnetic recording (SMR) [1] has attracted attention as a new recording method of a hard disk drive (HDD). Although SMR can realize narrow track, it has remarkable performance deterioration due to the influence of inter-track interference (ITI) [2]. Therefore, improving the performance of the low density parity-check (LDPC) encoding / decoding method combining the LDPC code [3] and the sum-product (SP) decoding in the SMR is considered to be an effective means for further increasing the density of the HDD. In this study, we modify the log-likelihood ratio (LLR) calculated as the decoding reliability by the a posteriori probability (APP) decoder in the LDPC encoding / iterative decoding system, and observe the improvement of the decoding accuracy by computer simulation of the SMR of the plane recording density 4 T bits / inch^2 specification. As a result of iterative decoding by modifying the LLR corresponding to the parity check information "0" and "1", the tendency of error saturation was eliminated. Moreover, improvement of SNR to achieve error free was obtained. Read / write system Figure 1 shows the read / write system in SMR. The input sequence passes through the 128/130 (0, 16/8) RLL encoder and the LDPC encoder to be converted to the recording sequence, which is recorded on the discretized granular medium [4]. The LDPC code is composed of 4096 byte sector, and 30 sector of data sequence is written and read to obtain a bit error rate (BER) performance. An array head with three readers reads the recorded data from the three adjacent tracks, where the signal-to-ratio (SNR) at each reading point is defined as SNR = 20 $\log_{10}$ (A /σ_s) [dB] by the saturation level A of the isolated reproduction waveform and the RMS value σ_s of the system noise falling within the bandwidth equal to the channel bit rate f_c. Then, the reproduced waveform passes through an LPF (low-pass filter) with a cutoff frequency x_h = 0.4 normalized by f_c and a two-dimensional finite impulse response (2D-FIR) filter having the number of taps for a reader N_t = 15. The characteristic from the recording head to the 2D-FIR filter output is designed to be the partial response class-I (PR1) characteristic [5]. The APP decoder calculates the LLR using the constraint of PR channel from the 2D-FIR filter output sequence, as the decoding reliability. The SP decoder corrects the LLR using the LDPC code of parity check matrix, where i_{sp} is the maximum iterations of SP decoding. The SP decoder returns the improved LLR to the APP decoder as the extrinsic value. The SP decoder output sequence after the turbo equalization of maximum iteration i_{global} passes through the hard decision unit and the RLL decoder to obtain the output sequence. The BER can be obtained by comparing the input sequence and the output sequence. LLR modulator We propose introducing a LLR modulator to improve the SP decoding. First, the modulator checks the correctness of LLR. As the column weight of LDPC is 3, the parity check information sequence is composed of "0", "1", "2", or "3". In this study, we boost the LLR if the parity check information is "0" or "1", because the LLR is likely to be correct. If the LLR with parity check information "0" is larger than or equal to 0.30, it is multiplied by 3.0, and if the LLR with parity check information "1" is larger than or equal to 0.30, the LLR is multiplied by 1.15. Figure 2 shows the BER performance for SNR, where the iteration parameters are set to i_{global} = 17 and i_{sp} = 15. The symbols of red circle and green filled circle show the cases with and without the modulators, respectively. From the figure, it can be seen that the LLR modulator improves the SNR by 0.5 dB to achieve no errors. The results show that modifying LLRs using the parity check information provides an effective iterative decoding. Acknowledgments This work was supported in part by the Advanced Storage Research Consortium (ASRC), Japan.Introduction

HV-08. Thermal decomposition of the polymeric lubricant and the viscoelastic effects on the head-disk interface in heat-assisted magnetic recording.

P. Chung[1]
1. Energy Engineering, Inje University, Gimhae-si, The Republic of Korea

Magnetic recording system is currently evolving with the new recording techniques such as heat-assisted magnetic recording (HAMR) to drastically increase the areal density of the magnetic layer, while the thermal stability issues still exist on the lubricant layer. Specifically, lubricant molecules can cause the unexpected situations including the evaporation and contamination of the head and other components since the molecules can be chemically decomposed due to the cyclic thermal stresses with extremely high temperature [1,2]. Along with the thermal degradation, the contact between the slider and the disk causes the elongational stress on the intervening polymeric lubricant film so that the lubricant molecule can be mechanically decomposed as well as the anchored molecules can be also decoupled from the carbon overcoat [3]. Therefore, it is critically important to understand the molecular scale effects of the non-equilibrium perturbation on the decomposition and decoupling of the lubricant layers under the high temperature conditions to develop the sustainable lubricant materials for the HAMR systems. In this study, we investigated the thermal lubricant decomposition and the layer decoupling under the vertically elongational forces applied to the functional oligomeric film, which is similar as the contacting behavior between the head and the disk, by modeling the confined PFPE films with the static bottom and moving top substrates. To precisely estimate the thermos-mechanical molecular decomposition and decoupling phenomena, we utilized the full atomistic molecular dynamics, which fundamentally catches the intramolecular and intermolecular binding characteristics for the decoupling and decomposition phenomena in a few molecular systems. In addition, we performed the coarse-grained non-equilibrium molecular dynamics with the elongational deformation similar as the extensional flow experiment using atomic force microscopy (AFM) (Fig. 1) to investigate the the viscoelastic properties of the lubricant layers as a function of a portion of fragmented molecules, which is correlated to the thermos-mechanical conditions (e.g., temperatures, the length of heated cycles, and the elongation rate). Linear lubricants (Fomblins Ztetraol and ZTMD) as well as star-like lubricants (TA-30 and QA-40) were modeled for the lubricant layer to study the molecular structural effects on the lubricant decomposition. We also provide a nanostructural analysis of the lubricant layer for the future development of the HDI systems.

HV-09. Numerical Study of Particle Rebound on the Slider Air Bearing Surface.

F. Cui[1], *H. Li*[1], H. Shang[1], S. Shen[1], S. Wu[1] and S. Liu[2]
1. School of Power and Mechanical Engineering, Wuhan University, Wuhan, China; 2. Department of Mechanical Engineering, Colorado School of Mines, Golden, CO, United States

Higher areal density of hard disk requires the ultra-low flying height slider, which increases the probability of contact between the slider and hard disk surface. Micro and nanoscale lubricant droplets and metal particles produced in collision can enter the head-disk interface (HDI) and cause serious damage to the slider and hard disk [1, 2]. Our previous work has numerically investigated the air flow patterns, particle trajectories and interaction between particles and slider surface in HDI, which is of critical importance to the reduce of particle induced damage [3-6]. However, all previous work only considers the collision between the particle and flat surface. In this work, the mechanism of particle rebound in HDI is studied. Three types of particles collision are modeled and simulated, including the P-S (particle and surface), P-E (particle and edge) and P-P (particle and particle) collision. It is assumed that all surfaces of slider are smooth, and all particles are spherical. Collision of spherical particles with other objects is considered an elastic point contact. The subsequent action of particles after collision, which includes the rebound on the surface and adherence to the surface, is calculated with considering the collision energy loss. The trajectories and accumulation/distribution of particles on the air bearing surface (ABS) are visually presented. The particle material is alumina, and all Al_2O_3 particles have a diameter of 150 nm, a density of 3800 kg/m^3, and an initial velocity of $(U_p, V_p, W_p) = (0.8U_d, -0.2U_d, 0)$, where U_d is the local hard disk rotating speed. One hundred particles are released one after another at the leading edge of a femto-sized slider (850×700 μm). The initial x coordinates (x_0) of particles equal zero. The initial y coordinates (y_0) of particles are randomly generated in the range of 0 μm to 700 μm. The initial distance between particles and hard disk (z_0) is randomly generated in the range of 150 nm to 250 nm. Firstly, it solves the modified Reynolds equations to get the slider attitude as shown in Fig. 1(a) [7]. Since the air pressure gradient is necessary for calculating the air flow velocity and easy to be calculated on the rectangular mesh, an algorithm is applied to achieve the data transformation between the triangular mesh and the rectangular mesh. Then, it solves the Navier-Stokes equations with the second order slip boundary conditions to get the air flow velocity pattern, as shown in Fig 1(b). Finally, particle movement equations are solved by using the fourth order Runge–Kutta method [4]. Some simulation results are shown in Fig. 2. The comparison of Fig. 1(b) and Fig. 2(a) indicates that particle trajectories basically follow air flow streamlines. Fig. 2(a) also shows trajectories and final distribution of randomly released particles. Sixty-five particles adhere to ABS, twenty particles straightly go through HDI without collision, and fifteen particles go through HDI after the rebound on ABS. Especially, particle trajectories show that particle P2 goes through HDI after a P-E collision, compared to the straightly passage of particle P1. Fig. 2(b) shows the P-E collision causes a large z-direction displacement of particle P2, which helps the particle P2 to move away from ABS and go through HDI finally. Correspondingly, a large negative z-direction velocity of particle P2 is shown in Fig. 2(c). The P-E collision of particle P2 also causes a greatly reduce of x-direction velocity as shown in Fig. 2(d). Dynamic performance of particle rebound and the statistical analysis of accumulation/distribution of particles on ABS will be furtherly presented in the full paper.

HV-10. Frequency analysis of disturbance torque exerted on a carriage arm in hard disk drives using Hilbert-Huang Transform.

S. Koganezawa[1]
1. Kansai University, Suita, Japan

1. Introduction Currently, hard disk drives (HDDs) are widely used as external storage devices. In HDDs, flow induced vibrations (FIVs), i.e., the vibrations of carriage arms and disks due to the internal flow of HDDs, are serious contributors to head positioning errors. To develop higher capacity HDDs, reducing head positioning errors is inevitable. Many experimental and analytical studies have been conducted thus far to reveal the internal flow in HDDs and to understand the mechanisms of the disturbance torque exerted on head-stack assemblies for mitigating FIVs. Most studies have exclusively used Fourier spectral analysis for frequency domain analysis (e.g., [1]-[3]). The Fourier spectral analysis, however, must be used for signals under restricted conditions: the system must be linear, and the signal must be stationary and periodic. The internal flow of an HDD is an extremely complex phenomenon, and it is governed by non-linear Navier–Stokes equations. Therefore, the results of the Fourier spectral analysis are not always adequate. Further, if both fine frequency-resolution and high frequency spectra are required for Fourier spectral analysis, the time series data must have a long time-span and a fine time-step. Because it takes a significant amount of time to conduct a computational fluid analysis with such requirements, the results of the Fourier spectrum analysis tend to have a coarse frequency-resolution. The Hilbert–Huang transform (HHT) proposed by Huang et al. is a useful method for analyzing a nonlinear and non-stationary signal, and it has been applied to seismic signal analysis [4]. HHT consists of two parts: ensemble empirical mode decomposition (EEMD) and Hilbert transform (HT). EEMD is a way to decompose time series data into intrinsic mode functions (IMF) considering the envelope of the waveform. After EEMD is conducted, HT is executed, and the analytic signal is generated afterward. Then, the instantaneous frequency and amplitude are calculated from the analytic signal as time series data; therefore, it is possible to analyze the nonlinear and non-stationary signal. In this study, we applied the HHT to the time series of the torque exerted on the carriage arm, which is calculated using finite element analysis. Then, a frequency analysis using FFT and HHT was conducted, and their results were compared. 2. Computational fluid dynamics analysis of HDD A finite element (FE) model for fluid dynamics analysis was produced by referring to a 3.5-in HDD. The computational region for air flow was the inner space of the HDD, which was cut out between two disks. The FE model had a voice-coil-motor (VCM) carriage and a flexible printed circuit. The head suspensions were excluded from the FE model. The disk diameter was 95 mm, and the rotational speed of the disks was 7,200 rpm. The VCM surface was divided into five areas, and the disturbance torque exerted on each area was calculated. ANSYS CFX, a code for fluid analysis, was used for air-flow simulation. Large eddy simulation (LES) was employed as the turbulence model. The time step was 2.0×10^{-5} s, and the number of time steps was 15,000. Thus, the time span of the simulation was 0.3 ms, and the last 5,000 time-series data were used for frequency analysis. At first, contour-plot animations of the flow velocity and vorticity were made and visually observed. When the carriage arm is at the position where the head is tracking the outermost track, several periodic flow patterns are observed: vortex shedding at the arm-tip at approximately 500 Hz, fluctuation of strong vorticities inside the arm hole at approximately 1000 Hz, and vorticities between the disk and arm and the outside of the disk at 700 to 1000 Hz. Next, a Fourier analysis was conducted using the same simulation results. Although the time series of the torque exerted on the carriage arm seems to have a regularity or periodicity involving such specific frequencies as seen in the animations, there was no specific peak in the Fourier spectra, as shown in figure 1. At low frequencies less than 1000 Hz, the magnitudes of the Fourier spectra are almost constant, and with increase in frequency, the magnitude of the Fourier spectra decrease. Then, the frequency analysis using HHT was performed. The disturbance-torque time series, which is identical to the data used for FFT analysis, were divided into 11 IMFs by the EEMD process. Each IMF was analyzed using HT. Figure 2 shows the HHT results. Fluctuations in frequency were observed at approximately 500 Hz and 800 Hz. The spectra at these frequencies are caused by flow-fluctuations such as vortices, as observed in the flow-animations. Comparing the HHT with FT spectra, the results confirmed that, in the Fourier spectra, the energy of the non-stationary phenomenon, whose frequency and amplitude are fluctuating at a specific frequency, diffuses over a wide frequency-band, and that forms the broadly expanded spectra, especially at low frequencies. Therefore, it is necessary for more precise head positioning to decrease torque-fluctuations due to non-stationary phenomena, such as a vortex shedding around an arm, which are not always observed in the power spectrum obtained by the FFT analysis.

