The perovskite manganites having the general formula $R_{1-x}A_xMnO_3$ [R = La^{3+}, Pr^{3+}, etc., and, A = Sr^{2+}, Ba^{2+}, etc.] have enticed considerable attention during the last three decades because of colossal negative magnetoresistance and mutiferroicity.[1,2] The parent compound $RMnO_3$ containing Mn^{3+}:$t_{2g}^3 e_g^1$ ion is an antiferromagnetic insulator but the introduction of charge carrier (e_g hole in Mn^{4+}:t_{2g}^3) by Sr^{2+} substitution for R (= La^{3+}, Pr^{3+}, Nd^{3+}) induces ferromagnetism and also metallic like resistivity for x = 0.2- 0.5.[3] The simultaneous occurrence of ferromagnetism and metallic resistivity is understood in terms of Zener's double exchange interaction [4]. On the other hand, cobaltites of the formula $RCoO_3$ are nonmagnetic insulator at low temperatures but they also show ferromagnetism and metallic resistivity when holes (Co^{4+}) are introduced by partial substitution of Sr^{2+} for R^{3+} ion for x = 0.2-0.5 [5]. The occurrence of ferromagnetism in hole-doped cobaltites is can be understood without recourse to the Zener's double exchange interaction but by Stoner's type - band ferromagnetism [6]. Hole-doped cobaltites show much smaller magnetoresistance (5-7% for H = 7 T) at the ferromagnetic transition temperature (T_C) compared to colossal magnetoresistance (= 50-100 %) for the same field at T_C [7]. Hence, it will be interesting to investigate the effect of Co substitution for Mn on magnetism, electrical resistivity and magnetoresistance. Zero-field cooled and field-cooled magnetization and *ac* susceptibility measurements in $La_{0.7}Sr_{0.3}Mn_{1-x}Co_xO_3$ were interpreted in terms spin glass (SG) or cluster glass (CG) state that evolves with Co substitution for the doping range x =0.3-0.9.[8]. Magnetic and magnetoresistance in rare earth cobaltites other than R = La are still scarce. Tryonchuck *et al*.,[9] investigated $Pr_{0.5}Sr_{0.5}Mn_{1-x}Co_xO_3$ by neutron diffraction and revealed that the magnetic ground for the compounds with composition range 0.1 £ x £ 0.25 is SG or CG state, whereas, a new inhomogeneous FM state appears for higher Co doped compounds. While $Pr_{0.5}Sr_{0.5}MnO_3$ shows paramagnetic to ferromagnetic transition (T_C = 250 K) followed by antiferromagnetic transition. On the other hand, $Pr_{0.6}Sr_{0.4}MnO_3$ undergoes only a temperature driven PM to FM transition near room temperature (T_C = 305 K), however, a first order magneto-structural transition occurs at a still lower temperature (T_{MST} = 86 K) which causes a step-like decrease in the temperature dependence of magnetization[10]. Here, we investigate the effect of Co substitution on magnetism, electrical resistivity and magnetoresistance in $Pr_{0.6}Sr_{0.4}Mn_{1-x}Co_xO_3$ (x = 0 to 0.1). We observed that the long range FM order persists for low doping (x = 0.05) with a radical downshift in T_C (260 K). Surprisingly, the magnetostructural transition of the parent compound shifts down to low temperature with 5% Co doping, but disappears for 10% doping. A decrease in magnetization as well as increase in electrical resistivity (r) [from ~0.055 W-cm for x = 0.0 to ~ 0.15 W-cm for x = 0.1 at room temperature] with Co doping have been observed, which clearly indicates destabilization of ferromagnetic DE interaction. For both the compounds x = 0.0 and 0.05, r shows a clear peak at their respective T_C, whereas, such feature is absent in x = 0.1 (Fig. 1. (a)-(c)). The temperature dependent magnetoresistance (MR), defined as MR = [r (7T) - r (0T)]/r (0T) x 100 %, also shows a peak at T_C for both the compounds x = 0.0 and 0.05. However, the MR for x = 0.1 does not show a peak at T_C but a huge enhancement in MR at low temperatures occurs with increasing Co doping [from 45 % for x = 0.0 to 65 % for x = 0.1 at 10 K under 7 T magnetic field] (Fig. 1. (d) and (e)). The origin of large MR at low temperatures for Co doped compounds will be explained in the framework of spin dependent transport between neighbouring FM grains (tunneling magnetoresistance). A common observation in perovskite manganite films is that the Curie temperature (T_C) decreases with the reduction of film thickness, which limits their potential for spintronic devices, such as field-effect transistors, magnetic tunnel junctions, and nonvolatile magnetic memory [1,2]. This is the so-called "dead layer" effect. Recently, many efforts have been made to increase the T_C of ultrathin perovskite manganite films by superlattice interface control and precise strain tuning [3]. $La_{0.67}Sr_{0.33}MnO_3$ (LSMO) films have drawn increasing interest due to their colossal magnetoresistance effect, high T_C, and half metallicity [4,5]. First principle calculations indicate that the T_C of LSMO films can be increased by more than an order of magnitude by controlling orbital ordering in LSMO/$BaTiO_3$(BTO) superlattices [6]. Here, we synthesized (001) oriented $[LSMO(3u.c.)/BTO(3u.c.)]_n$ superlattices (denoted as SL-n, where n = 3, 4, 10 is the number of cycles and u.c. is the shortening of unit cells) using pulsed laser deposition (PLD) and reveal the relationship between the origin of high T_C and manganese e_g orbital occupancy through the use of x-ray linear dichroism (XLD) measurements. It is found that the regular intercalation of BTO layers between LSMO layers can effectively enhance ferromagnetic order and increases the T_C of ultrathin LSMO films due to the orbital occupation of $e_g(x^2–y^2)$ in Mn^{3+} ions. Figure 1(a) shows the cross-sectional high-resolution transmission electron microscopy (HRTEM) of the SL-3 sample on a (001) oriented $SrTiO_3$ substrate, endorsing high quality epitaxial growth of LSMO/BTO superlattice. The image shows atomically sharp interfaces between the LSMO and BTO layers highlighted by red arrows. There is no obvious interdiffusion at the interfaces, and the LSMO and BTO layers are fully strained to the $SrTiO_3$ substrates. The temperature-dependent magnetization for SL-n films with n = 3, 4, 10, as well as a LSMO(3) sample with the thickness of 3 u.c., are shown in Fig. 1(b). The T_C of the superlattices is significantly improved compared to the LSMO(3) film, of which T_C is around 45 K (see the inset). For the SL-10 sample, the T_C reaches a maximum value of $T_C \sim 310$ K. For (001) oriented LSMO films, supposing that $e_g(x^2–y^2)$ is occupied in Mn^{3+} ions, the intralayer double exchange between Mn^{3+} and Mn^{4+} will become very strong and the interlayer double exchange will decline in strength. This can result in a high T_C of thin film samples. In our LSMO/BTO films, the lattice parameter of the BTO (a = 0.397–0.403 nm from a tetragonal to rhombohedral phase) is larger than that of LSMO (a = 0.387 nm), resulting in a ~ 4% lattice mismatch. The LSMO layers are in a high tensile strain state ($c < a$), causing occupancy in the $e_g(x^2–y^2)$ orbital. We have confirmed the manganese e_g orbital occupancy in relation to XLD measurements, which is an extremely sensitive probe for the electronic structure and the d orbital (e_g) electron occupancy. Fig. 1(c-d) show the XLD spectra of Mn, as well as the in-plane and out-of-plane x-ray absorption spectroscopy (XAS) spectra, of SL-3 and SL-10 samples. The area under the XLD curve at the L_2-edge peak (DXLD) representing the difference between the relative occupancies of the $e_g(x^2–y^2/3z^2–r^2)$ orbitals, is negative, implying a preferential occupancy of the $e_g(x^2–y^2)$ orbital. Thus, the interfacial tensile strain induces in-plane orbital ordering of the $e_g(x^2–y^2)$ orbital occupancy in the LSMO layers, achieving in-plane double exchange ferromagnetic coupling between Mn^{3+} and Mn^{4+} ions with high T_C. Our findings create new opportunities for the design and control of magnetism in artificial structures and offer considerable potential for applications in novel magnetoelectronic applications, including nonvolatile magnetic memory working far above room temperature.

BR-03. Electrical Conduction Mechanism for Investigation of Charge Ordering in $Nd_{0.5}Ca_{0.5}MnO_3$.