HV-11. Dynamic Performance of Head-disk Interface in HAMR Using Molecular Dynamics Simulation Method.

T. Shu[1], H. Li[1], S. Shen[1], X. Dai[1], W. Shen[1] and F. Cui[1]
1. School of Power and Mechanical Engineering, Wuhan University, Wuhan, China

Heat-assisted magnetic recording (HAMR) technology is a great way to achieve higher storage density [1-6]. In HAMR, dynamic performance of head-disk interface (HDI) is critical important for the read/write stability. Lubricant bridge formation and lubricant transfer can significantly deteriorate HDI performance. In this work, a three-dimensional full atom model of slider-lubricant-substrate system is established to study dynamic performance of HDI in HAMR, including variations of local gas pressure and weight percentage of PFPE lubricant in the process of rapid heating and cooling. The material of slider and substrate is diamond-like carbon, and the main ingredient of lubricant is perfluoropolyethers (PFPE). The chemical structure of PFPE can be expressed as X-(OCF2-CF2)*p*(CF2)*q*-O-X, (*p*/*q*=0.8-1.3), which is random co-polymer with a linear backbone chain. here the end groups, -X, are $-CF_3$ [1]. The relationship among flying height (FH), PFPE lubricant thickness and local gas pressure is also investigated. The initial pressure of gas bearing which is filled with helium is 20 atm. It is reflected by the number of helium atoms. The whole simulation time is 1 ns, and the time step is 0.001 ps. The temperature increases from 300K to 700K in the heating process, then reduces to 300K after cooling. Fig. 1 shows the three-dimensional PFPE lubricant morphological change with different FHs and lubricant thickness (denoted as *Th*). The PFPE lubricant is initially stable and smooth. After rapid heating and cooling, PFPE lubricant becomes rough due to the desorption of some molecules on its surface. And there are still some PFPE molecules adhered to the slider because of the attraction force between them. However, the number of PFPE molecules on the slider varies greatly depending on the slider flying height and lubricant thickness. Fig. 2(a) shows that the weight percentage of PFPE lubricant on the substrate reduces more significantly when the flying height is smaller with the increase of lubricant temperature from 300K to 700K. The remaining percentage of lubricant adhered to the substrate is reduced to 72%, 85% and 89% with the flying height of 2 nm, 3 nm and 4 nm, respectively at the temperature of 700K. Fig. 2(b) shows that the weight percentage of PFPE lubricant reduces significant with a larger lubricant thickness when heating temperature increases from 300K to 700K. And at the temperature of 700K, the decrement of PFPE lubricant is 35%, 15% and 13% with the lubricant thickness of 2 nm, 1.5 nm and 1 nm, respectively. It indicates that a larger proportion of lubricant is remained on the substrate with a smaller PFPE lubricant thickness. But the number of the molecules adhered to the substrate is still smaller when lubricant is thinner.

A rotary magnetic sensing system, which consists of a patterned ferrite-magnetic (FM) ring, a set of magnetoresistors (MRs) and a signal-processing unit for generation of position information, is commonly used in rotary stages or motors for position control. The magnetic signal for positioning can be generated by excitation coil [1-2] or polarities [3-4] from FM medium. The 2nd method is the focus of this paper in which the alternative polarities are made through perpendicular magnetization over the FM ring; from which magnetic signals the anisotropic MR sensors can then generate position signal based on measured magnetic profile from the FM ring. Several factors that may affect overall accuracy of the rotary platform. Firstly, position accuracy is determined during pattern writing process caused by assembly errors between writing head and the FM ring in the magnetization platform. Another crucial factor for pursuing high precision magnetic sensing accuracy is the geometry tolerance such as roundness, isotropy and homogeneity of the FM ring. Besides, errors induced by assembly between the FM ring and the MRs would lead to signal distortion [5]. A MR sensor discussed in this paper consists of two sets of Wheatstone bridge; each bridge contains four MRs that are stacked in quarter period of polarity. According to the principle of MR output signal, the magnitude and magnetization angle of magnetic flux originated from patterned media would induced the resistance changes of MRs packaged in a sensor. Namely, different magnitude and magnetization angle of magnetic flux distribution can lead to different output voltages. When two sets of Wheatstone bridges are properly arranged in the moving read head, output signals can be generated in form of sine and cosine waveforms from which a Lissajous graph can be depicted for positioning feedback. With perfect sine and cosine waveforms, an ideal Lissajous graph is a perfect circle. By dividing Lissajous graph into equivalent divisions, higher resolution can be achieved. The difference between ideal and distorted Lissajous graphs can then be used to determine position error [6]. The inevitable assembly error of MR sensor in manufacturing can cause the angle between magnetization vector and magnetoresistance to vary, which directly affect the resistance value, resulting in imperfect sinusoidal output voltage, which then becomes an obstacle for increasing resolution and position accuracy. Effect of assembly errors including eccentricity I1, offset I2 from rotary platform's rotation center, and pitch, roll, yaw errors of the MR sensor read head relative to the surface of FM ring as depicted in Fig. 1 will be discussed in the context of position accuracy through a commercial available FM rotary scale. The commercial FM rotary scale has pre-magnetized 256 polarities mounted on a precision rotary platform. The assembly errors can be categorized to eccentricity between rotary stage and the FM ring and the assembly errors due to sensor itself are shown in Fig. 1(a) and Fig. 1(b), respectively. The Os and Oe represent the center point of rotary platform and rotary scale. l1 and l2 respectively represent the eccentricity between rotary platform and magnetic ring and eccentricity between sensor and rotary platform. Both experimental and analytical approaches are conducted in this study. In the experiments, this FM ring was first assembled with least eccentricity by calibrating with high-resolution digimatic indicator, leading to minimum eccentricity l1. To investigate the effects of assembly error of sensor on accuracy, the MR sensor read head was fixed on a linear precision stage, which was aligned with the centerline of rotary platform. As such, the eccentricity l2 could be known from the linear precision stage. In the analytical method, magnetic flux density distribution of the rotary scale with assembly error is obtained through 3D finite-element simulation. By putting the simulated outputs into flux density and circuit voltage equations, the output of the MR sensors in the read head can then be attained. The sensor assembly offset error discussed in this study is set from 0 mm to 0.5 mm with step of 0.1 mm, and rotational assembly error such as pitch, roll and yaw error are both ranged from 0° to 2° with step of 0.2°. Fig. 2(a) shows the simulated accuracy distribution at 0.2 mm flying height over three polarities on stack lines by y offsets plot with offset of read head ranging from 0 mm to 0.5 mm. At different offset, the distribution of accuracy is found to shift to the left side as the offset is increased. The simulated accuracy errors caused by assembly error of read head including pitch, roll, and yaw errors are shown in Fig. 2(b). The result of pitch error percentile is marked on left vertical axis, whereas roll and yaw error percentiles are indicated on right vertical axis. It is found that pitch assembly error up 2° contribute more significant effect on accuracy error caused by roll and yaw assembly errors. The pitch assembly error can worsen accuracy nearly 115% relative to perfect assembly. On the other hand, degradation of accuracy caused by roll and yaw assembly errors is found only 6.4% and 3.5%, respectively relative to perfect assembly.

Introduction Multiple layer magnetic recording may be possible with the advent of microwave-assisted magnetic recording (MAMR) [1], [2]. In a MAMR system, recording on a medium with high uniaxial anisotropy is made possible by applying a high frequency (HF) magnetic field at the resonance frequency of the medium, leading to a reduction in the switching field. If two discrete recording layers, RL1 and RL2, have different resonance frequencies, selective recording on one or other of the layers may be possible by adjusting the frequency of the spin torque oscillator (STO) used to generate the HF field. The magnitude of the coercivity reduction is related to the strength of the HF field in the medium. As STOs typically have dimensions from 20 - 40 nm the HF field strength decreases rapidly with distance from the STO. For this reason, if multiple recording layers are to be used each layer must be as thin as possible and the separation between the layers cannot be large. However, if the separation between the recording layers is small, magnetostatic interactions between them are large. This can make it difficult to implement selective recording due to the magnetostatic interaction favouring parallel alignment of the magnetisation of both recording layers. It may be possible to counteract the influence of the magnetostatic field by introducing antiferromagnetic exchange coupling between the two recording layers, e.g. by using Ru or Ir spacers [3], and this is the topic of this work. The aim is to optimise the antiferromagnetic exchange coupling and to determine the effect on recording performance. The Model Dual layer recording media with a 7 nm RL1 / 2 nm Spacer / 5 nm RL2 / 3.5 nm Air / Write Head structure were modelled. Each recording layer was an exchange coupled composite (ECC) structure with M_s = 750 emu/cm^3 in all layers and the hard layers below the soft layers. In the model the medium grains were discretised into 1 nm-thick layers with the exchange coupling constant between layers of the same material being 10 erg/cm^2. After optimisation of the layer thicknesses and other parameters RL1 had a 3 nm hard layer and a 4 nm soft layer. The soft layer had K_u of 3×10^6 erg/cm^3 and the exchange coupling between the hard and soft layers was 4 erg/cm^2. RL2 was formed of a 2 nm hard layer and a 3 nm soft layer. The soft layer had K_u of 5×10^6 erg/cm^3 and the exchange coupling between the hard and soft layers was 6 erg/cm^2. The hard layer K_u of both recording layers was a variable parameter. The field distribution from a write head with a 36 nm wide main pole and a 30 nm gap between the main pole and the trailing shield was calculated using a finite element model. A STO was placed 5 nm behind the main pole to generate the HF field in the media. The STO was modelled as a 36 nm wide, 36 nm high and 14 nm thick field generating layer (FGL) with M_s of 1591 emu/cm^3 and coherent rotation of the FGL magnetisation was assumed. Results The effect of the magnetostatic interaction on the switching of the magnetisation of RL1 is shown in fig. 1. In the calculation a 4 ns field pulse was applied to an 8 nm × 8 nm grain containing two discrete recording layers, RL1 and RL2. The hard layer H_k (= $2K_u$ / M_s) was varied and the maximum H_k that could be switched by the combination of the head field and STO field was calculated as a function of HF field frequency. The magnetisation of RL2 was fixed either "up" or "down" and, as fig. 1 shows, the result was to change the maximum switchable H_k of RL1 by about 17 kOe: this difference was due to the magnetostatic field from RL2 acting on RL1 and is measured by the quantity ΔH_k. Next, antiferromagnetic exchange coupling with a strength J_{IL} was introduced between RL1 and RL2. The inset to fig. 1 shows the effect of J_{IL} on ΔH_k. When J_{IL} was about -0.17 erg/cm^2 the influence of the magnetostatic field was eliminated and ΔH_k was zero. Tracks were written on media with two recording layers using HF field frequencies of 20 GHz and 50 GHz. The bit length was 30 nm (847 kfci) and the head velocity was 5 m/s. The temperature was 300 K and distributions of grain size (16.5%), M_s (4.25%), K_u (8.5%) and easy axes (3°) were included. The signal to noise ratio (SNR) was calculated for tracks recorded on each layer using the sensitivity function of a 20 nm wide magnetoresistive (MR) read head. Fig. 2 shows the results as a function of J_{IL}. For RL1 the SNR increased by about 1.2 dB when J_{IL} was optimised, compared with the case when J_{IL} was zero. A small amount of ferromagnetic coupling between RL1 and RL2, e.g. J_{IL} = 0.1 erg/cm^2, caused a sharp decrease in the SNR of RL1. The SNR of RL2 was higher due to the layer being nearer to the write head and consequently experiencing higher head field gradients and HF fields. The SNR of RL2 was almost unchanged by J_{IL} until J_{IL} reached -0.3 erg/cm^2. Reversing the order of the hard and soft layers in RL1 to put the hard layer next to the non-magnetic interlayer made RL1 more resistant to the magnetostatic fields from RL2, but reduced the SNR. This was because magnetisation reversal was initiated in the soft layer and this layer experienced a smaller HF field when it was further from the STO. The authors would like to thank the ASRC for their support of this work.

HV-14. A General LDPC code Design Framework for High-density Magnetic Recording with 2D-ISI.

L. Kong[1] and X. Jiang[2]
1. Nanjing University of Posts & Telecommunications Nanjing, NANJING, China; 2. Donghua University, Shanghai, China

Increasing the density of the magnetic recording and scaling down the track pitch have led to a dramatic destroy in the reliability of magnetic recording system, such as Bit-patterned media recording (BPMR), shingled writing (SW), and two-dimensional magnetic recording (TDMR), suffering from the two-dimensional (2D) inter-symbol interference (ISI) which is made up of inter-track interference (ITI) and conventional (down-track) ISI. The 2D-ISI severely degrades the performance of data detection in these systems, and becomes the major impairment for the high-density magnetic recording systems beyond 1Tb/in^2[1]. Due to the computational burden of the symbol-based Bahl-Cocke-Jelinek-Raviv (BCJR) 2D detectors (2D-DETs) that has prohibitive complexity for the typical 2D data size over 2D-ISI channel, suboptimal 2D channel detectors with lower complexity have been proposed in [1]-[2], such as iterative row- column soft decision feedback algorithm based on gaussian approximation (IRCSDFA-GA). Besides 2D signal processing techniques, advanced channel coding also provides an effective approach to combat the 2D-ISI, which facilitates the 2D-ISI magnetic recording with a higher area density (AD). Due to the well-known superior capacity-approaching abilities in the additive white Gaussian noise (AWGN) channels, low-density parity-check (LDPC) codes are believed to be indispensable for high-density 2D-ISI magnetic recording systems. Existing LDPC codes optimized for symmetric, AWGN-like channels are not optimal for magnetic recording channels due to channel asymmetry. Unlike the highly complex LDPC codes optimization of [3], a low-complexity detector-aware code design algorithm has been proposed for dense 2D-ISI channels in [4], However, the proposed approach captured the error characteristics of 2D-ISI channels by means of the specific 2D-DET and need be operated for the different 2D-DET resulting in poor transplantation of the designed codes. In this paper, we present a general LDPC code design framework for high-density magnetic recording with 2D-ISI, which is transparent to the 2D-DET that the system employs. Specifically, C_{mg} is defined as the capacity margin between the symmetric information rate (SIR) of 2D-ISI channel and AWGN capacity for the given code rate. The new parameter captures the "mismatching" characteristics of the 2D-ISI channel and AWGN channel, which is the major reason why the codes optimized for AWGN channels do not perform well than the ones done for the 2D-ISI magnetic recording channels.

HV-15. Reduced Complexity Multi-track Joint Equalization and Detection of High Areal Density Magnetic Recording.

L.M. Myint[1], C. Warisarn[2] and P. Supnithi[3]

1. School of Science and Technology, Shinawatra University, Thailand, Pathum Thani, Thailand; 2. College of Advanced Manufacturing Innovation, King Mongkut\'s Institute of Technology Ladkrabang (KMITL), Bangkok, Thailand; 3. Telecommunications Engineering Department, King Mongkut\'s Institute of Technology Ladkrabang (KMITL), Bangkok, Thailand

In ultra-high areal density magnetic recording systems such as bit patterned media recording (BPMR) system, the width of a reader is expected to be relatively wider than the track pitch, thus, it will detect the magnetic field from the main track as well as those from the adjacent track which in turn resulting severe inter-track interference (ITI) effect on the readback signal. In the literature, multi-track joint detection techniques using array reader (AR) have been proposed to tackle ITI problem in future high areal density (AD) system [1-4] because it can provide a significant performance gain by processing multiple readback signals concurrently at the expense of high complexity. Most of researches focus on the data recovering from the single track or the number of tracks less than or equal to the number of readers while ITI effect from the sidetracks is alleviated. Considering the readback signal contains the significant contributions from the adjacent tracks, the system can generate the estimated data sequences not only from the main tracks but also from their adjacent tracks by employing the multi-track joint detection technique and AR. Therefore, in this paper, we propose a multi-track joint equalization and detection technique for a high AD magnetic recording system to recover the recorded data on four consecutive tracks (two tracks directly under the readers and two immediate sidetracks) by processing two readback signals from an array of two-reader. Given that each readback signal contains the substantial contributions from the side-tracks, we expect to achieve the estimated data from the sidetracks with the acceptable reliabilities for further decoding process. To reduce the detector's complexity, we also propose to use a multi-track Viterbi detector using a simplified trellis with parallel branches to recover data on the sidetracks. In the simulation model, we consider a discrete high areal density BPMR system with multi-track multi-head as shown in Fig. 1. The system is a two-head four-track system (2H4T) in which the data from four consecutive tracks, i.e., $a_{1,k}$, $a_{2,k}$, $a_{3,k}$ and $a_{4,k}$ are recovered by processing the readback signals, i.e., $r_{2,k}$ and $r_{3,k}$ from the array reader assuming that the centers of two head are aligned those of 2nd and 3rd track. To generate each readback signal, we use a two-dimensional (2-D) BPMR channel matrix with size of 5x3 and its coefficients are computed by a 2-D Gaussian pulse response using the parameters of areal density 4 Tb/in^2 from [4]. In the model, the readback signal, $r_{2,k}$ has the contributions mainly from the data on the 2nd track, $a_{2,k}$ as well as partially from the data on the 1st and 3rd tracks, $a_{1,k}$ and $a_{3,}$ (insignificantly from the 0 and 4th track). Similarly, the readback signal, $r_{3,k}$ contains the contributions from the data on the 2nd, 3rd and 4th track, $a_{2,k}$, $a_{3,k}$, $a_{4,k}$. In the equalization system, we employ two (2-D) equalizers, I and II, with size of 3x5 and two special (2-D) generalized partial response (GPR) targets, I and II, with size of 3x3, $G_1 = [0, g_{1,2}, 0; g_{2,1}, g_{2,2}, g_{2,3}; g_{3,1}, g_{3,2}, g_{3,3}]$ and $G_2 = [g_{1,1}, g_{1,2}, g_{1,3}; g_{2,1}, g_{2,2}, g_{2,3}; 0, g_{3,2}, 0]$ and they are designed using the minimum mean squared error (MMSE) method. Notice that some coefficients of target are set into zero aiming at reducing the trellis's complexity. The two readback siganls are sent to the system. Assuming that the system is well synchronized and no frequency offset, the signal sequence is the difference between two readback signals, i.e., $r_{2,k}$ and $r_{3,k}$. Assuming the sequence $\{r_{2,k} - r_{3,k}\}$ contains the contributions of the data on all four tracks, it is also fed to both equalizers as shown in Fig.1(a). Finally, the equalized signals $d_{2,k}$ and $d_{3,k}$ are processed in the multi-track joint Viterbi detector to generate the estimated data from four tracks. For the detector, the states and input symbols in trellis are considered with only the data, $a_{2,k}$, $a_{3,k}$, thereby resulting only 16 states and 4 outgoing branches at each state. To recover the sidetracks' data, $a_{1,k}$, $a_{4,k}$ are considered as parallel branches between each state transition as shown in Fig. 2(a) [5]. In Viterbi algorithm, the branch with the minimum metric value among all parallel branches is selected as the survival path. To compare the proposed (2H4T) system, we consider a multi-track system employing a four-reader array (4H4T) in Fig.1(b). In this system, we consider a multi-track joint Viterbi detector employing a trellis with 256 states and 16 branches as a full-fledged system. The performance comparison of proposed 2H4T multi-track system and 4H4T multi-track system is shown in Fig.2(b). When we study the BER performance of both systems for recovering the on the center 2nd and 3rd tracks, $a_{2,k}$, $a_{3,k}$ (solid lines), the proposed method is significantly inferior to the 4H4T system as we expected. However, the proposed method is outperformance over the latter for the performance recovering the data on the outer 1st and 4th tracks, $a_{1,k}$, $a_{4,k}$ (dotted lines). Notice that the BER performances of the center and outer tracks are very similar in the proposed method. The performance of proposed method is not as good as the full-fledged system, but it can generate the estimated data sequence from the sidetracks with the acceptable reliabilities and then they can be improved by using a robust channel coding system. Acknowledgement: This work was partly supported by the Thailand Research Fund (TRF) and Shinawatra University (SIU).

HW-01. Effect of Si doped on magnetic and magnetocaloric properties of Ni-Co-Mn-Sn alloys.

S. Ghosh[1], P. Sen[2] and K. Mandal[1]

1. Condensed Matter Physics and Material Sciences, S.N.Bose National Centre for Basic Sciences, Kolkata, India; 2. Physics Group, Variable Energy Cyclotron Centre, Kolkata, India

Magnetocaloric effect (MCE) refers to thermal response of a magnetic material when subjected to changes in an external magnetic field, which is quantified by isothermal change in entropy (ΔS_M) and adiabatic temperature change (ΔT_{ad}). [1] During last decade, Ni-Mn based Heusler alloys have been found to show a large inverse MCE across their first order magneto-structural transition (FOMST). [2-3] However, a small amount of Co doped (replacing Ni) in these alloys enhances the ΔS_M value but the appearance of field induced hysteresis across the FOMST reduces the net refrigerant capacity (RC) of that material in higher doping concentrations. [4] Therefore to develop inverse MCE properties of Hesuler alloys, we have to reduce the thermal hysteresis significantly to make their real use as refrigerant material. Herein, the magnetic and MCE properties of polycrystalline $Ni_{48}Co_{1.5}Mn_{35}Sn_{15.5-x}Si_x$ (x = 1, 2, 4) Heusler alloys (prepared by arc melting furnace) have been investigated by magnetic measurements. M-T curves of x = 1, 2 and 4 alloys are measured during zero field cooled (ZFC) and field cooled cooling (FC) mode under 100 Oe field within the temperature range of 5 K to 400 K. All the alloys are found to show FOMST along with a second order magnetic transition (Ferro-Para). The characteristic transition temperatures: austenite start (A_S), austenite finish (A_f), martensite-austenite transition temperature [$T_A = (A_S+A_f)/2$], martensite start (M_S), martensite finish (M_f) and austenite-martensite transition temperature [$T_M = (M_S+M_f)/2$] are determined from M-T curves which are plotted as a function of Si content, shown in Fig. 1(a). It is found that the structural transition temperature shifts to the lower temperature with increasing Si substitution in place of Sn. The transition width ($\Delta T = T_A - T_M$) is found to decrease with Si substitution. It is well known that decrease in e/a ratio and as well as the increase in cell volume reduces the structural transition temperature in Heusler alloys. Here the substitution of Si in place of Sn does not change the valence electron number but reduces the cell volume, having smaller atomic radius of Si than Sn. Therefore, in our case an opposite effect has been observed: decrease in cell volume reduces T_M. This can be explained by considering the degree of crystallographic present in the sample. [5] Similar effect has been observed in other reported Si doped Heusler alloys. [5] Isothermal M-H curves for x = 1, 2 and 4 alloys are carried out across their structural transition at 5K interval in the field range of 0 - 50 kOe during heating protocol [Fig. 1]. ΔS_M, an important parameter in MCE studies, can be calculated using Maxwell's equation [4] by numerical integration of the isothermal M-H curves. ΔS_M is plotted as a function of temperature for different field change of x = 1, 2 and 4 alloys, shown in Fig. 2. The obtained values are 10.86, 5.46 and 2.42 $Jkg^{-1}K^{-1}$ for x = 1, 2 and 4 respectively due to a filed change of 50 kOe. It is found that with enhancing of Si substitution, ΔS_M decreases to a lower value due to being the less sharp of across martensitic transition with increasing x. As expected, ΔS_M increases monotonically with the applied field changes till the peak of ΔS_M occurs across T_A due to the twin boundary motion and motion of the spin walls. The obtained ΔS_M value, 10.86 $Jkg^{-1}K^{-1}$ for x = 1 is comparable to other reported similar kind of alloys. [6] Refrigerant Capacity, another key parameter in MCE studies that estimate the usefulness of the material as a refrigerant, can be calculated from the temperature dependence of ΔS_M curve.[4] The calculated values are 171.7, 161.1 and 71.6 J/kg for x = 1, 2 and 4 respectively. Due to first order transition, the hysteresis loss should be subtracted from the RC value to get the net RC of these studied materials. The magnetic hysteresis losses of x = 1, 2 and 4 alloys are obtained from their respective M-H curves and plotted in Fig. 2(d) for the temperature region of 105 K – 220 K. The average hysteresis losses (HL) are found to be 52.1, 19.3 and 8.6 J/kg for x = 1, 2 and 4 respectively under field change of 0 - 50 kOe which in turn reduces the RC value to its net values 119.6, 141.8 and 63 J/kg. It is interesting to observe that due to Si substitution average HL drastically decreases to 8.6 J/kg for x = 4 which is very much lower than other reported values of same families. [4, 6-7]

HW-02. Magnetocaloric effect, large coercivity and exchange bias in melt-spun rare earth intermetallic compound SmNi.