A. Swain[1] and V. Gorige[1]
1. School of Physics, University of Hyderabad, Hyderabad, India

Colossal magnetoresistance in manganites has been extensively investigated for the last two decades. However, the phenomenon of charge ordering (CO) and its consequent effects do not seem to have been fully explored [1]. The parent manganite, $LnMnO_3$ (Ln = rare earth cation) is an antiferromagnetic-insulator (AFMI) due to superexchange interaction with nearest neighbor Mn^{3+} ions. The partial substitution of divalent cation at Ln site results in two valence state of Mn (i.e. Mn^{3+} and Mn^{4+}) and the physical properties are controlled by Mn^{3+}/Mn^{4+} ratio. Particularly, the equal concentration of Mn^{3+} and Mn^{4+} in manganites leads to localization of conduction electron by resulting in AFMI behavior, called charge ordering (CO) [2]. The destabilization of CO by some means may lead to a ferromagnetic-metal (FMM) behavior with huge magnetoresistance (MR) and mostly this can be achieved by applied magnetic field, which is power consuming process [3]. There is a quest for alternative approaches to suppress the CO other than the magnetic field for low power consumption. In view of this, an attempt was made to demonstrate the suppression of CO by reducing particle size in $Nd_{0.5}Ca_{0.5}MnO_3$ (NCMO) manganite system. Even though the magnetic and electrical properties are strongly correlated in these manganites, unfortunately, there is no comprehensive study on CO suppression by analyzing electrical transport mechanism. In this work, we are presenting a detailed investigation of the effect of particle size as well as the applied magnetic field on CO behavior in NCMO manganite system by studying electrical transport properties. The samples with different particle sizes (20-400 nm) were synthesized by using a citrate-based sol-gel method by sintering at different temperatures (700-1350 °C). The samples were characterized by physicochemical characterization techniques. The electrical transport measurements were carried out by using PPMS (Quantum Design) in an applied magnetic field ranging from 0-12 T. The electrical resistivity data were analyzed by considering appropriate theoretical models in different temperature regimes. The phase purity of all the samples was confirmed by x-ray diffraction (XRD) and the Rietveld refinement of the data reveals that all the samples crystallize in orthorhombic structure with '*Pnma*' space group. The crystallite size of the samples was estimated from full-width at half-maxima of the XRD peaks by adopting Williamson Hall method. In addition, the grain and particle sizes were obtained by scanning and transmission electron microscopy techniques, respectively. The crystallite, grain, and particle sizes were found to increase with increasing sintering temperature. Since the samples crystallized in orthorhombic structure, it was expected that the variation in particle size might cause changes in orthorhombic strain (OS), which may result in considerable changes in physical properties [1]. The estimated OS (*ac*-plane and along *b*-axis) of the unit cell versus particle size plot shows a significant change around 50 nm, which can be attributed to the CO crossover in these samples. In fact, the CO crossover is in agreement with data obtained from temperature dependent magnetization, which appears as a broad hump (T_{CO}) ~ 240 K [4]. As the charge and spin degrees of freedom of electrons are strongly coupled in these systems, the temperature dependent electrical resistivity (ρ-T) is expected to show CO signatures around T_{CO}. Unfortunately, the ρ-T data is not showing any anomaly around T_{CO}. It is known that the activation energy of charge carriers is more sensitive as compared to resistivity. However, surprisingly, when the temperature-dependent activation energy curves were plotted, a hump around 240 K was noticed signifying CO behavior. Interestingly, it is getting suppressed for the samples with a particle size below 50 nm and with the applied magnetic fields above 4 T. To understand more clearly CO crossover as a function of particle size as well as applied fields, the ρ-T curves were obtained in presence of magnetic fields. The FMM behavior along with metal-insulator transition (T_P) started appearing in the applied field ≥ 4 T, which signifies the CO melting. The ρ-T data around T_{CO} was fitted with Small Polaron Hopping (SPH) and Variable Range Hopping (VRH) models in different temperature regimes. Well above the T_P, the data were fitted with SPH model and the polaron activation energy was calculated. Further, just above T_P the ρ-T data was fitted with VRH model and charge carrier density values were estimated. The variation of the obtained parameters with particle size and applied magnetic fields were showing significant change around 50 nm as well as the applied fields ~ 4 T. Further, field-induced FMM behavior in these samples was analyzed in terms of grain/domain boundary, electron-electron, and electron-magnon interactions. The effect of the relative contributions of these terms on CO melting is discussed in the full paper. Finally, the MR% was calculated around T_{CO} and it was found that the value of MR% is double for CO samples (particle size > 50 nm) when compared to CO suppressed samples (particle size < 50 nm). In conclusion, the observed CO crossover in NCMO around 50 nm particle sizes can be attributed to the prominent surface spin disorder, planar discommensurations and induced lattice strain effects arising due to large surface to volume ratio of the nanoparticles.

Magnetoresistance (MR) effect is at the heart of modern information storage, which represents the electrical resistance change ratio of materials or devices under the application of external magnetic field. In order to realize large MR value, lots of promising materials and structures were proposed. Extraordinary MR (EMR) [1, 2] in some non-magnetic semiconductors has gained much attention owing to the large MR magnitude and linear magnetic field dependence, which can be ascribed to inhomogeneity of carrier density or mobility. Recently, large MR value was realized by exquisitely coupling the magnetic response of materials and the nonlinear transport effect of diode [3, 4]. However, these devices could not satisfy the requirement of high sensitivity at low magnetic field and small work current simultaneously. Here, we utilized the negative MR and large resistivity of ZnCoO magnetic semiconductor films to realize high magnetic-field sensitivity with small work current at room temperature. In our experiments, ZnCoO magnetic semiconductor films of 60 nm were cut into a stripe with 7 mm in length and 2 mm in width. As shown in Fig. 1(a), linear voltage-current (V-I) curves and about -13% MR values were observed. Here, MR is always defined as $MR=(V_H-V_0)/V_H$, where V_H and V_0 are the voltage detected with and without applied magnetic field respectively. Then a Zener diode was connected between electrode 1 and 4 to fabricate a diode assisted ZnCoO device (DAZD). Fig. 1(b) shows the V-I curves and MR value of the DAZD with 9.1V Zener diode under different magnetic fields. A sharp increase in voltage by several orders was observed at critical transition current I_C=0.375 mA under 0T, which is directly related with the Zener Diode. When the applied current is smaller than 0.375 mA, the voltage dropped on the diode is smaller than the critical voltage (U_C) of Zener diode and the diode could be considered as open circuit, which results in a small measured voltage because of the voltage attenuation with the increase of distance. When the voltage dropped on the diode is larger than U_C, the diode can be considered as short circuit and electrode 4 and 1 turn into short-connected, which results in a sudden increase in the detected voltage. As shown in Fig. 1(b), the MR value of the DAZD is high up to -1539% at 0.1T, -3958% at 0.4T, -5359% at 1T and -6850% MR at 6T with small work current, which is a higher sensitivity in low magnetic field compared with the Si, Ge, GaAs nonmagnetic semiconductor. As shown in Fig. 1(c), the MR value and the shape of MR curve could be tuned by the applied current. For I = 0.380 mA and I = 0.428 mA, the MR value is almost the same (~ -850%), but the former one is much higher than the later one in magnetic field sensitivity and the shape of the MR curves changes from sharp to obtuse. Generally, the MR value of DAZDs was closely related to the transport property of Zener diode and ZnCoO films. Here, we measured the MR value of DAZDs connected by Zener diodes with different threshold voltage. With the increase of Zener diodes' threshold voltage, the MR_{max} value increases at first, then remains nearly unchanged as shown in Fig. 2(a). This is because that the Zener diodes' sharpness of resistance transition increases with the increase of U_C and keeps the same when U_C larger than 6.8V as shown in Fig. 2(b). This work may have potential application in the area of magnetic sensor industry with the advantage of low power consumption.

BR-06. Negative spin Hall magnetoresistance in antiferromagnetic Cr_2O_3/Ta bilayer at the low temperature region.

Y. Ji[1], J. Miao[1], K. Meng[1], J. Chen[1], X. Xu[1], Y. Wu[1] and Y. Jiang[1]
1. School of Materials Science and Engineering, University of Science and Technology Beijing, Beijing, China

Spin Hall magnetoresistance (SMR) is a MR effect that there is no charge current in the ferromagnetic (FM) layer, which depends on the relative orientation between the magnetic moments of FM layer and the spin direction injected from normal metal (NM), therefore ferromagnetic insulators (FMIs) are widely applied in SMR.[1] Recently, A. Manchon investigated the physical origin of SMR in antiferromanets and predicted that should be observable with other antiferromagnetic insulators such as NiO, CoO, Cr_2O_3 etc. [2] Unsurprising, we observed a nearly 0.1% SMR ratio in Cr_2O_3/W with 9 T.[3] Soon after that, a negative SMR has been observed in both NiO bulk crystal and films.[4-6] 50 nm Cr_2O_3 film was grown on Al_2O_3 (0001) substrate by pulse laser deposition and a 5 nm thickness of Ta layer was in-situ grown on the surface of Cr_2O_3 film by magnetron sputtering. Then, we manufactured 400 μm×40 μm hall bar for electrical measurements by electron beam lithography and Ar ion etching. A 400 μm×40 μm hall bar for electric measunremts was patterned on the surface of sample. Fig. 1(a) show the angle-dependent magnetoresistance measurements on Cr_2O_3/Ta bilayer with a constant field 3 T. Fig. 1(b) shows the angle dependence of SMR for Cr_2O_3/Ta bilayer with 3 T at various temperature, where the corresponding temperature dependence of SMR is described in Fig. 1(c). Interestingly, as the temperature decreases, SMR changed from positive to negative monotonically. In order to explain above observations, the magnetization structure of Cr_2O_3 need to be taken into account. As known, a surface magnetization exists at the (0001) surface of the magnetoelectric antiferromagnet Cr_2O_3.[7] Therefore, Cr_2O_3 can be divided into two parts: surface ferromagnetism and bulk antiferromagnetism, both will contribute to SMR. The surface ferromagnetism leads to the positive SMR, while the negative SMR origins from the bulk antiferromagnetism. To confirm this conclusion, the Hall resistance measurements were carried out in Cr_2O_3/Ta bilayer at different temperature, shown in Fig. 2(a) and Fig. 2(b). When the temperature is higher than 250 K, the slopes of hall curves are all positive and abnormal Hall effect (AHE) can be observed. In addition, AHE signals get stronger with the increasing temperature, which origins from surface ferromagnetism of Cr_2O_3. On the other hand, as the temperature is lower than the transition temperature, the slopes of hall curves are all negative and no AHE signals can be found. In other words, surface ferromagnetism may vanish, or bulk antiferromagnetism may cover the surface ferromagnetism up.[7] In conclusion, we observed a negative SMR ratio in Cr_2O_3/Ta bilayer below 250 K, which is attributed to magnetization of Cr_2O_3The observations of negative SMR in antiferromagnet, like NiO, Cr_2O_3, pave the way for applications in antiferromagnetic spintronic devices.