J. Kurian[1], A. Chelvane[2], A. Morozkin[3], A.K. Nigam[4], S.K. Malik[5] and *N. R*[1]

1. Physics, Indian Institute of Technology Madras, Chennai, India;
2. DMRL, Hyderabad, India; 3. Lomonosov Moscow State University, Moscow, Russian Federation; 4. TIFR, Mumbai, India; 5. UFRN, Natal, Brazil

It is now well-known that the non-equilibrium, rapid solidification technique, namely, melt-spinning can be optimized to either stabilize metastable phases or to synthesize amorphous/highly crystalline intermetallics and alloys. It is of recent interest to study giant magnetocaloric materials in their melt-spun form, as the technique is fast and energy saving. In particular, highly crystalline La(Fe, Si)$_{13}$ and RNi_2 (R=Rare earth) compounds have been melt-spun for improvement of their magnetic and physical properties [1, 2]. Our recent studies on melt-spun, textured equiatomic rare earth intermetallic compounds RNi (R = Gd, Tb, Dy, Ho and Er) reveal substantial magnetocaloric effect and relative cooling power values in the neighbourhood of ferromagnetic transition [3]. In the present work, the magnetic properties of SmNi compound prepared by melt-spinning technique are studied. Room temperature X-ray diffraction study on melt-spun SmNi confirms that this sample crystallizes in orthorhombic CrB-type structure (Space group *Cmcm*, No. 63) similar to its arc-melted analogue. While the EDAX analysis ascertains the composition, the scanning electron microscopy image reveals the presence of micron sized grains in the melt-spun sample. The temperature dependent magnetization of melt-spun SmNi compound shows a ferromagnetic transition at about 45 K (T_C). A signature of a possible spin reorientation transition at 15 K is also observed in the low field magnetization data. Magnetization vs field (M-H) data at 5 K and 10 K display hard ferromagnetic behaviour. The saturation magnetization value is only 0.23 μ_B /f.u. for the melt-spun SmNi which is somewhat close to the value of 0.36 μ_B / f.u. reported for the single SmNi along the magnetic easy *b* axis. These values are far too less than the theoretical *gJ* value expected for Sm^{3+} ion. It had been suggested that crystalline electric fields (CEF) and complex canted magnetic structure of SmNi results leads to the observed low magnetization values. Magnetocaloric effect of this sample has been studied in terms of isothermal magnetic entropy change (ΔS_m). Using the M-H isotherms measured close to T_C, ΔS_m has been calculated. The maximum isothermal magnetic entropy change, ΔS_m^{max}, is about 1 J/kg K for the melt-spun SmNi for 50 kOe field change, at 47.5 K (Fig. 1) and is almost close to the result obtained on arc-melted sample. The CEF effects of rare earth ion play a dominant role in diminishing the magnetocaloric effect in this SmNi sample when compared to other heavy rare earth-based RNi compounds. It is interesting to note that the magnetocaloric effect changes sign below ~20 K, as competing antiferromagnetic interactions are known to exist in the non-collinear canted magnetic structure of SmNi. In addition, the ΔS_m^{max} values vary linearly with magnetic field change while a Heisenberg ferromagnet within a mean field approximation is known to depict $(\Delta H)^{2/3}$ dependence for ΔS_m^{max}, as shown by FeB-type ErNi. The average coercive field (H_c) at 10 K is ~23.9 kOe for the melt-spun SmNi and it is important to note the assymmetric M-H curve at this temperature and below. The large H_c value could have resulted from the huge magnetocrystalline anisotropy in the sample. The asymmetry in the low temperature M-H curve suggests possible exchange bias in this single phase intermetallic compound that hosts canted magnetic structure where ferromagnetic interactions are reported along *b* axis and antiferromagnetic interactions along *c* axis. It is observed from the heat capacity studies on arc-melted SmNi that magnetic specific heat contribution extends up to about 130 K which is much above T_C [4]. The magnetic entropy change could be accounted not only to the Rln2 value of ground state Sm^{3+} ions but also to the thermal excitations within the CEF levels or Schottky effect. In fact, the paramagnetic susceptibility is fitted to the modified Curie-Weiss law that includes a Van Vleck contribution.

HW-03. Burst-like superelasticity and elastocaloric effect in Ni-Fe-Ga-Co magnetic shape memory alloys.

J. Liu[1] and D. Zhao[1]
1. Ningbo Institute of Materials Technology and Engineering, Ningbo, China

Elastocaloric cooling has been recognized as one of the most promising environmentally friendly alternatives to the state-of-the-art vapor compression cooling technique. The origin of eCE reveals that the thermodynamic and kinetic properties of the martensitic transformation determine the elastocaloric performance. Up to now, the reported eCEs in SMAs are all designed based on the thermoelastic martensitic transformation, in which the martensite grows or shrinks elastically with the variation of temperature and stress. In this work, burst-like superelastic deformation and related eCE are reported in [011] oriented $Ni_{50}Fe_{19}Ga_{27}Co_4$ magnetic shape memory single crystals at high temperature. The effect of the burst character on superelastic curve and eCE has been investigated. Besides, thermal and stress induced different martensitic structures are also identified. The $Ni_{50}Fe_{19}Ga_{27}Co_4$ ingot was arc-melted in an argon atmosphere and the single crystal was grown by the Bridgman method. A high temperature back-reflection Laue camera was used to determine the orientation of the crystal. Rectangular (nominal dimensions: $4 \times 4 \times 8$ mm^3) samples with the long axis along the [011] and [001] axis of the austenite were cut from the single crystal. The stress-strain curve and temperature change of the sample were monitored by a T-type thermocouple. Fig. 1 shows the compressive stress-strain curves with a strain rate of 2.8×10^{-3} s^{-1} at different temperatures. The commonly observed superelasticity above austenite transition temperature (320 K) does not occur in a wide temperature range of 60 K, until it suddenly appears once reaching a critical temperature of 388 K. During the phase transformation, intermittent acoustic noise was heard. The stress oscillations and audible noise are considered as the typical characters of burst martensitic transformation. In this sample, the burst and thermoelastic transformations occur alternately. A burst is first observed at the beginning of the transformation, and finishes in a few milliseconds. Large quantity of elastic energy instantaneously generates in the burst. A part of the elastic energy was dissipated by the mean of the acoustic noise. After the burst, the thermoelastic transformation subsequently takes place. In this stage, the internal stress accumulated in the burst relaxes in order to minimize the system energy, thus the stress to drive transformation is reduced. As the transformation proceeds, the burst in a small scale appears again (as indicated by the arrows in the figure), which is followed by a thermoelastic transformation as well. In the temperature range of 418-438 K, the gradually shortened transformation region and the disappearance of superelasticity result from the increasingly insufficient stress to induce the phase transformation. The cooling curve upon unloading at different initial temperatures is plotted in Fig. 2. When the initial temperature is below 388 K, the absolute value of temperature change is below 1 K because of the absence of phase transformation. At the temperatures of 388, 398, and 408 K, the complete stress induced austenitic transformation gives rise to a large cooling effect. Further increasing the temperature, the stress of 300 MPa is increasingly insufficient to induce a complete phase transformation, leading to a decrease of cooling effect. Under the stress of 300 MPa, an elastocaloric temperature window of 40 K and a maximum cooling effect of 6.1 K are obtained. In contrast, a broader temperature window and higher ΔT values (about 11 K) are observed in [001] oriented $Ni_{50}Fe_{19}Ga_{27}Co_4$ single crystal with normal superelastic behavior. This suggests the strong crystallographic anisotropy in elastic cooling effect for this single crystal.

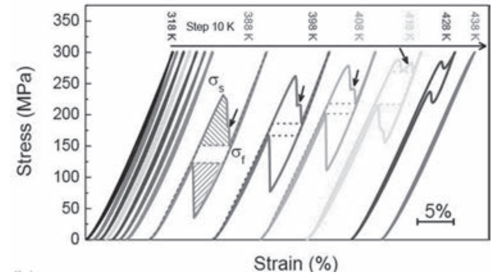

Fig. 1. Stress-strain curves with a strain rate of 2.8×10^{-3} s^{-1} at different temperatures for [011] oriented $Ni_{50}Fe_{19}Ga_{27}Co_4$ single crystal. The dotted curves are thermodynamic equilibrium superelastic curves. The hatched area represents the hysteresis loss caused by burst character. The arrows point out the bursts in a small scale.

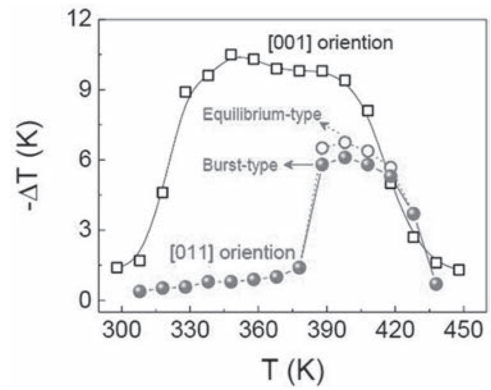

Fig. 2. Adiabatic temperature change induced by rapidly releasing the stress of 300 MPa at different initial temperatures for [001] and [011] oriented $Ni_{50}Fe_{19}Ga_{27}Co_4$ single crystals.

HW-04. Evaluation of different magnetocaloric heat exchanger stacks in a demonstrator with upcycled Nd-Fe-B permanent magnets.

The energy demand in cooling is expected to outdo the global demand in heating by the year 2070 [Isaac]. To tackle that problem it is worth to investigate alternative cooling technologies among which magnetic cooling is the most promising and can be more energy efficient than the currently used gas-compression techniques [Zimm]. However this technology comes with its own challenges. The most prominent magnetocaloric material, the rare-earth element Gadolinium is expensive and not abundant. Also the best magnets in the world contain rare-earth elements like Neodymium and Dysprosium. This means that a conventional approach to magnetic cooling would have an ecological footprint which is worse than that of conventional cooling. Therefore, we now present the first magnetocaloric demonstrator (figure 1) based on recycled permanent magnets in order to improve the ecological footprint of this technology drastically [Gauß+Gutfleisch]. The recycled magnets have been produced by Urban Mining Company. To assess the overall performance and viability of the demonstrator as a testing device, AMR-type heat exchangers made from Gd spheres have been used. With Gd it is possible to achieve a temperature span of up to 33K (figure 2b). This shows the viability of the demonstrator as a device that is capable of testing materials. One of the most prominent alternatives to Gadolinium are compounds based on lanthanum iron and silicon which come with their own problems such as brittleness and degradation. To mediate these problems a metal bonding for these has been developped which protects it from the environment and enables a long term use in magnetocaloric devices [Radulov]. While the magnetocaloric effect of La-Fe-Si is large, it is limited to a narrow temperature region. For a magnetic cooling device that is based on the AMR design, this means that it is necessary to stack compounds with different transition temperatures in order to increase the achievable thermal span (figure 2 a). This can be easily done and tested in our demonstrator and has been done for our bonded materials. By stacking 5 different compounds it was possible to increase the achievable thermal span from 8.1K to 20.6K. The results show that the bonding procedure does not harm the magnetocaloric properties and it protects the magnetocaloric material from a possibly harmful environment such as a water based heat exchange fluid. This twofold approach of using upcycled Nd-Fe-B as a magnetic field source and substitution of Gd by La-Fe-Si drastically improves the ecological footprint of magnetic cooling and will help in the commercialization of the technology. To complement the demonstrator, a finite element model has been developed that resembles the demonstrator and gives more insights to the physical behavior and more possibilities to test new ideas. The model shows a very good correlation to the experimental measurements and will help in the optimization of the stacking of different materials in the demonstrator. This is a key problem that needs to be adressed to be able to utilize the full potential of the very high entropy change of La-Fe-Si.

HW-05. Design of an Efficient Magnetic Circuit for a Magneto-Caloric Air-Conditioning System.

C. Jäschke[1], P. Schegner[1] and J. Seifert[1]
1. Technische Universität Dresden, Dresden, Germany

I Introduction A highly efficient and cost-effective magnetic circuit is necessary to build an applicable air-conditioning system, which exploits the magneto-caloric effect [1]. Since the magneto-caloric material (MCM) and permanent magnets are the most expensive parts in the magnetic circuit, their demand needs to be minimized. This paper shows the general design of a magnetic circuit, which meets these requirements. II Basis Structure of the Magnetic Circuit Figure 1 shows the geometry of the magnetic circuit and Fig. 2 the corresponding results of a FEM computation. The MCM is stored in magneto-caloric material chambers (MCMCs), which are embedded in the stator and have a cross section of 50 mm × 10 mm. The presented magnetic circuit is capable to generate a high change of the flux density inside the MCMCs, while using a small amount of magnets. Its working principle is explained considering any leg of the magnetic circuit. Each magnet inside the outer rotor generates a magnetic flux density, which is concentrated by a pole shoe. After passing the air gap between rotor and stator, a pole shoe at the middle yoke further compresses the flux density. This highly concentrated flux density permeate a MCMC and is led to the inner yoke. Since half of the magnets in the outer rotor have an opposing orientation, the magnetic fluxes in all legs are compensated in the inner as well as in the outer yoke. By using a motor to turn the outer rotor stepwise, each pole shoe of the magnets is moving from one middle yoke to its neighbour. Meanwhile, the magnetic fluxes commutate from the penetrated middle yokes to their neighbouring. After completion of the commutation process, only half of the eight MCMCs are permeated by a high magnetic flux density. The other MCMCs, which are not directly exposed to the flux density of the magnets, are also covered by middle yokes. These act as magnetic shield and reduce magnetic stray fields inside the MCMCs. This results in a high change of the flux density between two working steps. III Optimisation of Pole Shoes and Permanent Magnets Electrical sheets made of silicon steel, which are commonly applied in electrical machines, are quite cheap and have a saturation flux density of ≈ 2 T. By using pole shoes to concentrate the emitted flux density, the proportions of the magnets can be chosen to operate near their optimum operating point. This allows generating high flux densities, while using a minimal amount of magnets. Figure 1 shows the achieved flux density change in a MCMC, by using different quantities (volumes) of magnets (type *N50*). Since the proportion of the magnets also affects the level of stray fields inside the magnetic circuit, their optimal proportion slightly differs from the point of maximum energy output. Therefore, a mathematical optimisation algorithm was applied to determine the optimal proportion of the magnets for each simulation case. Starting from a flux density of 1 T, the required volume of magnets increases approximately proportional to the achieved flux density. For a flux density change of over 1.4 T, the amount of magnets disproportionately increases with rising flux density. This behaviour is caused by the increasing magnetic stray fields inside the magnetic circuit, which arise due to the increasing size of the magnets and the higher flux density inside the electrical sheets. The MCMCs are placed inside the gaps between opposing pole shoes of the magnetic circuit. Due to the high thickness of the gap, the geometry of the pole shoes has a significant impact on the flux density inside the MCMCs. If the ends of the pole shoes were right-angled, high inhomogeneous flux densities would appear at the edges and causing a low flux density inside the chamber. Rounding the edges of the pole shoes reduces this effect, yielding higher flux densities in the MCMCs. However, the highest flux density will be obtained, if the contour is designed as a Rogowski profile. In [2], W. Rogowski derived an equation for the optimal geometry to minimize the electrical field strength at the boundary of a plate capacitor. Using this geometry yields the most homogenous distribution of the electric field between two parallel finite plates. Since the relations in electrostatic and magnetostatic are described by the same type of PDE, it is obvious that the Rogowski profile also yields the most homogenous magnetic field between two parallel pole shoes. Simulations with several kinds of pole shoe contours confirm this behaviour. Figure 2 exemplary shows the distribution of the magnetic flux density inside a MCMC by using two different pole shoe contours. In this case, the flux density change is about 0.1 T higher, if using the Rogowski profile instead of pole shoes with right-angled ends. IV Summary and Outlook The general geometry of an effective magnetic circuit was designed, which is able to generate magnetic flux densities of up to 2 T. In future work, the design will be further optimised, in order to reduce the size and weight of the magnetic circuit. V Acknowledgment The research project leading to the results described in this paper is funded by the Federal Ministry for Economic Affairs and Energy (FKZ: 03ET1374A) on the basis of a decision of the German Bundestag.

HW-06. Magnetic properties and magnetocaloric effect of Ni_2Mn_{1+x}-Sn_{1-x} Heusler alloy thin films.

H. Yako[1], T. Shima[1] and M. Doi[1]
1. Tohoku Gakuin University, Tagajo, Japan

INTRODUCTION Ternary Heusler alloys defined as the stoichiometric composition X_2YZ with the $L2_1$ structure have attracted considerable attention due to their valuable transport and magnetic features. These compounds exhibit half-metallic behavior, magnetoresistance, magnetocaloric, shape memory and thermoelectric effects. The Heusler alloys Ni_2MnGa and off-stoichiometric $Ni_2Mn_{1+x}Z_{1-x}$ (where Z = In, Sn and Sb) are typical examples of the ferromagnetic shape memory alloys due to physical phenomena such as the large magnetic field induced strain [1], the giant magnetocaloric effects [2] and the giant magnetoresistance [3]. Especially, Ni-Mn-X (where X = Ga, In, Sn) based magnetic shape memory alloys have been proposed as solid state energy efficient refrigerant with their remarkable first order transition feature [4-8]. Most of the magnetic refrigeration materials have been studied in bulk sample. However, by changing the sample shape, it is expected to realize the efficient heat exchange and the downsized cooling device. In this study, in order to evaluate the influence on magnetic properties and magnetocarolic effect due to substrate material, heat treatment temperature and composition in $Ni_2Mn_{1+x}Sn_{1-x}$ Heusler films were investigated. EXPERIMENTAL PROCEDURES $Ni_2Mn_{1+x}Sn_{1-x}$ with x = 0.3, 0.4 and 0.5 thin films were prepared by co-deposition of Ni, Mn and Sn using an ultra high-vacuum magnetron sputtering system (ULVAC, QAM4) directly onto a thermally oxidized Si and an MgO (100) single crystal substrates at room temperature. The targets were commercial products with purities higher than 99.99 at.% for Ni and Sn and 99.9 at.% for Mn. The base pressure was under 8.5×10^{-7} Pa. High-purity argon was introduced at 0.2 Pa during sputtering. $Ni_2Mn_{1+x}Sn_{1-x}$ thin films were subsequently annealed for chemical ordering. The annealing temperature, T_a was changed from 300 °C to 600 °C. The nominal thickness of the $Ni_2Mn_{1+x}Sn_{1-x}$ thin film was fixed at 300 nm. The composition of the films was determined by energy dispersive X-ray spectrometer (EDS). The structure was analyzed by X-ray diffraction (XRD) with Cu Ka radiation. Magnetic properties were measured using a vibrating sample magnetometer (VSM) and a superconducting quantum interference device (SQUID) magnetometer. In addition, the thermo magnetization curves applying magnetic field of 1 kOe were performed with using SQUID. RESULTS AND DISCUSSION XRD patterns for the Ni_2Mn_{1+x}-Sn_{1-x} with x = 0.3, 0.4 and 0.5 thin films deposited on SiO_2 sub. at different T_a were characterized. XRD patterns of $Ni_2Mn_{1+x}Sn_{1-x}$ with x = 0.4 thin films are shown in Fig. 1. T_a was (a) 300 °C, (b) 400 °C, (c) 500 °C and (d) 600 °C. The peak from the Heusler structure was not observed for the present films with T_a = 300 °C and 600 °C. On the other hand, (111) and (311) peaks were clearly observed for T_a = 400 °C and 500 °C. This result indicates that the film possesses the $L2_1$ structure and the best T_a to obtain the $L2_1$ structure is thought to be 500 °C. Among $Ni_2Mn_{1+x}Sn_{1-x}$ thin films with x = 0.3, 0.4 and 0.5, x = 0.4 shows the maximum value of the saturated magnetization, M_s of 220 emu/cm^3. This value is smaller than the one for bulk sample (250 emu/cm^3). This is thought to due to the partially crystallization of $L2_1$ structure of $Ni_2Mn_{1+x}Sn_{1-x}$ thin films deposited on thermally oxidized Si substrate. In order to further improve crystal orientation and magnetic properties of $Ni_2Mn_{1+x}Sn_{1-x}$ thin films, optimum buffer layer or single crystal substrate should be used. In addition, the isothermal magnetic entropy change was evaluated from the magnetization data by using the Maxwell relation. The effect of substrate and composition on magnetocaloric effects has been investigated.

Fe_2P-based compounds with large magnetocaloric effect are attracting materials for magnetic refrigeration near room temperature. Traditionally, the Fe_2P-based compounds are prepared by ball milling combined with a long period of annealing at high temperature [1,2]. Spark plasma sintering (SPS) is a newly developed synthesis process characterized by the simultaneous application of pressure and a pulsed continuous current. In this work, we report on the structural and magnetocaloric properties of $Mn_{1.15}Fe_{0.85}P_{0.65}Si_{0.13}Ge_{0.2}B_{0.02}$ prepared by SPS technique. Compounds with the same nominal composition were obtained with different sintering temperatures (T_{SPS}), namely, sintered at 700, 800, 850 and 900 °C under a pressure of 50 MPa for 15 min. Analyses of X-ray diffraction patterns demonstrate that all compounds crystallize in the hexagonal structure with space group of P-62m. The thermal magnetization curves on heating and cooling reveal that the compounds undergo first-order magnetic transitions due to the observation of clear thermal hysteresis, as shown in Fig. 1. The different sintering temperatures have influences not only on the transition temperature but also on the temperature span of the transition. The transition temperatures on heating are found to be 273, 282, 267 and 261 K for T_{SPS} = 700, 800, 850 and 900 °C, respectively. Scanning electron microscope (SEM) and energy disperse spectroscopy (EDS) measurements suggest that the compounds consist of Fe_2P-type main phase and phosphorus-free secondary phase. Isothermal entropy change (ΔS_T) for the studied compounds have been calculated from the isothermal magnetization data using Maxwell relation. Upon a field change of 3 T, the maximum values of $-\Delta S_T$ are found to be 6.4, 14.0 and 15.1 J/kg●K for T_{SPS} = 800, 850 and 900 °C, respectively. The results manifest that the SPS method is suitable for preparing magnetic bucks with excellent magnetocaloric properties.

Magnetic nanoparticles have attracted a lot of interest due to their importance and potential application in a variety of fields. The complex magnetic behavior exhibited by nanoparticles is governed by many factors, including their size, composition, shape, morphology, and shell-core structure. The increased surface to volume ratio and tailored structure in nanoparticles introduces many size dependent phenomena which may be used to change their chemical and physical properties. Nanostructured magnetic materials are suitable candidates for magnetic refrigeration due to a presence of a large magnetocaloric effect (MCE) in the superparamagnetic system and reduced hysteresis losses. Magnetocaloric nanoparticles have a broader entropy change over a wider temperature span which results in a higher relative cooling power (*RCP*). The *RCP* measures how much heat can be transferred between the cold and hot heat exchangers in an ideal refrigeration cycle. Increasing the *RCP* not only increases the amount of refrigeration obtainable from the particular refrigerant and field excursion, but also tends to increase the thermodynamic efficiency of the cycle. Improvement in *RCP* mainly relies on broadening the magnetic entropy change by either coupling two phases of magnetic materials with desirable properties or nanostructure synthesis with the main motivation rooted in their inherent tendency to have distributed exchange coupling, which will broaden the magnetic entropy curve. As a result, to have a comprehensive understanding of various factors that can affect the magnetic and structural properties of materials, in this research, different-sized yttrium-iron nanoparticles were synthesized through alkalide reduction chemical synthesis. Powder X-ray diffraction measurements at room temperature were carried out to study the crystal structures. Surface morphology and size of the synthesized powder alloys were characterized by scanning and transmission electron microscopy. The composition of the powders was determined from energy dispersive X-ray fluorescence. Magnetization measurements were performed using vector vibrating sample magnetometer (VVSM) with standard zero field cooling (ZFC), field cool cooling (FCC), and field cool warming (FCW) techniques. The XRD measurements of the annealed nanoparticle samples fit the yttrium-iron hexagonal closed pack structure and a phase prototype similar to Th_2Ni_{17}, with space group $P6_3/mmc(194)$. The average particle size of four samples were observed to be 22, 38, 62 and 76 nm, in good agreement with crystallite size estimated from XRD data using Scherrer relation. The magnetic and structural properties of these nanoparticles were measured at different fields and temperatures to study the effect of field, temperature, and particle size variations on the critical parameters, such as Curie temperature (T_C), blocking temperature (T_B), phase transitions, saturation magnetization (M_s), remnant magnetization (M_r), and coercivity (H_c). The temperature dependent magnetization, M(T), under different applied magnetic field up to 20 KOe indicated a change in samples' T_B, which is defined as the temperature corresponding to the maximum point on the ZFC curve after its divergence from the FCC curve. As shown in Fig. 1a, for the 38 nm sample, T_B increases by increasing the applied field up to 2 KOe and then decreases with further increase in the applied field. The non-monotonic field dependence of the peak temperature in nanoparticles is attributed to the anisotropic energy barrier distribution of the particles, and to the slowly decreasing magnetization above T_B. Moreover, T_B increased as the size of nanoparticles increased (Fig. 1b). Results display that T_C of nanoparticles depends on both size and shape conditions as it decreased by reducing the particles size. The shape effect is more prominent at sizes less than 40 nm. Additionally, the phase transition became more dominant in low applied filed whereas it is smoothened by increasing the field due to particles' magnetic saturation. Moreover, magnetic couplings between particles appear stronger for larger particles. The saturation magnetization and coercivity of these nanoparticles were size and field dependent and they both decreased by reducing nanoparticles' size. Furthermore, as shown in Fig. 2, H_C and M_S are temperature dependent and they both decrease by increasing temperature since more thermal energy is supplied and individual electron spins become more likely to be in higher energy states, pointing randomly, opposite to their neighbors and less aligned, leading to a reduction in the total magnetization. Therefore, a smaller field is required to reduce remnant magnetization to zero, leading to coercivity reduction. In summary, the comprehensive results of this research are promising and novel as they suggest that the physical and chemical properties of magnetic materials can be customized to suit them in a number of applications in variety of fields such as material science, medicine, engineering, nano-electronics, information technology, etc.