Abstract: A systematic investigation on the effect of sputtering power, substrate temperature and film thickness on the structural and magnetic properties of DC magnetron sputtered Mn_2VGa Heusler alloy films have been carried out by using x-ray diffraction, SQUID magnetometry and magnetic force microscopy (MFM). In plane (IP) and out of plane (OOP) magnetization measurements carried out on tetragonal Mn_2VGa thin films shows strong OOP magnetization (which is absent in the reported cubic Mn_2VGa films) which is close to the IP magnetization value. The observed IP and OOP magnetic moment at 5 T is 1.62 μ_B and 1.26 μ_B respectively and the IP and OOP coercivity is 2 KOe and 2.2 KOe for 100 nm thick film deposited at 75 W power and 450˚C substrate temperature. The crystallinity and magnetization (both IP and OOP) was found to decrease as the substrate temperature and film thickness was reduced due to the off stoichiometric film growth. MFM images shows patch like domain pattern with decreasing magnetic phase contrast with decrease in substrate temperatures and thickness. A disorder dependent scattering below 67 K and a minimum around 25 K is observed in resistivity measurement for the film deposited at 400 ˚C substrate temperature. Introduction Half-metallic ferromagnetic Heusler alloy films are being used as spin injection electrodes in spintronic devices such as magnetic random access memory (MRAM) and read head of hard disc drives due to their peculiar electronic band structure where majority (minority) carriers exhibit conductive nature and minority (majority) carriers exhibit semi conductive or insulative nature [1]. This gives 100% spin polarization at the Fermi level for these alloys (half-metallicity). Ramesh Kumar *et al*. have shown the ferrimagnetic nature and half-metallicity in Mn_2VGa alloy through neutron diffraction, magnetic, transport and magneto-transport studies [2,3]. The reported Curie temperature for Mn_2VGa is 783 K which is well above the room temperature and the magnetic moment is 1.88 μ_B which is suitable for spintronic applications. For device applications, it is essential to fabricate thin films of this material with desirable physical properties. In this paper, first time we report the existence of OOP magnetization along with the IP magnetization in tetragonal Mn_2VGa Heusler alloy films .A systematic investigation on the effect of thickness and substrate temperature on the IP and OOP magnetization has been carried out. Results and discussion XRD measurements showed tetragonal crystal structure for the films irrespective of the sputtering parameters. Better crystallinity was observed for films deposited at elevated power (75 W) and substrate temperature. Figure 1a shows the XRD patterns of 100 nm thick films deposited at 75 W power and different substrate temperatures. The interesting observation from the magnetization measurement is the presence of strong OOP magnetization along with the in plane component in the films as shown in figure 1b which was absent in the cubic Mn_2VGa films [4]. The magnetization value at 5 T (M_{5T}) for the film deposited at 500 ˚C substrate temperature is 255.2 emu/cc (1.62 μ_B/f.u) for the IP and 198.9 emu/cc (1.26 μ_B/f.u) for the OOP configuration. Even though the IP magnetic moment value of 1.62 μ_B/f.u is different from the expected integer value of 2 μ_B/f.u (as per Slater-Pauling rule) for the cubic Mn_2VGa, it is better than the earlier reported value of 1.56 μ_B/f.u for the cubic Mn_2VGa film [4]. The coercivity value at 5 K for the IP and OOP configurations are 2 KOe and 2.24 KOe respectively for the film deposited at 500 ˚C substrate temperature which differ significantly from the reported soft magnetic behavior of bulk sample. Magnetic moment (IP&OOP) was found to decrease with the decreases in substrate temperatures as shown in figure 1b. This could be due to the poor crystallinity of the films at lower substrate temperatures. The M-H curve for the room temperature deposited film shows a diamagnetic behavior (possibly dominated by the Si substrate) both in IP and OOP measurements. It was observed that the IP and OOP magnetization has gradually decreased as the substrate temperature and thickness was lowered. Temperature variation of resistivity shows a metallic behavior with a dominant disorder dependent scattering for T < 67 K and electron–phonon scattering in the high temperature regime (T > 67 K). A minimum was observed around 25 K, possibly due to the disorder enhanced coherent scattering of conduction electrons.

Introduction: Spintronics is the spin based technology which utilizes the electronic spin degree of freedom in addition to its charge [1,2]. For realization of spintronic devices, special materials are required; i.e., their electrical conduction should be by only one type of spin carriers. Realization of spin-polarized transport occurs in materials classified as half-metals, spin gap-less semiconductors and magnetic semiconductors. These materials can be either ferro-, ferri- or fully compensated ferrimagnets. The necessary condition in all these materials is that they show integer magnetic moment. In order to retain spin polarization at room temperature, these materials should also possess high magnetic ordering temperature. From the last decade, quaternary Heusler alloys (QHAs) gained importance in the search for spintronics materials [3]. Kundu *et. al.* studied certain Co-based QHAs such as CoRuMnSi [4]. We probe this alloy using a joint experimental and theoretical study. Experimental techniques: Polycrystalline CoRuMnSi alloy was prepared by arc-melting followed by annealing for 7 days at 800 °C. Room temperature powder X-ray diffraction (XRD) pattern was analyzed usign Fullprof suite. There are three nondegenerate crystal arrangements in the Y-type structure [5]. By keeping Si at 4a site in F-43mspace group, the configurations are I) Mn at 4b, Co at 4c and Ru at 4d sites, II) Mn at 4c, Co at 4b and Ru at 4d sites, and III) Mn at 4d, Co at 4c and Ru at 4b sites respectively. Reitveld refinement was carried out for all the configurations including disorder. Magnetization measurements were carried out using Physical property measurement system. Electrical resistivity (ρ) measurements were done using four probe contact method by applying 5 mA current. Theoretical details: Spin resolved band structure calculations were carried out with the help of Quantum ESPRESSO [6]. Exchange correlations were taken in GGA approximation. Four atomic face centred cubic primitive cell was used. All the three configurations were fully relaxed with different initial magnetic states. The parameters such as energy cutoff, charge density cutoff, kpoints sampling in Brillowin zone etc. used in simulations are same as mentioned elsewhere [7]. Results and Discussion: (i) Crystal structure: XRD pattern of CoRuMnSi can be indexed in LiMgPdSn type structure with lattice parameter of 5.78 Å. However, due to 50% anti-site disorder between tetrahedral site atoms (as revealed from refinement), the crystal symmetry reduces to $L2_1$. Refinement considering 50% anti-site disorder of tetrahedral atoms gives the best fit [Fig. 1 (a) and (b)]. In configuration I, Co and Ru occupy tetrahedral sites while in configuration II, it is between Mn and Ru. XRD refinement is unable to distinguish between these two configurations. However on the basis of electronegativities, one can conclude that Mn occupies octahedral site and hence configuration I with 50% antisite disorder (between Ru and Co) is the actual structure [1,5]. Theoretical simulations also confirm the configuration I as the ground state. (ii) Magnetization and electrical transport: For QHAs composed of at least two elements having more than half-filled d electrons, the saturation moment obeys the following Slater Pauling rule [2,5] M_s=N-24, where N is the total number of valence electrons. The alloy has a moment of nearly 4 μ_B at 3 K (see Fig.2(a)), which is consistent with the SP rule as it contains 28 valence electrons. It is found to be ferromagnetic with T_C > 400 K(see Fig.2(b)). In Fig. 2c, ρ-T data is shown, which indicates metallic nature above 50 K. Theoretical results: Configuration I with ferromagnetic state is found to be the ground state among the three configurations. It has spin moments of 0.99 μ_B, 0.16 μ_B and 2.85 μ_B on Co, Ru and Mn respectively. Its spin resolved DOS and band structure are shown at the bottom panel of the Fig. 2. Minority spin band has a gap of 0.58 eV and the Fermi level lies nearly 23 meV above the top of the valence band. Minority spin band has metallic bands crossing the Fermi level. The energy differences among the three configurations is quite large (> 16 mRy/atom) and hence no disorder is expected to occur in atomic sites other than on the tetrahedral ones. Conclusion: CoRuMnSi crystallizes in $L2_1$ structure as revealed by XRD pattern. Magnetization measurements reveal that it is ferromagnetic with a moment ~ 4 μ_B/f.u. and T_C of more than 400 K. Absence of T^2 contribution to ρ(T) indirectly suggests the half-metallic nature. Theoretical simulations predicts that the material is a half-metallic ferromagnet in the ground state configuration with a moment that is consistent with the experimental value. Energy differences among the three configurations is quite large and hence disorder in the atomic positions is not possible. In view of these, this alloy appears to be a promising candidate for spintronics applications.

Spintronics is the emerging field of electronics, utilizing not only the charge of electrons but also their spins, which offers many advantages (such as non-volatility, high speed, low power consumption, etc.) over conventional electronics. For driving the spintronics devices, fully polarized spin current is essential, which can be generated using the special type of magnetic materials such as half-metallic ferromagnets (HMF), spin-gapless semiconductors (SGS), etc. However, SGS materials, because of their unique band structure, have gained a lot of interest for potential spintronics applications due to their exceptional magnetic and transport properties over HMF. SGS materials exhibit a band gap in one spin channel and a zero band gap in the other spin channel at the Fermi level (E_F), which leads to 100% spin-polarization at the Fermi level. SGS properties have been observed in Heusler alloys (e.g., CoFeMnSi, Mn_2CoAl, CoFeCrAl, Ti_2MnAl, etc.), oxides (Co-doped $PbPdO_2$), zigzag silicene nanoribbons, and strained Ti_2C monolayer. Among the known SGS candidates, Heusler alloys have attracted much attention due to their very high Curie temperature (T_C). CoFeMnSi is an equiatomic quaternary Heusler alloy (EQHA), which crystallize in the Y-type structure, and is experimentally confirmed as a SGS material in bulk form. However, for spintronics applications, the unique properties of SGS have to be realized in thin films. Here, we report the structural, magnetic and transport properties of CoFeMnSi (CFMS) epitaxial thin film grown on single crystal MgO (001) substrate using pulsed laser deposition (PLD) system. The temperature dependence magnetization (M-T) indicates that the Curie temperature (T_C) of the film is well above 400 K. The magnetic field (H) dependence magnetization (M-H) measurements gives the saturation magnetization (M_s) value of 3.28 μ_B/f.u. at 300 K. The electrical resistivity of the film is indicating a semiconducting behaviour with TCR value of -7×10^{-10} Ω.m/K which is comparable with the TCR values reported for SGS Heusler alloys and is much less than the TCR values of classical semiconductors. Nearly temperature independent and low electrical conductivity of the order of 2.86×10^3 S/cm indicates a possible SGS behaviour and in agreement with experimentally reported SGS behaviour. One of the main impacts of the SGS materials is that they can be used as the SGS/semiconductor heterostructures to enhance the spin injection efficiency due to smaller conductivity mismatch as compared to the HMF/semiconductor heterostructures. Therefore, SGS behaviour with high Curie temperature (T_C) makes CFMS thin films as a potential candidate for fabricating the practical spintronics devices. (e.g., spin vale, magnetic tunnel junctions etc.).

BR-10. Interplay between structure and anisotropic magnetoresistance in Ta/NiFe/Ta thin films.