Temperature change of a magnetic material associated with an external magnetic field change in an adiabatic process is defined as the magnetocaloric effect (MCE). Recently, a large magnetic entropy change has been found and intensively studied in perovskite manganites, owing to the possibility to sue these materials as active magnetic refrigerants in the magnetic refrigeration technology. Manganite perovskite of single crystalline and polycrystalline of hole- doped $R_{1-x}M_xMnO_3$ (R = rare-earth ion; *M* = divalent alkali) has attracted many experimental and theoretical attention in $La_{0.7}Ca_{0.3}MnO_3$ one among many reasons due to optimum Mn^{3+}/M^{4+} ratio influence MCE significantly. Magnetic phase transition imply MCE significant performance which most first-order magnetic phase transition (FOMT) has high maximum entropy change with narrow temperature span meanwhile second-order magnetic phase transition (SOMT) vice versa. Many works reported the way to transform FOMT to SOMT in $La_{0.7}Ca_{0.3}MnO_3$ via *A*-site doping [1], *B*-site doping with transition metal (Fe, Ni, Co, Cu) [2]. In the present paper, we report in detail MCE of polycrystalline $La_{0.7}Ca_{0.3}MnO_3$ which made as pressure dependence of 1, 3 and 5 GPa and named as P_1, P_3 and P_5, respectively. The large value of magnetization in this compound shows that all the samples exhibiting ferromagnetic-paramagnetic (FM-PM) phase transition at Curie temperature. It makes $La_{0.7}Ca_{0.3}MnO_3$ become comparable as magnetocaloric materials in magnetic refrigerant technology. The polycrystalline $La_{0.7}Ca_{0.3}MnO_3$ samples were synthesized by a standard solid-state reaction. A stoichiometric mixture of La_2O_3 (99.99%), $CaCO_3$ (99.99%), $MnCO_3$ (99.99%), powders were previously milled and mixed with a small amount of alcohol using a planetary ball mill of the PM 100 typefrom Retsch (Germany). The resulting mixture was preannealed in air at 850 °C for 16 hours. Next, the powder was additionally annealed at 1000 °C for 16 hours. The resultant powder was then pressed into pellets with different pressure of P_1, P_3 and P_5 and fired in air at 1100 °C for 24 hours. X-ray diffraction (XRD) measurement was made on powdered samples using Cu-Kα radiation. The magnetic measurement versus the temperature (100-300 K) and magnetic field (0-10 kOe) were performed on Physical Properties Measurement System (PPMS) magnetometer (Quantum Design) using VSM mode. Fig. 1 shows the temperature dependence of the magnetization under an external field of 100 Oe for the $La_{0.7}Ca_{0.3}MnO_3$ which pressed into pellets at 200 °C with different pressure. A Curie temperature was obtained. The values are found to be 278 K, 272 K, and 270 K which-exhibiting a ferromagnetic - paramagnetic (FM-PM) phase transition. As can be seen in the insert of Fig. 1 with increasing pressure, the Curie temperature decreased gradually. On the other hand, compared with unpressed sample $La_{0.7}Ca_{0.3}MnO_3$ the Curie temperature (256 K) was increased around 22 K (not show). Isothermal *M-H* curves have been measured at various temperatures in the vicinity of T_C. To determine the type of the phase transition for $La_{0.7}Ca_{0.3}MnO_3$, the measured data of the *M-H* isotherms were transferred into *H*/*M* vs. M^2 plots. According to the Banerjee criterion[3], the positive slope in *H*/*M* vs. M^2 (*M* is the experimentally observed magnetization, *H* the magnetic field) plots means that FM to PM phase transition is second order. For the pressure dependence of $La_{0.7}Ca_{0.3}MnO_3$ the positive slopes in the temperature region 245-278 *K* for 1 GPa, 236-278 *K* 3 GPa are clearly seen in the Fig. 2 (a), (c) respectly, implying that $La_{0.7}Ca_{0.3}MnO_3$ belongs to the materials displaying a second-order transition. Fig. 2 (b), (d) shows the magnetization isotherms of $La_{0.7}Ca_{0.3}MnO_3$ for 1 GPa, 5 GPa from 203-300 *K* respectively. Isotherms in an increasing field (closed square) are measured only I the vicinity of T_C. It should be noted that there is very clear, little, and almost no magnetic hysteresis during the increase and decrease of fileds for three samples, respectively. The magnetic entropy as a function of temperature calculated by using the isothermal magnetization data under applied external magnetic fields. We found the maximum magnetic entropy change $-\Delta S_{Max}$ on various external magnetic fields from 4 kOe to 10 kOe. The values are = 1.2 J●kg^{-1}K^{-1}, 0.8 J●kg^{-1}K^{-1}, and 0.6 J●kg^{-1}K^{-1},with the pressure increase the entropy changes decrease. δT_{FWHM} of 44.7 K, 50.9 K and 72.6 K and *RC* values about 56.4 J●kg^{-1}, 50.9 J●kg^{-1}, and 49.9 J●kg^{-1} for 1 GPa, 3 GPa, and 5 GPa samples, respectively. The $-\Delta S_{Max}$ data versus the applied magnetic field are plotted. interestingly they can be decscribed well by the power law of $|-\Delta S_{Max}|=a\times H^n$ (the solid line). Having taken into account this power law for three samples and their *M/H* data up to 10 kOe .Such results indicate that the master curve $|-\Delta S_{Max}|=\alpha\times H^n$ for the field-dependent entropy change proposed by Franco *et al*.

HX-01. Calculation Method of Transformer Residual Flux by Using Hysteresis Loops of Different Frequencies.

W. Yuan[1], Y. Shangguan[1] and J. Yuan[1]
1. Dept. of Electrical Engineering, Tsinghua University, Beijing, China

Abstract: Residual flux in the transformer core can cause inrush current at re-energization, resulting in energization failure or power system resonance. In this paper, a new residual flux calculation method based on hysteresis loops of different frequencies is proposed. This method needs no complex hysteresis models. It conducts the time-domain iteration to calculate the transient current and the decline trajectory of H-B of the transformer core by using directly hysteresis loops of different frequencies and the de-energization current, until H=0 to get the residual flux. This method takes the current slopes and the corresponding dynamic magnetic property into consideration. 1 Introduction Because of the hysteresis property of ferromagnetic material, the residual flux will remain in the transformer core after de-energization. At re-energization, it may cause the total flux to exceed the saturation flux and cause inrush current, resulting in energization failure, transformer damage, or power quality decline. Therefore, it is necessary to know the residual flux, so as to eliminate the consequences. Calculation methods of residual flux based on the hysteresis loop have already existed, but most of them require complex hysteresis models, like Preisach model[1]. In these methods, hysteresis models are built firstly according to the measurement of material, then the residual flux is calculated with the models. Not only the model establishment is very complicated, but also most models are built with static measurement, which introduces calculation error. A new calculation method of residual flux by using directly hysteresis loops is proposed in this paper. It skips "model establishment" and takes the dynamic magnetic property into consideration. 2 Principle of residual flux calculation method by using hysteresis loops of different frequencies Under the excitation of the sinusoidal current of different frequencies and amplitudes, the hysteresis loops of ferromagnetic material are different. There are many curves passing through a certain point on the B-H plane. If the current decline rates are different, the core works with different B-H variation rates related to hysteresis loops of different frequencies. The current waveform after de-energization is related to de-energization phase, transformer internal parameters, and external circuit parameters. Usually, the current declines gradually, as shown in Fig.1. Because of the nonlinearity and the multi-value property of BH curves, the current and the magnetic field inside the core need to be calculated iteratively in the time domain. At each time step, the amount known includes previous H, B and two current magnitudes. The point on the B-H plane and the current slope can be decided. Afterwards, a specific hysteresis loop can be selected from several hysteresis loops that pass through the pre-decided point, as shown in Fig.2. The relationship between the current slope and the hysteresis loop slope needs to be obtained by preparation. 3 Specific implementation of residual flux calculation The overall idea is that the transient current and the H, B of the core are calculated iteratively with the de-energization current and hysteresis loops of different frequencies, until H=0 to get the residual flux. The key is ΔH, ΔB calculation when Δi is known. 3.1 Preparation Based on core and winding structure, obtain hysteresis loops of different frequencies and amplitudes by simulation. Record H, B values, and the relationship between current slope k_i and hysteresis loop slope k_{BH} at each point. Then, rearrange these data into a table, in which the independent variables are (H, B) and k_i, and the dependent variable is k_{BH}. 3.2 Calculation procedure (1) Record the current i at de-energization, calculate H according to the magnetic circuit, and get B according to the hysteresis loop before de-energization. (Or follow step (1').) (1') Record i at de-energization and at the moment Δt earlier. Calculate H and get B at the two moments as step (1). (2) If following step (1), calculate the inductance L of the transformer with H, B. If following step (1'), calculate the electromotive force e of the winding directly with ΔB. (3) Set a proper time step and do the transient circuit calculation, according to R, L (or e), C of the transformer and R_{out}, L_{out}, C_{out} of the external circuit, to get next i. (4) Decide the present point on the B-H plane with previous H, B. Calculate current slope with last i and the new i. Search the table to get k_{BH}. (5) Calculate ΔH, ΔB according to Δi, to get next H, B. (6) If H=0, B at this time is residual flux. End. Otherwise, return to step (2). At step (2), L or e is calculated only with previous H, B. To get better results, after step (5), L or e can be recalculated with the average of previous H, B and next H, B. Then carry out step (3)~(5) again, until the error meets the requirement. 4 Conclusions The transformer residual flux can be calculated through time-domain solution, according to the de-energization current and transformer circuit parameters. A series of hysteresis loops of the core material can be obtained by applying sinusoidal current of different frequencies and amplitudes, to obtain the multi-valued dynamic magnetic property for every point on the B-H plane. In the iteration, the property can be used to calculate magnetic field and current. This method avoids the computational complexity and error caused by the establishment of complex hysteresis model.

HX-02. Influence of the Winding Geometry and its Materials on the Resonance Behavior of Transformer Coils.

M. Nilges[1] and P. Schegner[1]
1. Institute of Electrical Power Systems and High Voltage Engineering, Technische Universitaet Dresden, Dresden, Germany

I Introduction Voltage stress due to steep impulses during switching operations of e.g. vacuum circuit breakers and ongoing harmonics caused by converters are a well-known but still increasing problem in the field of transformer design and operation [1]. In order to investigate the behavior of transformers during such impulses and oscillations, several models have been developed [2,3]. However, with increasing complexity of the coils, all studies show minor to major deviations in computation, compared to the corresponding measurements. Due to a high number of turns in the high voltage coils of transformers, the errors caused by simplifications or inaccurate data of the interwinding geometry can be tremendous. Hence, it is necessary to know which parameters are influencing the resonance behavior significantly and need to be represented accurately, while other parameters may be neglected. Therefore, a parameter study has been carried out, in order to analyze the resonance behavior of a simple coil geometry, based on FEM computations. II Setup For the following parameter study, the simple dry-type coil in Fig. 1a is analyzed. The inner diameter of the coil is 272mm and consists of 200 turns divided on 12 layers. The cross section of the wires is 1.4mm×4mm. The pronounced resonance frequency (RF) of the coil is ≈50kHz. Figure 1b to 1e show five of the seven parameters, which are being adjusted during the study. These are the thickness of the wire coating d_C, the distance between the consecutive turns d_T, the distance between the layers d_L, the displacement between two layers δ_L and the displacement of the first turn on each layer d_e caused by rising to the next layer. Additionally, the rel. permittivity of the wire coating $\varepsilon_{r\ coat}$ and the rel. permittivity of the epoxy resin between the layers $\varepsilon_{r\ EP}$ are varied. The number of simulations and therefore the computation time increases significantly with the number of the parameter variations. Therefore, only three variations for each parameter are applied: 100%, 80% and 50% of their initial values. The RF, as well as its resonance peak (RP), are used to analyze the influence of the parameters. Since the RF cannot be calculated directly by FEM-computations, it is estimated by performing a frequency sweep. To reduce the computation time, the frequency step size is set to 512Hz. The resulting RF and its RP are calculated for each parameter combination, using a cubic spline interpolation of the amplitude response. III Characterizing the Influence A representative value is necessary to characterize the influence of any parameter for all investigated cases. In order to calculate such a value for the RFs (and RPs), the following steps have been carried out. At first, one parameter is chosen for characterization. Following, a distinct combination of the six remaining parameters is picked. For this combination, the mean value over the resulting RFs of the three parameter variations is calculated. The relative deviations of the three states from their mean value give a characterization for the current combination. Subsequently, this method is used successively over all remaining combinations of the parameter permutations. The resulting deviations can already be used for a classification of the influence of any parameter. Furthermore, dependencies of other parameters can be obtained. However, to characterize the influence of the regarded parameter with only one representative value, the global maximum of all deviations η_{max} will be used. Other statistical methods as quantiles, distribution functions, etc. may be used likewise. IV Results Exemplarily, Fig. 2a and 2b show the resulting deviations of the parameters d_T and $\varepsilon_{r\ EP}$. Regarding these figures, the deviation forms steps for several groups of parameter combinations. These steps show the dependency of the regarded parameter to other parameters. If there is no dependency, the value of the deviation will not change. In contrast, the difference between two parameter combinations increases with a rising dependency of the changing parameter. The comparison of Fig 2a and 2b shows, that the parameter d_T is sensitive to changes of other parameters while its own influence is relatively low. However, the parameter $\varepsilon_{r\ EP}$ is behaving vice versa. It has a high influence on the RF and shows only a slight dependency of other parameters. Further evaluations of the computation results yield more dependencies and a deeper understanding of these behaviors. Considering the RF and using the representative value as introduced in section II, the highest deviation over all permutations for parameter d_T is only $\eta_{max\ T}$≈0.1%. Considering the highest overall deviation in Fig. 2b, the influence-value of parameter $\varepsilon_{r\ EP}$ is $\eta_{max\ EP}$≈8%. The other influences are $\eta_{max\ C}$≈7% (d_C), $\eta_{max\ dL}$≈14% (d_L), $\eta_{max\ \delta L}$≈0.2% (δ_L), $\eta_{max\ e}$≈0.4% (d_e) and $\eta_{max\ coat}$≈16% ($\varepsilon_{r\ coat}$). The influence-values for the RPs show a similar behavior. V Summary A parameter study has been carried out, in order to investigate the influence of several parameters on the RF and the RP of a dry-type transformer coil. The results show several dependencies and that the influence of three parameters is negligible.

HX-03. An Optimized Strategy Based on backflow power of Dual-active-bridge Converters with Extending Dual-phase-shifting Control.