H.W. Chang[1], M. Chan[2], D. Wei[2], C. Wang[3] and C. Ouyang[4]
1. Department of Physics, National Chung Cheng University, Taichung, Taiwan; 2. National Taipei University of Technology, Taipei, Taiwan; 3. Department of Applied Physics, Tunghai University, Taichung, Taiwan; 4. Department of Materials Science and Engineering, National Tsing Hua University, Hsinchu, Taiwan

Anisotropic magnetoresistance (AMR) effect, resulted from the anisotropic scattering of conduction electrons due to the spin-orbit interaction, has been extensively investigated due to wide applications in advanced spintronic devices, magnetoresistance heads, and magnetic field sensor [1-3]. Because of its relatively large AMR ratio and excellent soft magnetic properties, permalloy (NiFe) is the most adopted material for AMR devices. Ta was reported being able to improve microstructure and AMR ratio of NiFe films [3], and the sensing component typically contains a Ta/NiFe/Ta multilayer for desired microstructure and performance. In this study, in order to further understand relationship between the AMR rato and the microstructure, Ta/NiFe/Ta trilayer films are prepared on SiO_2/Si(100) substrates at room temperature (RT) by sputtering at the external magnetic field of 1 kG induced NdFeB sintered magnets. Structure, surface morphology, magnetic properties, and AMR of Ta/NiFe/Ta films with various working pressure and thickness of Ta underlayer and post-annealing temperature are reported, and the relationship between the AMR ratio and the microstructure is also discussed. X-Ray diffraction analysis show that the crystallinity of the NiFe(111) texture strongly depends on the working pressure (P_{Ta}) in the range of 2-8 mtorr, thickness (t_{Ta}) in the range of 0-5 nm of Ta underlayer and post-annealing temperature (T) of 150-400 ^{o}C at magnetic field of 1500 Oe. The studied films at P_{Ta} of 2-5 mtorr and t_{Ta} of 0-5 nm through proper post annealing (T = 150-300 ^{o}C) exhibit smooth interface and flat surface with low root-mean-square roughness. The in-plane magnetic anisotropy, induced by the applied magnetic field during deposition, with good soft magnetic property is obtained, and it is improved through post-annealing at appropriate T = 150-300 ^{o}C. Figure 1 (a) shows MR ratio versus magnetic field curves of Ta/NiFe/Ta films post annealed at various temperatures (T), and MR ratio of the films with various T, t_{Ta}, and P_{Ta} are summarized in Fig. 1(b)-(d), respectively. All studied Ta/NiFe/Ta films exhibit a typical MR ratio and good MR properties. As shown in Fig.1 (b), with increasing T, MR ratio is improved from 1.5 % at T = RT to 2.5% at T = 300 ^{o}C resulted from enhanced NiFe(111) texture at first, and then reduced to 1.3 % and 0.9% at T = 350 ^{o}C and 400 ^{o}C, respectively, because of interdiffusion between NiFe and Ta layers. The above result indicates the optimal annealing temperature here is 300 ^{o}C. As shown in Fig. 1(c) and (d), for as-deposited films, the change of MR ratio with either t_{Ta} or P_{Ta} is similar to that of peak intensity and d_{csd} of NiFe(111) texture, and the MR ratio is significantly enhanced through post annealed at T = 300 ^{o}C due to improved NiFe(111) texture. Finally, the relationship between the structure and MR property is also revealed, except for the samples with rougher surface. MR ratio is found to increase with increasing d_{csd} as shown in Fig. 2. MR ratio increases from 1.3% to 2.5 % as d_{csd} grows from 11.1 nm to 15.6-16.0 nm. The results indicate that the structural defects especially planar defects suppress the MR ratio of the studied Ta/NiFe/Ta films. This study suggests that proper Ta underlayer and post-annealing are crucial in the MR properties for Ta/NiFe/Ta system.

BR-11. Different Phase Mn_2Ga films introduced by varying the Cr buffer thickness.

Y. Zheng[1], Y. Liu[1], L. Ren[1] and K. Teo[1]
1. Electrical and Computer Department, National University of Singapore, Singapore

I. INTRODUCTION Tetragonal Mn_xGa alloys in $L1_0$ or $D0_{22}$ phase have small α, high P and high PMA, tunable M_s which perfectly meet the requirement for STT-MRAM.[1-4] Cubic Mn_xGa alloys are not energetically favored and observed in the bulk, but can be deposited in thin films on certain substrate or buffer layer.[5] Usually, the cubic Mn_xGa can form half-Heusler or Heusler structure, in which a 100% spin polarization is predicated. Especially cubic Mn_3Ga is considered as a potential "half-metallic antiferromagnet" with zero spin magnetization moment from the modified Slater-Pauling rule m = Nv–24, where Nv is the number of valence electrons per formula. The "half-metallic antiferromagnet" could be useful because the material would be fully spin polarized, yet would be free from shape anisotropy and create no stray field. Kurt has realized the "half-metallic antiferromagnet" by doping Ru or Pt in the cubic Mn_2Ga materals.[5, 6] *II. EXPERIMENTS AND RESULT* Mn_2Ga films were deposited on MgO (100) substrate with a Cr buffer layer in an ultrahigh vacuum MBE chamber. Before depositing Mn_2Ga film, MgO substrate was annealed at 600 °C. Different thickness of Cr buffer layer was deposited at ambient temperature and subsequently *in-situ* annealed at 600 °C. The 7 nm Mn_2Ga film was then deposited at ambient temperature and subsequently *in-situ* annealed at temperature T_a = 400 °C. The film stack was finally capped with MgO layer of 4 nm at room temperature to prevent oxidation. The composition of the films was controlled by the Mn and Ga fluxes. The structural analysis was performed by x-ray diffractometer (XRD). Magnetization measurements were carried out using a vibrating sample magnetometer (VSM). Figure 1 shows XRD patterns for 7 nm thick Mn_2Ga films with different thickness of Cr buffer layer. For the films with Cr thickness larger than 5 nm, both Cr (002) and tetragonal Mn_2Ga (002) peaks can be clearly observed, indicating the films are tetragonal structure. For the films with ultrathin Cr thickness (1 nm and below), two $C1_b$-Mn_2Ga (001) and $C1_b$-Mn_2Ga (002) are observed. For the Mn_2Ga film with 3 nm Cr buffer layer, no Cr or any other Mn_2Ga peaks are observed, which means both Mn_2Ga phases are not overwhelmed. For the cubic phase of Mn_2Ga, lattice constant of 6.00 Å is found for the films with 1 nm Cr buffer layer or without buffer layer. The epitaxial relationship should be MgO(001)[100]//Mn_2Ga(001)[110]. For tetragonal phase of Mn_2Ga, the lattice constant decrease with the increase of the thickness of the Cr buffer layer for the tensile stress change. Usually the lattice constant varies much with the thickness of the Cr buffer layer or tetragonal MnGa since large lattice mismatch between Cr and MnGa (nearly 4%). However, it keeps nearly constant for cubic Mn_2Ga condition (5.99 Å is found for 30 nm Mn_2Ga on MgO substrate) since there is only about a 1% lattice mismatch between Cr and cubic Mn_2Ga. Hysteresis loops measured at 300 K for Mn_2Ga film with different Cr buffer layer thickness are shown in figure 2. The Hysteresis loops for the films with Cr buffer layer below 1 nm present the superparamagnetic state, which may be come from the small size ferromagnetic manganese compound clusters. All the Mn_2Ga films with Cr thickness larger than 1 nm show the PMA and the saturated magnetization value increase with the Cr thickness. This reflect the more and more tetragonal Mn_2Ga phase exist in the films. The square perpendicular hysteresis loop in figure. 2 (e) means rather pure tetragonal phase Mn_2Ga film when it is deposited on the 13 nm Cr buffer layer. The hysteresis loop shape change for the film with 40 nm Cr buffer layer may come from the strain relax. In summary, thin Mn_2Ga films were grown on MgO substrate with varying thickness of Cr buffer layer using molecular beam epitaxy. Cubic Mn_2Ga films with the half-Heusler $C1_b$ structure obtained when the thickness of Cr buffer layer is below 3 nm. Tetrogonal Mn_2Ga phase with high perpendicular magnetic anisotropy are obtained when the thickness of Cr buffer layer is above 3 nm.

BR-12. Generation of Néel field in anti-ferromagnetic nanowire by a sloped electric field.

K. Kubota[1], K. Yamada[2] and Y. Nakatani[1]
1. Graduate school of Informatics and Engineering, University of Electro-Communications, Chofu, Japan; 2. Faculty of Engineering, Gifu University, Gifu, Japan

Since a proposal of a racetrack memory, a magnetic domain wall motion in a magnetic nanowire has attracted attention as a novel technique for memory development [1]. Recently, it has reported that the domain wall motion velocity in Anti-ferromagnets (AFM) is much faster than that in ferromagnets [2-6] and, the DW motion in AFM has been gathering attentions. The DW in AFM with Dzyaloshinskii-Moriya interaction (DMI) can be moved by an external magnetic field and a spin-orbit spin transfer torque[4-5]. Whereas the DW in AFM without DMI can be moved by Néel field generated by Néel Spin Orbit Torque (NSOT) [7,8]. In this study, we propose a method to generate Néel field by using a sloped electric field (SEF) and demonstrate the DW motion in AFM by micromagnetic simulations. We used one dimensional nanowire with 360 nm of length and 1.0 nm of thickness. The nanowire is divided by rectangular prisms with dimension of 2.0×1.0 nm^2. The material parameters used in the simulations are as follows: the saturation magnetization M_s = 10000/4π emu/cm^3, the perpendicular magnetic anisotropy K_u = 2.0 Merg/cm^3, the homogeneous exchange stiffness constant A = 1.6 μerg/cm, the inhomogeneous exchange stiffness constant A_0 = 1.0/π Gerg/cm^3, and the Gilbert damping constant a = 0.01. In the simulation, we assumed that K_u is decreased by the electric field, therefore K_u is decreased linearly from left edge to the right edge in the wire by SEF (Fig. 1) [9]. The reduction rate of K_u is defined asΔKu (erg/cm^4) [9]. Because K_u changes by SEF, the DW energy ($\sigma = 4\sqrt{(AK_u)}$) [10] changes with the position in the nanowire. The DW moves in the direction of decreasing DW energy (K_u) even in AFM wire. An effective magnetic field should be applied to the moving DW. The directions of the effective field to M_1 and M_2 sublattices in moving DW in AFM should be opposite (Néel field) (see Fig.1). In this way, the Néel field is generated by SEF. To confirm the generation of the Néel field by SEF, we simulated the DW motion in AFM by SFE. Figure 2 shows the effect of the ΔK_u on the DW motion velocity (v). The Néel field (H_k) generated by the SEF can be obtained in the same method as [9]; $H^{\mathrm{eff}}_k = (\partial\sigma/\partial x)/2M_s$ (1). Figure 2 also shows the effective Néel field (H^{eff}_k) generated by the SEF and the DW motion velocity obtained by (where g and D are the gyromagnetic ratio and DW width, respectively). The simulation results agree very well with the DW velocity of $v_{\mathrm{Anlay.}}$ obtained by Eq. (1). It shows that Néel Field can be generated in AFM by SEF.

Spintronic devices rely on thin layers of magnetic materials, for they are designed to control both the charge current and the spin current of the electrons. Half-metallic ferromagnets (HMFs) have only one spin channel for conduction at the Fermi level, thus in principle this kind of material has 100% spin polarization for transport properties. Combined with the unique elemental selectivity of x-ray magnetic circular dichroism (XMCD), we can determine the local symmetries, the electronic configuration and the values of orbital and spin moments of specific element. X-ray absorption spectroscopy (XAS) measurements at the Co and Fe $L_{2,3}$ absorption edges were performed on beamline I06 at Diamond Light Source, U.K. Oppositely circular polarized X-rays with 100% degree of polarization were used to successively resolve XMCD signals from the respective elements. The light-helicity was switched in a saturating magnetic field of 1 T, which was applied at 60 degrees with respect to the film plane and in parallel with the incident beam. The XMCD was obtained by taking the difference of the XAS spectra, that is, $\sigma^- - \sigma^+$ by flipping the X-ray helicity.[1] Typical XAS and XMCD spectra of the 2.5-uc-thick Co_2FeAl film using total electron yield detection (TEY) are presented in Fig. 1. Both Co and Fe show a white line at each spin-orbit split core level without prominent splitting for both left- and right-circularly polarized X-rays, shown in Fig. 1a & 1d, indicating that the samples have been well protected from oxidation. The XMCD signals of Co (Fig. 1c) and Fe (Fig. 1f) point to the same direction, which indicates a ferromagnetic coupling between the two elements. The shoulder structures appear in the higher photon energy region of Co L_3 peaks, which is corresponding to the B2 structures due to the Co-Co bonding states. One of the most powerful aspects of the XMCD technique is that the average magnetic moment of each element can be calculated by applying the sum rules using the integrated intensity of the XAS and XMCD spectra. The orbital moment (m_l) of Co atom (0.17 μ_B/atom) and Fe atom (0.14 μ_B/atom) is a little bit large, compared with a previous study.[2] We believe the enhancement of orbital magnetic moment, implying the possibility of enhanced spin-orbit coupling (SOC), is derived from the interfacial contribution of Co_2FeAl/GaAs. The presence of Al decreases the localized magnetic moment on both Co and Fe sites, which is due to the empty majority bands. Therefore, the magnetic moment of Al is negative and is about -0.10 μ_B/f.u. In our 2.5-uc-thick sample, considering the calculated value of the moment at Al site, the total magnetic moment of the Co_2FeAl thin film has been evaluated as 3.41 μ_B/f.u. The theoretically predicated magnetic moment for Co_2FeAl thin films is very different, such as 3.8 μ_B/f.u., 4.89 μ_B/f.u.,[3] and 5.0 μ_B/f.u[4]. Compared with the data reported by S. Soni *et al*.,[5] an obvious reduction of Fe spin magnetic moments was observed. This loss could be attributed to either the site disorder in the bulk of the film, or the existence of a non-ferromagnetic interlayer close to the Al_2O_3 capping layer. The unique elemental selectivity of the XMCD technique has enabled direct observation of the relative magnetization of the Co and Fe, which indicates a ferromagnetic coupling of Co and Fe atoms.

BS-01. Reliability Comparison of Stator-Permanent Magnet Machine and Rotor Permanent Magnet Machine.

W. Li[1] and M. Cheng[1]
1. School of Electrical Engineering, Southeast University, Nanjing, China

I. INTRODUCTION Recently, flux-switching permanent magnet (FSPM) machines have attracted wide interests due to the merits of high power density and high efficiency, etc.[1]-[4]. The reliability of FSPM machine is qualitatively analyzed by changing the phase number of the motor, thermal calculation and fault tolerance control in some literature. However, the reliability quantitative analysis of FSPM machines has never been reported although it is an important issue for electrical machines. Hence, in this paper, a reliability assessment model of FSPM machine is established based on Markov method. Then, a reliability comparison between FSPM machine and Prius machine is conducted. The relationship between the reliability and the position of the PM is determined. Finally, the comparison results are essentially useful to guide the selection of application field for the stator-PM machine. II. THE RELIABILITY MODEL AND ANALYSIS OF MACHINE Reliability analysis, not only need to consider the health state and failure state of components and subsystems, but also need to consider their main faults on the system work. The reliability state of machine system are determined by comparing reliability criteria with the effects of every faults. Markov process is a non-aftereffect stochastic process and based on the change of system state. The next state is only associated with the present state and regardless of all previous states. The Chapman-Kolmogorov equations is the most commonly used method for calculating the Markov method[5] (1) where, the superscript T, and represents the transpose of the matrix, derivatives of state probability matrix and state transition matrix, respectively. $P(t)$ can be represented by a row vector. The elements in the state transition matrix represent the probability of state transition. The sign indicates the state transition direction, "-" means transfer out and "+" means transfer in. The sum of each reliable working state is equal to the system reliability: (2) The biggest characteristics of stator-PM machine is that PMs are located on stator. It is necessary to discuss the influence of the PM position on the reliability. The heat dissipation of the PMs are relatively easy due to the PMs are located on stator. Compared with the PM failure rate of three-phase FSPM machine, the PM failure rate of Prius machine is relatively big. Therefore, the PM failure rate multiplied by a coefficient w to represent the impact of heat dissipation on the failure rate. (3) where, λ_{PMPD} represent permanent magnet performance degradation. Using the Markov method, the reliability equation of FSPM machine system and Prius machine system are calculated. Comparing the reliability of these two machine systems, the curves and the difference between them are illustrated in Fig.1. There is almost no difference in their reliability. The reliability varied with *w* are illustrated in Fig. 2. With the increase of *w*, the rate of decline of surface increases. The reliability of three-phase FSPM machine system (w=1) is bigger than that of Prius machine system (w>1). Therefore, the PM on the stator is helpful to improve the reliability of the PM-machine. III. CONCLUSION The Markov method are used to evaluate the reliability of FSPM machine system and Prius machine system. The effect of every component fault on the reliability assessment is considered. The biggest difference between their structure is the PM position, which indicates that the PM position can influence the reliability. The effect of temperature on the failure rate of PM is considered in the process of reliability evaluation. By comparing their reliability, the application field of FSPM machine system is wide. The detailed process of reliability assessment and analysis will be elaborated in the full-paper.

BS-02. Torque Analysis and Improvement of Single-Phase Asymmetric-Stator-Pole Doubly Salient Permanent Magnet Machine.

M. He[1], W. Xu[1] and C. Ye[1]

1. School of Electrical and Electronic Engineering, Huazhong University of Science and Technology, Wuhan, China

Abstract—Doubly salient permanent magnet machine (DSPMM) has received extensive attentions recently due to its simple structure, high reliability, high torque density, *etc.* An improved 4/4 stator/rotor single-phase asymmetric-stator-pole doubly salient permanent magnet machine (SP-ASPDSPMM) is proposed in this paper. Firstly, it investigates the topologies and operation principle based on graphical description and torque expression. Then, the effect of main structure parameters on the torque is studied based on two-dimensional finite element algorithm (2-D FEA). And then, comprehensive comparison on main electromagnetic performances for the two machines is made. Finally, one prototype for the improved structure is made and tested. It indicates that lower cogging torque, lower torque ripple and stronger starting performance can be obtained by the improved structure. The theoretical results are well validated by the experiments. I. Introduction Doubly salient permanent magnet machine (DSPMM) has been studied extensively in recent years due to its high torque density, high efficiency, high reliability, *etc.* [1]. However, the torque density of traditional DSPMM with concentrated windings is limited by its unipolar flux linkage. To obtain bipolar flux linkage and improve the electromagnetic performances, one 4/6 stator/rotor single-phase DSPMM with full-pitch winding configuration is developed in [2, 3]. They could offer higher efficiency and lower copper cost with the same output power. But they suffer from low material utilization ratio and poor starting performance. To solve the problems mentioned above, one 4/4 stator/rotor single-phase asymmetric-stator-pole doubly salient permanent magnet machine (SP-ASPDSPMM) is proposed in [4]. Based on the analysis results of [4], the torque density can be further improved by the SP-ASPDSPMM. But the torque ripple of it is relatively high and may deteriorate its operation performance. Therefore, one improved SP-ASPDSPMM is proposed in this paper to further improve its electromagnetic torque performance and other electromagnetic performances. This paper is organized as follows. In Section II, the topologies and operation principle for the SP-ASPDSPMMs are investigated. After that, the effect of main structure parameters on torque is performed based on two-dimensional finite element algorithm (2-D FEA) in Section III. In Section IV, comprehensive comparison of the original and improved structures on main electromagnetic performance indexes is made. Then, one prototype for the improved machine is made and tested in Section V. In Section VI, some conclusions are drawn. II. Topologies and Operation Principle Topologies for the original and improved 4/4 stator/rotor SP-ASPDSPMM are shown in Fig.1. It is known that the pole shoe, step air gap and auxiliary teeth are introduced in the improved structure. For limited space, more details will be given in the full paper. III. Effect of Main Structure Parameters on Electromagnetic Torque In this section, some design specifications are given and the effect of designed structure parameters on electromagnetic torque is studied based on 2-D FEA. More details will be given in the full text. IV. Performance Comparison In this section, the no-load air-gap flux density, output torque, torque ripple, starting torque, losses and other performances of the two machines are compared comprehensively. Fig. 1 shows the components of torque of both machines. The average torque for the original and improved structure is 0.72 and 0.59 Nm, respectively. However, the peak-to-peak value of torques for both machines are 2.67 and 1.29 Nm, respectively. Thus, the average torque for the improved structure is 18% lower than that of original one and the torque ripple for the former is 52% lower than that of the latter. Compared with the original machine, the value of reluctance torque for the improved model is higher around the θ=0°&45°rotor position and it reaches the minimum at θ=22.5°&67.5°rotor position, where the reactive torque reaches its maximum. Besides, the peak-to-peak value of cogging torque for the improved structure, 0.39 Nm, is 65% lower than that of the original one, 1.11Nm. Thus, the torque ripple could be much reduced. More results will be given in the following full paper due to the limited space. V. Experiment To verify the feasibility of proposed machine, a prototype with 750W and 25,000 rev/min is manufactured. The static torque, starting torque with different currents and other performances are tested and the measured results will be given in the full manuscript in details. VI. Conclusion An improved 4/4 stator/rotor SP-ASPDSPMM is proposed in this paper. The special topology and operation principle are investigated. The effect of designed structure parameters on the electromagnetic torque is analyzed based on 2-D FEA. The performance comparison of main electromagnetic performance indexes between the original and improved structure is made. It indicates that the average torque, cogging torque and torque ripple are 18%, 65% and 52% lower than those of original one, respectively. One prototype for the improved structure is made and the measured results are in good agreement with the theoretical analysis results based on 2D FEA with considerably small errors.