Z. Feng[1] and S. Chi[1]
1. Hebei University of Technology, Tianjin, China

Abstract: To improve the efficiency of extending dual-phase-shifting, this paper presented an optimized strategy to make backflow power to be minimum. The small range of phase shift in conventional DPS control at light load could lead the whole system to be out-of-balance. While the secondary inner phase shifts extended from positive to negative, the character of inner phase in the method was optimized. By establishing mathematical models of transmission power, backflow power and relation of phase, the paper comparatively analyzed different working modes of the extending dual-phase-shifting control, and designed a strategy to make the backflow power to be minimum. Finally, building the simulation model of different modes to verify the advantage of the control method. Then an experimental prototype was developed based on this strategy, and the experimental resulted verify the effectiveness and feasibility of the proposed control strategy. In the early 1990s, a topology of isolated bidirectional dual-active-bridge DC-DC converter was proposed. [1] Because of the isolation, two-way mobility, power adjustable, DAB had became the first choice as DCDC converter.[2] In recent years, the research and analysis of DAB circuit mainly focused on how to improve the transmission efficiency, including reducing the back-flow power, soft switching, reducing current stress and other measures.[3] Based on the previous literature, this paper compares the control methods of dual-phase-shifting, and analyzes the principle of phase-shift optimization based on extended dual phase-shifting model. By analyzing the transmission power and the backflow power of the above control methods, the optimal control strategy with the goal of efficiency optimization is given and verified by experiment. I. principle of extending dual-phase-shifting control In the extending dual-phase- shifting, the inner phase shift of primary bridge is D_1' and the secondary side is D_1'', where$|D_1'|=|D_1''|=D_1$. The phase-shift between two full bridges is D_2. According to the size of D_1 and D_2, the extended dual phase shift can be divided into three working states: $0 < D_1 < D_2/2$(status 1), $D_2/2<D_1<D_2$(status 2), $D_2 < D_1 < (D_2+1)/2$(status 3) Fig1(a)(b). The limit of D_1 and D_2 is $2*D_1-D_2\leq 1$. The transmission power formula for each state is $P=[nU_1U_2(-3D_1^2-2D_2^2+4D_1D_2-2D_1+2D_2)]/(4fL)$ (status 1) $P=[nU_1U_2(D_1^2-D_2^2-2D_1+2D_2)]/(4fL)$ (status 2) $P=[nU_1U_2(3D_1^2+D_2^2-4D_1D_2-2D_1+2D_2)]/(4fL)$ (status 3) Status 1 is heavy-load;status 2 is light-load;status 3 is reverse direction transmission. Transmission power formula of traditional dual-phase-shift and extending dual phase shift in the light-load is changed into $D_1 = 1-D_2/2-P/(4KD_2)$ (traditional) $D_1 = 1\pm\sqrt{(1+D_2^2-2D_2+P/(2K))}$ (extending) where $K = nU_1U_2/(8fL)$ When $P = 0.2$, it can be seen from the figure that the adjust-range of D_1 in the conventional dual-phase-shift is 0.06-0.3, and the adjust-range of D_2 is 0.05-0.68 Fig1(c). The adjust-range of D_1 in extended dual-phase-shift 0.06-0.68 and the adjust-range of D_2 is 0.11-1 Fig1(d). II. Optimal control of backflow power The sum backflow power formula of the primary and secondary side is $Q = \int U_{ab}i_L(t)\,dt + \int U_{cd}i_L(t)dt = nU_1U_2(2D_1-D_2)^2/(4fL)$ The Lagrange multiplier method is used to analyze the backflow power of state 1 as follows: $F(D_1,D_2,\lambda) = 2K(2D_1-D_2)^2 + \lambda[2K(-3D_1^2-2D_1+4D_1D_2-2D_2^2+2D_2)-P]$ $dF/dD_1 = 8(2D_1-D_2) + 2\lambda(-6D_1-2+4D_2) = 0$ $dF/dD_2 = -4(2D_1-D_2) + 2\lambda(4D_1+2-4D_2) = 0$ $dF/d\lambda = 2K(-3D_1^2-2D_1+4D_1D_2-2D_2^2+2D_2) - P = 0$ To simplify the above formula, the relation of D1 and D2 is showed as $\lambda(D_1-2D_2+1) = 0$. While $\lambda = 0$, the formula is changed as $D_1 = 2D_2$. From the previous section the relationship does not exist in state 1. While $\lambda \neq 0$, the formula is changed as $D_1 + 1 = 2D_2$. Taking the relation into the formula of the transmission power, the relations of D_1 and D_2 is showed as: $D_1 = \sqrt{(1-2(1+P/(2K))/3)}$ $D_2 = [1+\sqrt{(1-2(1+P/(2K))/3)}]/2$ When the port voltage fluctuates, there is little backflow exist in state 2. The backflow power is showed as: $Q = nU_1U_2[(1-U_1/(nU_2))(1-D_1)]^2/(16fLU_1/(nU_2))$ $(U_1 < nU_2)$ $Q = nU_1U_2[(1-U_1/(nU_2))(1-D_1)]^2/(16fL)$ $(U_1 > nU_2)$ The formula shows that backflow power is only related to D1. So while $0< P < nU_1U_2/(16fL)$, the relation of D1 and D2 is showed as $D_1 = 1-\sqrt{(1-P/(2K))}$ $D_2 = 1$ While $nU_1U_2/(16fL)< P < nU_1U_2/(12fL)$, the relation of D1 and D2 is showed as $D_1 = [1+\sqrt{(1-3P/(2K))}]/3$ $D_2 = [2+\sqrt{(4-6P/K)}]/3$ III. Simulation and experiment In order to verify the theory, a low-power DAB experimental platform based on the TMS320F28035 controller was built. The parameters of simulation and experimental is:port voltage U1=U2=30V; frequency f=20kHz; additional inductor L=425.58uH; transformer ratio n=1:1. Fixed transmission power, the simulation result shows the curve of D1 and D2 Fig2(a). From the results, it can be seen that the phase shift angle is greatly improved compared with the traditional double-phase-shifting control. And the optimal control algorithm obtained in the previous section is verified experimentally to greatly reduce the back-flow power Fig2(b)(c)(d). IV. Conclusion This paper analyzes the extending dual-phase-shifting control which widens the range of the phase-shift at light load, optimizes the function curve of the phase-shift and makes the system adjustment more flexible. Meanwhile it inherits the advantage of zero backflow power in light-load state in the traditional dual-phase-shifting and proposes a control strategy in heavy loads state to improve the system power factor.

Abstract—Firstly, this paper analyzes the ability of power transformers to withstand the DC bias by a novel analytical criteria. The proposed criteria is obtained from the nonlinear equivalent circuit, which considers the effects of nonlinear inductances. Secondly, The validity of the proposed analytical criteria is verified by the finite element analysis results and experimental results (flux density, current, stress and vibration, noise), which indicates that the proposed analytical criteria is effective to evaluate the ability to withstand the DC bias of power transformers. *Index Terms*—DC bias, nonlinear equivalent circuit, power transformers, vibration and noise. I. Introduction The phenomena of the DC grid, geomagnetic storm change, DC voltage of converter transformers and other factors can result in DC bias. The DC bias leads to strong saturation of transformer cores and thus nonlinear operations. As a result, this effect can cause the increased magnetic leakage flux in cores, metal structure losses, temperature raises, local overheating, dielectric breakdown, and noise vibration as well as permanent damage to the transformer itself [1],[2]. To simplify the evaluation process and avoid the cost of the initial prototype for the required over-excitation multiples, this paper proposes a novel analytical criteria based on the nonlinear equivalent magnetic circuit considering the effects of inductances to evaluate the ability to withstand the DC bias of power transformers. The proposed criteria demonstrate that the peak values of the exciting current at the saturation conditions of transformers resulting from the DC bias and overvoltage should be close. The derivation process in terms of the transformers, exciting currents, and hysteresis loops are presented. To verify the effectiveness of the proposed analytical criteria to evaluate the ability of withstanding the DC bias, the simulation by a finite element method and experiments were conducted for a single-phase four-leg power transformer. II. Study of simulation and experiment and discussion of result In order to solve the modeling issue of the special structure in the power transformer, a model can be established by considering the magnetic circuit length, the cross-sectional area, the magnetization curve, and the effect of the nonlinear characteristic in the power transformer core. TABLE I shows the basic parameters of the single-phase four-leg power transformer. The transformer magnetic circuit model is established for considering the transformer structure, size, and nonlinear effects as in Fig. 1 and Fig. 2. Based on the transformer nonlinear models in Fig. 1 and Fig. 2, The transformer DC bias capacity is analyzed in the next section. the analytical criteria to calculate the DC bias capacity is illustrated in Fig. 3. Fig. 4 shows the maximum DC bias of the ability to withstand DC bias in power transformers. As shown in Fig. 4(a), the peak value of the exciting current at I_{DC}=1.91 A (DC bias) caused by the transformer saturation and the peak value of the exciting current at U_{in}=2809.1 V(overvoltage) caused by the transformer saturation are close to each other. Since it is difficult to directly evaluate the ability to withstand DC bias in power transformers, this finding contributes to the criteria to obtain the maximum DC bias based on the peak values of the exciting current for the saturation condition of the transformers caused by DC bias and overvoltage. As demonstrated in Fig. 4(b), the blue curve represents the relationship between the peak current and the overvoltage, while the red curve depicts the relationship between the peak current and the DC bias. The result indicates that the intersection point of the two curves is the maximum value of the DC bias where the power transformer can stand with a value of 1.91A. To verify the validity of the analytical method, the transformer model is simulated using the finite element method (FEM), and then the experiment is conducted. A one-phase four-leg transformer was established in Magnet software. As shown below, Fig. 5 is the flux density distribution of the transformer core without DC bias, and Fig. 6 is with a DC bias of 2.5A. Fig. 7 shows the setup of the experimental system, wherein the AC supply provides the input voltage with a value equal to or greater than 2000V by the step-up transformer. Fig. 8 shows the results of the exciting current using the analytical method, FEM, and the experimental method under different DC biases and the power transformer noise values under different DC biases. III. Conclusion This paper has presented a novel analytical criteria to estimate the maximum value of the DC bias that the transformer can withstand. The proposed analytical criteria was obtained based on the electrical circuit and magnetic circuit of the transformers by considering the core length, cross-sectional area, magnetization curve, and nonlinear effects. It has indicated that the peak values of the exciting currents at the saturation conditions caused by the DC bias and the overvoltage are close with each other. The analysis results of the proposed analytical criteria have been verified by the simulation results and experimental results, which shows good coincidence. Hence, the research provides a new insight in to the DC bias analysis of power transformers and the established models and analytical criteria can be applied to other transformer topologies.

I. INTRODUCTION Due to the air-gap iron-core structure and working state of AC and DC excitations, magnetically controlled saturated reactors (MCSRs) have strong vibration and noise, which will become one of the restricting factors for MCRs application and development. So far, research on MCSRs focused on the current harmonic characteristics and harmonic optimization [1], however, there are few studies on vibration noise and none of them analyzed the influence of different DC bias on vibration[2-3]. The main reasons for the vibration of MCSRs are the electromagnetic force generated by the air-gap on both sides of the magnetic valve and the magnetostrictive effect of the silicon steel of the iron-core material[4]. The electromagnetic force is directly affect by silicon steel used in MCSRs magnetization properties; similarly, the magnetostrictive force of the reactor is also closely related to the magnetostrictive properties of the silicon steel[5]. In different DC bias, silicon steel could present different magnetization and magnetostrictive properties. The vibration study of MCSRs based on the magnetic properties of silicon steel under practical working conditions has not been involved yet, so it is necessary to study the electromagnetic vibration of MCSRs under AC and DC excitations. Multi-group magnetization and magnetostriction properties curves of silicon steel under different DC bias are measured firstly to support the computation. Then Based on the measured constitutive relations, an electromagneto-mechanical coupling model for MCSR considering magnetostrictive effect and electromagnetic force effect is proposed. Vibration regulation of MCSRs was obtained based on finite element method, which compared and analyzed magnetic field, stress and vibration displacement of MCSRs, the resulted comparative analysis and regulation provides a theory basis for further analysis of vibration and noise reduction. II. MCSRS VIBRATION MODEL A. Measurement of magnetic properties of silicon steel under DC bias. In order to ensure the accuracy of MCSRs vibration calculation, the magnetic properties of silicon steel under different DC bias were measured in this thesis. The obtained basic magnetization curve and magnetostrictive curve are applied to the simulation calculation of vibration noise of MCSRs by using the interpolation method to make the calculation result more accurate. B. Electromagneto-mechanical coupling model of MCSRs. The total energy of the reactor's electromagnet-mechanical system includes the magnetic field energy, the strain energy, the current potential energy, the magnetostrictive energy and the power produced by the electromagnetic force. Based on the energy variation principle, the magnetic vector potential A and mechanical deformation u can be calculated by minimization of the total energy functional. III. MCSR IRON-CORE VIBRATION CALCULATION In this thesis, the single-phase MCSR is regarded as the research object. In calculation, AC excitation (, f=50Hz) and DC excitation I_{DC}=0A, 2A, 4A is applied. Fig.1 (a) shows the magnetic flux density distribution of MCSR at t=0.025s with different DC bias. As can be seen from the figure, with the DC bias increases, the amplitude of the MCSR flux density also increases. Magnetic flux amplitude of magnetic valve is greater than the other locations. The stress distribution of MCSR under different DC bias is shown in Fig. 1 (b). The figure shows, the stress amplitude and deformation of the MCSR also increase with the increase of the DC bias, and similar to the magnetic flux density distribution, which shows that the amplitude and distribution of the magnetic flux density directly affect the stress of the reactor iron-core. In addition, the stress of the reactor iron-core is mainly concentrated on the magnetic valve, the T-type contact surfaces, the lower iron yoke and the upper iron yoke on the side of the saturated magnetic valve. The rainbow plot shown in Fig.1 only gives the data values for the reactor magnetic field and vibration at a point in time, to study the change of MCSR vibration with time, the test points in the simulation model are needed to embed. According to the distribution of magnetic flux density and stress distribution of MCSR iron-core, taking into account the symmetry of the structure and the particularity of the magnetic valve, six points of A, B, C, D, E and F are selected as the focus of study thus to analyze reactor vibration changes over time. Point A is the point on the upper iron yoke, point B is the point at the T-type contact surfaces, point C is the point of the yoke, point D is the point of the central iron-core column, point E and point F are respectively the magnetic valve 1 and 2. The relationships between displacement and time under different DC bias is shown in Fig.2. IV. CONCLUTION The magnetic flux density, stress and displacement of MCSRs increase with the increases of DC bias, the vibration of the T-type contact surfaces and the magnetic valve are the most intense. Therefore, the vibration reduction work should focus on the T-type contact surfaces and magnetic valve. In the reactor air-gap filled with negative giant magnetostrictive material, negative deformation of the negative giant magnetostrictive material under magnetic field is used to counteract the original mechanical deformation of the reactor, so as to achieve the effect of reduction.