I. INTRODUCTION Small electric vehicles called city commuters travelling short distances have attracted much attention because of its small battery and low price. However, as the small city commuters have limited space inside the car, it is important to develop an in-wheel motor that incorporates a traction motor inside the wheel in order to utilize effectively space inside the car [1-2]. As one of the in-wheel motor, an in-wheel axial-gap motor, which is flat shape and can insert a reduction gearbox into the center of the stator core, has been proposed [3-5]. Cost reduction is required for traction motors in addition to the high performance such as small size, high output, high efficiency, and wide operation range of constant output. A neodymium sintered magnet has been used in conventional traction motors to satisfy the above strict required performance. The neodymium sintered magnet has high residual magnetic flux density and high coercive force, and a good squareness of B-H curve. However, it has a disadvantage of high price. Inexpensive electric city commuters are required to further reduce the motor cost. Therefore, in this study, the neodymium bonded magnet is adopted for a proposed in-wheel motor. Although characteristics of the neodymium bonded magnet is lower than that of the neodymium sintered magnet, the neodymium bonded magnet is inexpensive and have relatively high residual magnet flux density. One of the advantages of neodymium bonded magnet is that eddy current loss does not occur. Therefore, it is possible to suppress the heat generation of the magnet and rotor which is difficult to cool. However, neodymium bonded magnets have disadvantages of poor squareness, and irreversible demagnetization occurs even under normal operation. For this reason, the performance of the motor varies depending on different irreversible magnetization due to the different operating condition. This paper discusses that irreversible demagnetization in motor operation of the neodymium bonded magnet used in the in-wheel axial-gap motor is suppressed by improving the apparent squareness of B-H curve by applying reverse magnetic field at manufacturing the magnet. II. STRUCTURE OF PROPOSED MOTOR Fig.1 (a) shows an overall view of the proposed motor. The rotor is structured by inserting neodymium bonded magnets into a spoke shape rotor support using non-magnetic stainless steel to maximize the magnetic torque. This coreless rotor structure can suppress iron loss because of decreasing the magnetic flux density in the stator core. III. RESULTS OF ANALYSIS Fig. 1 (b) shows the B-H characteristics of the neodymium bonded magnet. FE analysis is carried out with two magnets: an ordinary neodymium bonded magnet and an irreversibly demagnetized neodymium bonded magnet previously subjected to reverse magnetic field after magnetization. The B-H characteristic of the magnet with preliminarily demagnetizing was created assuming that a reverse magnetic field of -222000 A/m is applied at manufacturing the magnet. The strength of this reverse magnetic field was determined from the magnetic field strength at the center of the magnet in the demagnetization analysis with the current density of 11.0 A/mm^2 and current phase angle β = 90 deg in order to withstand irreversible demagnetization under motor operation which is a maximum current density of 8.4 A/mm^2. Fig. 2 (a) shows the analysis results of torque characteristics using ordinary magnet without preliminarily demagnetizing when the magnet thickness is changed to 10, 15, 20 mm under maximum current density of 8.4 A/mm^2. The torque decreases due to demagnetization during the rotation angles from 0 deg to approximately 10 deg, and the torque decreases greatly as the magnet thickness is thinner. In case of the magnet thickness of 20 mm which becomes the smallest torque reduction, the average torque of the steady state between rotation angles from 30 deg to 45 deg was 113.2 Nm. Fig. 2 (b) shows reduction rates of U-phase magnetic flux linkage both models with and without preliminarily demagnetizing under the demagnetization analysis. The magnet thickness of both models is constant at 20 mm. The condition of demagnetization analysis was: the rotor does not rotate, current phase angle is β = 90 deg. The reduction rates of U-phase magnetic flux linkage at the maximum current density of 8.4 A/mm^2 was 3.2% in the model without preliminarily demagnetizing, while 0.3% in the model with preliminarily demagnetizing. It is evident that the demagnetization resistance is improved by preliminarily demagnetizing. Fig. 2 (c) shows the analysis result of torque characteristic using the model with preliminarily demagnetizing. The average torque between rotation angles from 30 deg to 45 deg was 111.1 Nm, and slightly 1.9% lower than the average torque of 113.2 Nm of the model without preliminarily demagnetizing. In contrast to the decrease in the residual magnetic flux density of 6.9% by preliminary demagnetization, the decrease in torque can be suppressed, and the occurrence of irreversible demagnetization under motor operation can be suppressed. IV. SUMMRY In this paper, irreversible demagnetization in motor operation of the neodymium bonded magnet used in the in-wheel axial-gap motor was suppressed by improving the apparent squareness by applying reverse magnetic field at manufacturing the magnet.

BS-04. Study of Dual Airgap Stator and Rotor Permanent Magnet Machines with Halbach Array Configurations Using Phase-group Concentrated-coil Windings.

D. Chen[1], L. Fang[1], Z. Feng[1] and B. Bai[1]
1. School of Electrical Engineering, Shenyang University of Technology, Shenyang, China

Abstract— This paper presents a new structure of dual airgap stator and rotor permanent magnet machines to improve the electromagnetic performance and reduce torque ripple by incorporating the halbach array magnet configurations, phase-group concentrated-coil windings, and an unaligned arrangement of two stators. Firstly, the electromagnetic and mechanical structure of the dual airgap stator and rotor permanent magnet machines with halbach array (DASHAPMM) is designed, and the stator structure, rotor structure and winding distribution are given. Secondly, a quantitative comparison is performed between the proposed DASHAPMM and DASSTPMM (dual airgap stator and rotor permanent magnet machines with spoke-type configurations using phase-group concentrated-coil windings). The machine performance including back electromotive force, cogging torque, and electromagnetic torque are first analyzed by a finite element method under the same operating conditions. Finally, a prototype of the DASHAPMM and DASSTPMM is manufactured, and some key simulation results are verified by experimental tests. *Index Terms*— Dual airgap stator, machine, halbach array, spoke-type, phase-group concentrated-coil windings, comparison. I Introduction In recent year, to achieve wide speed range and high torque density in a constrained space of direct-drive applications, permanent magnet synchronous machines (PMSMs) are commonly applied comprising all power ranges due to their significant advantages such as high torque, power density and high efficiency[1]-[2]. Many novel topologies of PMSMs with high torque density have been proposed. However, a common challenge for both types of PMSMs exists from the viewpoint of production cost since the raw materials of rare earth PMs have the problem of high price and limited supply. In addition, another challenge in terms of pulsating torques, including cogging torque and torque ripple, is an important issue in PMSMs, especially in those PMSMs with dual airgap structures or spoke-type configurations featuring flux focusing effects [3]. However, although various traditional approaches, such as skewing, as well as tooth or magnet shaping, have been demonstrated to effectively reduce cogging torque and torque ripple, these approaches inevitably introduce performance degradation and manufacturing difficulties. Furthermore, these approaches are commonly considered independently after fulfillment of the requirements for torque/power densities. In this paper, an advanced design procedure for PMSMs, including both stator-PM and rotor-PM machines, is proposed to comprehensively improve machine performance including torque/power density, efficiency, cogging torque, and torque ripple. The DASHAPMM interior PM machine termed the rotor-PM machine configuration, are investigated for the direct-drive applications, in which the phase-group concentrated-coil windings and an unaligned arrangement of the two rotors/stators are utilized. Adoption of phase-group concentrated-coil windings is implemented to obtain a unity displacement winding factor, and enhance the flux focusing effects together with the use of halbach array PM configurations. The unaligned arrangement of two rotors/stators will help to not only achieve further flux magnification by alternating the PM flux from one air gap to the other while keeping the flux relatively constant in the magnet, but also suppress the cogging torque and torque ripple. A quantitative comparison is performed between the proposed DASHAPMM and DASSTPMM. The machine performance including back electromotive force, cogging torque, and electromagnetic torque are first analyzed by a finite element method under the same operating conditions. Finally, a prototype of the DASHAPMM and DASSTPMM is manufactured, and some key simulation results are verified by experimental tests. II. Study of simulation and experiment and discussion of result The structure of DASHAPMM and DASSTPMM as in Fig. 1 and Fig. 2. The magnet width, rotor and stator teeth width as well as the stator slot width within one group phase are designed to be the same as θ equaling $\pi/2$(elec.) for obtaining the unity displacement winding factor, while the stator slot width between the two different phases will be $5\theta/3$ equaling $5\pi/6$ (elec.) for producing a balanced three-phase back EMF. Thus, a specific combination of stator slots and rotor/magnet poles depending on the stator winding construction can be deduced. The structure of rotor for DASHAPMM is halbach array, and the structure of rotor for DASSTPMM is spoke-type. Fig. 3 shows a comparison of the magnetic flux density distribution. Fig. 4 shows a comparison of the back EMF. Fig.5 shows the manufactured motor and experimental system for DASSTPMM and DASHAPMM.The rotor of DASHAPMM is in the process of being manufactured. III. Conclusion This paper has proposed a design technique for DASHAPMM, incorporating the advantages of the halbach array magnets, phase-group concentrated-coil windings, and an unaligned arrangement of two rotors/stators. A quantitative comparison has been carried out among the investigated machines with the aid of 2-D FEM. The prototype of the proposed DASHAPMM has been manufactured based on the specifications of a standard washer motor, and some key simulation results are validated by experimental tests.

BS-05. Unexpected Parasitic Torque Ripple Component Analysis in PMSM according to Parallel Winding Pattern Considering Eccentricity.

D. Lee[2], C. Jeong[2], S. Lee[2] and J. Hur[2]
2. Electrical Engineering Incheon National University, Incheon, China

Permanent magnet synchronous motor (PMSM) is widely used because of its high efficiency and high torque density [1], [2]. However, PMSM has a critical issue about torque ripple. The cause of the torque ripple of the permanent magnet motor is mainly divided into two types: one is structural reason and the other is harmonic component of the input power source (such as inverter output) [3]. In motor design perspective, the structural reason of torque ripple is the only factor that can be handled. The most popular phenomenon of torque ripple component caused by the structural reason of motor is cogging torque and thus, many researchers studied reduction methods of cogging torque [4]–[8]. As a result of these studies, many mitigation techniques of cogging torque were addressed. Since those techniques solve the cogging torque issue to some extent, this paper does not cover about the cogging torque. Instead, we investigated on torque component that had not drawn much attention and underestimated so far. It is the torque generated by circulating current in the parallel branch. This torque component is defined as 'unexpected parasitic torque' in this paper. In ideal condition, it is impossible to have circulating current in parallel winding. In reality, on the other hand, it is not possible to manufacture the motor in ideal condition. Therefore, the motors which have parallel branch can possibly produce unexpected parasitic torque component. To understand the phenomenon of parasitic torque generation, it is necessary to pay attention to the circulating current of the parallel windings. As mentioned above, the circulating current occurs by imperfect condition of motor; such as asymmetric magnetic strength of each pole, machining error of rotor and stator, unbalanced winding of each slot, rotor eccentricity and so on. Among these many imperfect conditions, in this paper, the eccentricity is considered which happens often in manufacturing process. In this analysis, the motor with 8pole and 12slot is used which is one of the most typical combinations of pole-slot number. The 8pole/12slot motor can have four possible cases of winding connection with double layer winding. Those cases are demonstrated in Fig. 1 with conceptual diagram of eccentric motor. As it is shown in Fig. 1 (a), the airgap lengths from each stator tooth (l_{g_U1}, l_{g_U2}, l_{g_U3}, l_{g_U4}) are different to each other when there is eccentricity. Thus, induced voltages by flux of permanent magnet at each slot winding will be clearly different. And then, since these slot windings are connected in series and parallel, those voltages of each winding will be superpositioned. Here, we can find the source of circulating current. When there is voltage difference between parallel windings, electrical potential occurs between those windings and this gives generation of the circulating current. Of course, the circulating current can be different according to the pattern of winding connection. Fig. 2 (a)–(d) shows the variation of circulating current under various eccentric conditions according to each winding connection cases and Fig. 2 (e)–(h) shows the parasitic torque component as a resultant of those circulating current. Here, winding connection case1 is omitted because it does not have parallel branch. The most noticeable point in Fig. 2 is that it is possible to have nearly zeroed circulating current and parasitic torque even though it has parallel circuit and eccentric rotor by looking at case 3. Other parallel connections, except the case3, show parasitic torque components that cannot be ignored. Since the parasitic torque increases in proportion to the rotation speed of the motor, it can be a fatal defect, particularly when high-speed operation is required. Thus in the case of high speed motor, the winding connection pattern of case3 is recommended. In the future, more detailed explanation about the correlation between parallel windings and eccentricity will be addressed. In such a process, it will be revealed that why there is minimum parasitic torque in the case3.

BS-06. A Study of New Design Process of Spoke Type Permanent Magnet Synchronous Motor Considering Post Assembly Magnetization Performance.

S. Lee[1], H. Kong[2] and W. Kim[3]

1. Intelligent Information Technology Fusion, Busan University of Foreign Studies, Busan, The Republic of Korea; 2. Gachon University, Seongnam, The Republic of Korea; 3. Gachon University, Seongnam, The Republic of Korea

Permanent magnet synchronous motors (PMSM) have been used for various applications due to its high efficiency and power density [1-2]. The advantage of PMSM is based on the fact that permanent magnet (PM) can be used to generate field flux without external current. As a result, the ability to generate the magnetic flux of the PM is a direct indicator of the performance characteristics of the PMSM. The Demagnetization, which means a decrease in magnetic flux generated in PMs, is one of the important considerations in the design of PMSM. Several studies have discussed the design of PMSM that take into account the demagnetization of PMs [3-5]. However, the studies of the design of PMSM that take into account the magnetization performance was relatively insufficient. This is because both the surface permanent magnet synchronous motor (SPMSM) and the interior permanent magnet synchronous motor (IPMSM), which are mainly used in industry, do not have any difficulty in post assembly magnetization. The post assembly magnetization is a method in which a rotor is assembled with PMs without magnetization and then magnetized using a magnetizing yoke. This magnetization method is used as a standard in mass production motors because of its high mass productivity and the ability to completely magnetize PMs. As a result, in the conventional SPMSM and IPMSM, there was no problem in the magnetization of the PMs, so it was not necessary to consider the magnetization performance in the design process. However, the spoke type PMSM which has been largely investigated in recent years, because it has high power density and low cost by using a concentrated flux structure [6-7], is difficult to be magnetized by post assembly magnetization unlike the conventional motors [8]. This is because the rotor structure for the magnetic flux concentration of the spoke type PMSM acts as a cause of deterioration of the magnetization performance in the post assembly magnetization. As a result, the performance such as power density and efficiency is inversely related to the magnetization performance related to mass production. In order to design the spoke type PMSM with high mass productivity and high performance, it is necessary to consider the magnetizing performance in the design process. In this paper, we propose a new design process of spoke type PMSM considering not only the demagnetization of PMs but also magnetism performance. Using the proposed design process, we designed a spoke type PMSM that provides equal mass production and high performance compared to existing motors. The designed spoke type PMSM improved the output density by about 20% and the price was about 25% lower than the SPMSM of the same specification.

BS-07. Development of IE4 Class Line-Start Permanent Magnet Motor from a Small Three Phase Induction Motor.

S. Rhyu[1], S. Khaliq[1], K. Lee[1] and R. Kim[1]
1. Intelligent Mechatronics Research Center, Korea Electronics Technology Institute, Bucheon, The Republic of Korea

Small three phase Induction Motors (IMs) are widely used in many industrial applications, such as blower and compressors, due to its lower cost, robustness and line start capability. However, IMs suffer from overall lower efficiency due to excitation penalty and higher rotor losses. On the other hand, PM synchronous motor can achieve higher power factor and efficiency; it lacks the line starting ability like IM. Line Start Permanent Magnet (LSPM) motor is developed to combine the advantages of direct line start ability and higher efficiency. LSPM motors can start directly from the grid due to the electromagnetic induction in the rotor cage bars, which produces cage torque during the asynchronous starting operation. Once the motor achieves rated speed, cage torque vanishes, and it behaves like permanent magnet synchronous motor (PMSM). Most of the LSPM motors developed in literature are 4-pole [1]. The manufacturing of a 4-pole LSPM motor is easier compared to 2-pole since it is not required to surround the shaft with PM and flux barriers to achieving higher performance, as it is essential in the latter. Furthermore, small-size IM (< 7.5 kW) have a significant potential for efficiency improvement due to a higher rotor loss component, however, at the same time, have limited space for PM insertion and flux barriers due to the presence of rotor cage [2]. However, 2-pole motors are considered suitable for the high-speed applications. In this paper, an LSPM motor is developed by modification to the small scale IM rotor with the aim to achieve almost unity power factor and operational efficiency to an IE4 or higher class motor. The 2-pole LSPM model is developed by inserting PMs in an off the shelf IM, HHT-05, considering minimum manufacturing cost. Stator outer dimension and slot design are kept same as in the basic IM model. Fig. 1 (a) shows the rotor assembly of the LSPM model. Only rectangular shaped PMs are utilized to mitigate the manufacturing cost associated with the unconventional PM shapes. PM thickness was kept 3 mm to withstand the stator magnetomotive force (MMF) during asynchronous starting which can cause irreversible demagnetization. Rotor cage bars were skewed by one slot pitch for a smooth back EMF and torque ripple reduction. Initially, the LSPM model was analyzed with Steady state Finite Element Analysis (FEA) to assess the no-load output back EMF. Then, dynamic starting performance and synchronizing ability was examined by directly applying line voltage to the stator in FEA simulation. Firstly, no load back EMF of the LSPM is analyzed by rotating the rotor at the rated speed. Back EMF, induced by PMs in steady state, is a crucial parameter to improve the performance of LSPM, i.e., high efficiency and unity power factor. Therefore, one winding turn/slot is increased in the LSPM compared to the basic IM to improve the back EMF while keeping a reasonable slot fill factor for feasible manufacturing. Fig. 1 (b) shows the back EMF of the unskewed and skewed rotor bars by one slot pitch. It shows that due to the slotting structure of stator and the presence of rotor cage produces higher order harmonics in the back EMF, which are smoothed out through skewing of the rotor bars. Furthermore, it is essential to analyze the dynamic starting performance of LSPM to verify the starting ability. Therefore, a dynamic simulation was performed with the FEA. The stator was supplied with the line voltage and frequency, i.e., 220 V and 60 Hz. Fig. 1 (c) exhibits the output load torque. The negative peaks in the torque output are due to the braking effect produced by the PMs during starting and affect the synchronization of LSPM with the stator MMF. However, the developed model achieves the rated torque after almost 0.3 S of starting. Fig. 1 (d) shows the load current waveform, which was also obtained through dynamic simulation. When LSPM is connected to the grid, it draws large unbalanced currents at the start. As the rotor starts rotating, it induces the voltage in the stator winding, and the stator currents become balanced finally at the rated speed as shown in fig. 1 (d). Table I (Fig. 2) summarizes the design specifications of basic IM and LSPM models and compares the output performance. Stator outer diameter and slot design are kept same in both models. Furthermore, the stack length was reduced by 15 mm in the LSPM model, which was enough to achieve the required efficiency and almost unity power factor. Additionally, smaller stack length also reduced the material cost in LSPM. Rated speed in both models is also different as IM rotor runs at a slip while LSPM rotor rotates in synchronism with the stator field during steady state. Therefore, a small increase in output power of LSPM is expected, as shown in table I. Rated current in the LSPM is found to be 19 % lower than the basic IM model, which in turn decreased the copper losses and also caused the improvement in power factor. Table I shows that IM exhibits 57 % higher copper losses compared to LSPM model. Also, the power factor in LSPM is 0.985 which is almost unity and 0.18 higher than IM. Furthermore, the efficiency of the LSPM at the rated condition in 94.7 %, which is 7.2 % higher than the basic IM model. Therefore, it is evident that the performance improvement in LSPM is remarkable with only small modifications. The detailed design of the developed model along with the experimental analysis will be presented in the full manuscript.