HX-06. Research on transformer core vibration Based on Thermal Analogy Method.

B. Zhang[1], J. Du[1] and N. Yan[1]
1. Shenyang University of Technology, Shenyang, China

I.Introduction With the increasing of voltage grade and capacity of power transformer, the problem of vibration noise becomes more and more prominent. The noise source of the transformer consists of three, core, winding, cooler or radiator. The core is the main source of noise. The reason for the noise is that the silicon steel sheet is in the effect of the alternating magnetic field, because the magnetostrictive effect produces the change of size, so that the core vibrates periodically with the change of excitation frequency.[1] At present, the simulation of magnetostriction is mainly based on numerical calculation method. There are three main types: piezomagnetic analogy method, piezoelectric analogy method and thermal analogy method. The methods of piezoelectric analogy method and piezoelectric analogy method are used to analyze the magnetostrictive materials. For the silicon steel sheet in motor or transformer core, the deformation of iron core caused by its magnetostriction is small, and its displacement is not enough to cause the obvious change of the magnetic field. Therefore, the numerical calculation of magnetostriction can be obtained by coupling method based on thermal analogy method. However, in the previous study, the above method only gave the motor example, and the magnetostrictive rate of the iron core adopted the method equivalent to the empirical formula, and the accuracy was not very satisfactory.[2] In this paper, a thermal analogy method is proposed to simulate the magnetostrictive effect of the silicon steel in transformer core. The magnetostrictive characteristic curve of silicon steel sheet was obtained by experiment. The finite element method and the interpolation of the curve were obtained. The vibration simulation of transformer core is realized by using magnetostrictive stress-thermal stress analogy method. II.Model The magnetostrictive characteristic curves of the magnetostrictive experiments of silicon steel sheet materials are obtained. The magnetic field distribution on the core of the transformer is obtained through the finite element method. Based on the distribution of the magnetic intensity vector in the finite element element, the curve of the magnetostrictive properties of the interpolated silicon steel is obtained, and the strain is obtained on each node. Because the strain of the node and the deformation of the node are to be coordinated with the shape function of the unit, it is difficult to solve directly. Therefore, the thermal analogy method is applied to the basic parameters of the thermal stress analogy calculation, and the equivalent model of parameters applicable to magnetostrictive stress - thermal stress is derived. Assumes that the thermal expansion coefficient and the initial reference temperature, get the node core area and temperature, and the results as a thermal analysis of the node temperature load, calculation of thermal stress by node coordinate displacement and stress. ANSYS software does not directly solve the function of magnetostriction effect, but the above analogy can directly solve the vibration displacement of each node in the transformer core through software. III.Exapmle The single-phase three-column core model for the dfp-270000/500 super high voltage generator transformer is modeled. The magnetic flux density of each node is obtained through the finite element electromagnetic field. Using the above analogy method, the thermal stress analogy is calculated, and the magnetostrictive stress and displacement of each node are obtained. Due to the transient field calculation, the magnetostrictive stress and displacement comparison of different time and frequency can be performed. At the same time, the vibration frequency simulation is carried out to determine whether the resonant phenomenon is possible. IV.Conclusion In this paper, the finite element simulation is used to simulate the thermal stress of magnetostrictive force. An example of magnetostrictive effect simulation of power transformer core is given. The calculation method can be used to simulate the vibration of transformer core in ANSYS software.

HX-07. Performance Optimization of a Novel Saturated Core Fault Current Limiter Considering Eddy current Loss of Permanent Magnet.

L. Wei[1,2], B. Chen[1], Y. Liu[3], H. Zhou[1], Y. Zhong[1], J. Yuan[1], K. Muramatsu[4] and C. Wang[1]
1. Wuhan University, Wuhan, China, Wuhan, China; 2. Department of Electrical Engineering, Kyoto University, Kyoto 606-8501, Japan; 3. Anhui Electric Power Research Institute, Hefei, China; 4. Department of Electrical and Electronic Engineering, Saga University, Saga, Japan

I. INTRODUCTION Due to the rapid development of power grid and renewable generations, the fault currents are approaching or even exceeding the existing rating interrupting capacity of circuit breakers [1]. With the development of permanent magnet materials (PMs), permanent-magnet-biasing saturated core fault current limiter (PMFCL) has been one of the most promising methods to limit the fault current [2]. However, there are two major problems limiting the development of PMFCLs: the demagnetization risks of PMs caused by large induced eddy current loss and the inadequate biasing ability of PMs. To reduce the eddy current loss of PMs and improve the biasing ability of PMs, this digest proposes a novel saturated core fault current limiter based on PMs (PMFCL). A novel magnetic structure can effectively reduce the eddy current loss of PMs, resulting in reducing the demagnetization risks of PMs. An optimal small section of cores can improve the saturation degree of cores and biasing ability of PMs. Compared with traditional PMFCLs, the proposed PMFCL has the advantages of better biasing ability of PMs, smaller eddy-current loss of PM, and lower risks of demagnetization. The principle and performance have been validated by various FEA simulation and optimization studies. II. BASIC PRINCIPLE AND OPTIMIZATION DESIGN OF PMFCL Fig.1(a) shows the basic structure of proposed PMFCL, which consists of iron cores, PMs and coils. A small section which of cross-section area is smaller than that of main core is proposed to improve the biasing ability of PMs. Under normal conditions, PMs drop cores I and II into deep saturation. The normal impedance of PMFCL is very low, and the AC flux will not flow through PMs, as shown in Fig.1(b). Under fault conditions, the fault current is large enough to drop cores I or II out of saturation alternatively, resulting in limiting the fault current. Compared with traditional PMFCLs, each PM will flow through half of AC flux produced by the fault current, the eddy current loss of PMs can be reduced effectively. Fig.1(c) shows the equivalent magnetic circuit of PMFCL. To improve the saturation degree of cores and the biasing ability of PMs, the parameters of small section should be optimized. In addition, the length and cross-section area of PMs also have an important influence on the reduction of eddy current loss of PMs. III. RESULTS OF FEA SIMULATION To validate the principle and performance of PMFCL, various FEA simulation and optimization studies of 220V/10A PMFCL were performed. The fault current with proposed PMFCL can be limited from 286.0A to about 97.0A. Fig.2(a) shows the flux density distribution of cores and PMs. Under normal conditions, cores I and II are driven into saturation by PMs. Under fault conditions, cores I and II are dropped out of saturation, respectively. The result comparison of eddy current loss of PMs is shown in Fig.2(b). Compared with traditional PMFCLs, the proposed PMFCL can reduce the eddy current loss of PMs from 188.9W to 24.5W (87% reduction), resulting in reducing the demagnetization risks of PMs effectively. Fig2(c) shows the magnetic flux density distribution of core I under normal conditions in the different lengths of small section. The flux density distribution along cores I without small section is not uniform. The saturation degree of cores and biasing ability of PMs can be improved by the small section. The parameters of small section also have a significant influence. In Case 3: L_b=0.14m, S_b=0.00243m^2, the saturation degree is optimal with B_{min}=2.001T. And the length of PM can be reduced from 70mm to 50mm, which has a 28.6% reduction. Therefore, the results of FEA simulation and optimization studies verify the excellent performance of proposed PMFCL. IV. CONCLUSION In this digest, a novel permanent-magnet-biased fault current limiter (PMFCL) has been presented. According to the theoretical analysis and optimization studies, the proposed PMFCL can reduce the eddy current loss of PMs and improve the biasing ability of PMs, and have excellent fault clipping performance. Compared with traditional PMFCLs, the proposed PMFCL can achieve a 87% reduction in eddy current loss of PMs. Hence, the proposed PMFCL can reduce the demagnetization risks of PMs effectively. Moreover, the biasing ability of PMs can be also improved by the optimal small section. The length of PM can be reduced by 28.6%. In addition, more detailed optimization and experimental studies will be analyzed in the full paper.

HX-08. Analysis of a Novel Near-Field Plate applied in Wireless Power Transmission System.

X. Zhang[1] and Z. Zhang[1]
1. Tianjin Normal University, Tianjin, China

There are many disadvantages in traditional power transmission mode, such as the wire is neither safe nor convenient, the installation of electric equipment is limited by the length of the wire, and the wire aging prone to leakage problems which will harm people's health. In order to overcome these shortcomings, the wireless power transmission mode is adopted in many aspects. The basic structure of the wireless power transmission system is divided into four parts: power source, transmitting coil, receiver coil and load. The power is transmitted through the transmitter coil in the form of electromagnetic waves, and the power is captured by the receiver coil and then transmitted to the load. During the electromagnetic wave propagates from the transmitter coil to the receiver coil, however, the electromagnetic wave produces a large amount of radiation to the surrounding environment, and the loss increases with the increased distance. This not only affects the surrounding other electrical equipment and cause serious harm to the human body. In view of the above problems, this paper presents a novel near-field plate to apply in the wireless power transmission system which not only reduce the power loss and improve the transmission efficiency of the system, but also gather the scattered electromagnetic waves around to reduce the radiation of the system to the surrounding environment. In order to see farther and smaller things, humans have invented telescopes, microscopes, and other tools. The principle of these tools is the use of a lens to interfere with the light waves, allowing one can see a clearer image of the object. The researchers found that the specific interference of light wave can reduce the loss of light wave in the transmission process and enhance the brightness of light. In other words, when the lens has multiple seams, and the distance between the seams and the seams is even times of half light wavelengths, the peak of the light passing through the lens is superimposed to make the brightness of the light stronger. According to the principle that interference of light wave by lens can enhance the brightness of light, a near-field plate is proposed and designed to improve the performance of wireless power transmission system. The near-field plate is constructed by the copper strip which is placed on the surface of a plate to design a special pattern. This special pattern of copper strip has a beneficial interference of electromagnetic wave, so that electromagnetic waves come together through the near-field plate to reduce the loss of electromagnetic wave. When the near-field plate is applied to the wireless power transmission system, the transmitter coil, the receiver coil and the near-field plate must achieve resonance, so as to enhance the electric field intensity at the receiver coil and to improve the transmission efficiency of the system. Through designing and simulation, the near-field plate has the better aggregation effect on the electromagnetic wave when it is designed with a small hole near its center, thus the receiver coil can receive more power. In this paper, a near-field plate is proposed as shown in Fig. 1. There is a small hole in the middle of the near-field plate, and its radius is about 2mm. The dark part near the hole and the outermost dark part are both copper coils. The light color part between the two copper coils is a slit. In addition, in order to guarantee the near-field plate have same resonant frequency with the transmitter coil and the receiver coil, a capacitance is connected to each of the copper coils in the near-field plate. The near-field plate is placed between the transmitter coil and the receiver coil. The wireless power transmission system with near-field plate is simulated. The current induced in the receiver coil is shown in Fig. 2. It can be seen that the current will be increased about 17%. The parameters of the near-field plate can still be optimized and the detail results will be given in full paper.

With the increase of total economy, the power supply, which injects vigor into our society, has the more crucial position. Whereas the power transformer acts as the significant element of power systems, the hot-spot temperature inside the transformer tank should be calculated and measured accurately[1]. Due to the hot-spot temperature has restricted the development of transformers, especially the oil-immersed transformer, so how to decrease the hot-spot temperature is a challenge for the researchers, engineers and manufacturers. Mineral transformer oil inside the transformer tank plays an essential role in transferring thermal, which produced by core loss[2], copper loss, stray loss and anomalous loss. Note, in 1995 Stephen had presented an innovative new class of heat transfer fluids, by suspending metallic nanoparticles to mineral transformer oil, exhibiting high thermal conductivities compared to those of fluids without adding nanoparticles[3]. Then the characteristics of cooling of transformer oil with nanoparticles can present excellent performance. Therefore, TiO_2 nanoparticles decorated with oleic acid to reduce agglomeration are added to mineral transformers oil as the coolant of a transformer. The transformer oil with different volume of fraction (0.001%, 0.002%, 0.004%, 0.01%, 0.02%, 0.04%, etc.) TiO_2 nanoparticle shows various performance through simulation and measurement. Through simulation and comparison finding the point of optimum operating temperature for each concentration. Then summarizing the optimum concentration from the results when oil-immersed transformer operates range from 343 Kelvin to 368 Kelvin for reducing the volume of a transformer at the same power. During the measurement, the signal-phase transformer with power 500VA whose brand is DELIXI is adopted. The diameter of TiO_2 particles is under 100nm[4, 5]. Measuring the temperature of transformer oil adopts thermocouples on the different position inside the transformer tank. Then, to compare and analyze those results among each other, the best fraction is chosen as the ideal parameters, which can be as a reference for engineers or manufactures.