BS-08. Design and Analysis of a Two-phase BLDC Motor with Hybrid Permanent Magnet Material for Only-pull Drive Technique.

T. Yazdan[1] and B. Kwon[1]
1. Electronic Systems Engineering, Hanyang University, Ansan-si, The Republic of Korea

I. INTRODUCTION Permanent magnets with high energy density are widely used for high performance permanent magnet (PM) machines. However, the cost increase of rare-earth magnets demand the effective utilization or the use of relatively thin magnets in PM machines. To reduce the consumption of rare-earth magnets, hybrid permanent magnets arrangements (combined with ferrite) have been used in various PM motors, and the demagnetization endurance has been investigated [1]-[2]. The surface type and the spoke type magnets forming the parallel and serial magnetic circuits have been employed for the purpose of torque improvement. However, spoke type magnets and the thin surface magnets suffer the greater risk of irreversible demagnetization. Traditionally, the thick magnets are utilized to ensure the healthy operation of PM machines without irreversible demagnetization [3]. Recently, an only-pull drive technique have been developed in [4] to protect the thin magnets from irreversible demagnetization and discussed a surface mounted PM (SPM) motor to validate the effectiveness. This paper proposed a two-phase radial flux brushless DC (BLDC) motor comprising of hybrid permanent magnet material on the rotor; NdFeB in SPM type and ferrite in spoke type configuration. The purpose of this hybrid topology is to improve the output torque and to save both types of magnets from irreversible demagnetization at a time. The electromagnetic performance of the proposed motor has been compared with that of a basic two-phase SPM type motor driven by the only-pull drive technique. Further, the operating point of the both magnet types has been analyzed to confirm the safe operation of the proposed motor without irreversible demagnetization. The merits and demerits of the proposed operation are also discussed. II. THE PROPOSED MOTOR TOPOLOGY AND PRINCIPLE OF OPERATION The topology of the basic and the proposed two-phase BLDC motors driven by the only-pull drive technique is shown in Fig. 1(a) and Fig. 1(b) respectively. The proposed motor contains a stator equipped with group concentrated winding [5] with an additional slot width between the phase groups to produce balanced back-EMF and a rotor decorated with thin surface type (NdFeB) and spoke type (ferrite) magnets. The flux flows from spoke magnets to the iron-poles, and passes from the surface magnets towards stator core, and returns back through the other surface magnet forming a serial magnetic circuit. All the conventional PM machines operate under both the magnetizing process (pull process) and demagnetizing process (push process) of the flux linkage at the risk of irreversible demagnetization of the magnets, which may result in the failure of machine operation. In the operation principle of the proposed motor, current is injected only for the increasing flux linkage that is only-pull process and will not go under decreasing flux linkage (push-process) which is caused by repulsion of alike poles from stator and rotor. The basic concept of pull process and push process is shown in Fig.1 (c). Each phase conducts for the span of 90 electrical degrees only in the region of pull process of flux linkage. Thus, one phase produces the torque alternately at any time. Regardless of applying the only-pull drive technique, the trailing edges of the standalone spoke type magnets are vulnerable to the external opposite fields that causes the partial demagnetization. Whereas, in the proposed motor, the surface magnets provide a shield to the trailing edges of the spoke type magnets and protects from intensive reverse fields during the operation. III. RESULTS AND DISCUSSION Using the only-pull drive technique for the proposed motor, the demagnetization profile and the electromagnetic performance are primarily investigated. To investigate the demagnetization profile, the motors are subjected to the overload current of 4.5A that is multiple of rated current of 1.5A and back-EMF is analyzed after the occurrence of overload current. However, the proposed motor having a hybrid permanent magnet material and driven with only-pull technique, executes safe operation without risk of irreversible demagnetization. The comparison is summarized in Fig. 2. As a result, the proposed motor topology can be a better solution for only-pull drive technique where spoke type magnets are involved. Further, the improved torque in the proposed motor has been observed. The detailed analysis and comparison results based on magnetic operating point will be presented in the full paper.

BS-09. Comparative Studies of Modular PMSMs with Symmetrical or Asymmetrical Six-Phase Windings.

L. Cheng[1], Y. Sui[1], *P. Zheng*[1], Z. Yin[1] and R. Ma[1]
1. Harbin Institute of Technology, Harbin, China

Nowadays, multiphase permanent-magnet synchronous machines (PMSMs) equipped with fractional-slot concentrated windings (FSCWs) are increasingly attractive for the industrial applications due to their high torque density, high efficiency and high fault-tolerant capacity [1, 2]. Meanwhile, owing to their characteristics of easy manufacturing, convenient transportation and high fault-tolerant capacity, the modular permanent magnet synchronous machines (PMSMs) are also favored by various industrial applications, such as electric vehicle and wind turbine applications [3]. Fortunately, the FSCWs, especially the single-layer FSCWs, are inherently easy to modular manufacture. However, due to the manufacturing tolerance, the additional mechanical gaps between the modules are inevitable which will affect the magnetic field distribution and hence the electromagnetic performances. The influences of the additional mechanical gaps on electromagnetic performances of three-phase modular PMSM have been investigated [4]. Nevertheless, the influences of the additional gaps between the modules in a six-phase modular machine have not been covered. Moreover, the influences of the mechanical gaps on the performances under post-fault operating conditions in a six-phase PMSM have not been investigated in current literature. Therefore, in this paper, the influences of the additional mechanical gaps on the performance under healthy, faulty and post-fault operating conditions of modular PMSM with symmetrical or asymmetrical six-phase windings are investigated. In this paper, firstly, by analyzing the slot star diagram of a conventional 12-slot/14(10)-pole three-phase PMSM with double-layer FSCW, three different six-phase winding layouts can be obtained by dividing the conventional 12-slot/14(10)-pole three-phase winding into two sets of independent three-phase windings as shown in Fig. 1. It can be found that the winding of scheme I is asymmetrical six-phase winding with an electrical angle of 30° between the two sets of three-phase windings and the other two schemes are symmetrical six-phase winding with an electrical angle of 60° between the two sets of three-phase windings. Scheme III will be abandoned because the electromagnetic performances of scheme III are all the same with II while its magnetic isolation capacity is much lower than scheme II. To enhance their magnetic isolation capacity further, the 12 double-layer slots are divided into 24 single-layer slots so that three 24-slot/14(10)-pole six-phase PMSM with unequal teeth can be obtained. And, the modular stators are used to enhance their practicability and fault-tolerant capacity, as shown in Fig. 2. It can be seen that for scheme I, there is only one modular method—one module with one coil. On the other hand, there can be two different modular methods—one modular with one coil and one modular with one-phase (one phase possesses two adjacent coils). The different modular methods will introduce different additional mechanical gaps which cannot be avoided resulting from the manufacture limitations and tolerances, as shown in Fig. 2. The influences of these mechanical gaps on the electromagnetic performances, such as the winding factor, average torque, torque ripple and stator magnetomotive distribution, are fully investigated. Moreover, the influences of these gaps under faulty operating conditions, such as one-phase open-circuit, two-phase open-circuit and one-phase short-circuit failure, and under post-fault operating conditions are also investigated.

BS-10. Reaserch on Flux Density Fluctuation for Brushless Double Rotor Flux-Switching Permanent Magnet Motor Considering Low Magnetic Coupling.

Z. Xiang[1]
1. School of electrical and information engineering, Jiangsu University, Zhen Jiang, China

I. INTRODUCTION. A type of machines family with feature of double rotors, in recent years, has attracted increasing attention due to its advantages of high power density, high efficiency, and high PM utilization [1]. And when the double rotors concept was put forward, various motor topologies have been proposed for obtaining the improved torque capability. Among the existing double rotors motors, a type of double-output double rotor permanent magnet (DO-DRPM) motors are particularly favored by the researchers, which because they can be connected with engine to achieve a highly-integrated hybrid powertrain and realize the function of power split and combination. Since the DO-DRPM motor generally has two independent rotors, the multi-operational modes can be performed in one motor frame, such as the four-quadrant energy transducer (4QT) [2]. It is noted that the 4QT usually needs brushes and slip rings to feed current, which causes the frequent maintenance and friction loss. Recently, an alternative brushless scheme is developed purposely for the DO-DRPM motor [3]. The new resulting motor can not only manage the power split and combination, but also avoid the brush and slip ring. However, regardless of the 4QT or the brushless DO-DRPM motor, their flux lines distribution between the inner and outer airgaps exhibits a certain extent of magnetic coupling. It will result in an irregular variation of the magnetic field, which brings difficulties to the independent control of the inner and outer motors, especially when they are designed with different pole pairs. Therefore, the analysis and evaluation of magnetic coupling is crucial and necessary for the type of the DO-DRPM motors. The purpose of this paper is to investigate the magnetic coupling for a brushless double rotor flux-switching permanent magnet (BDR-FSPM) motor. And by introducing the concept of flux density fluctuation, the magnetic coupling degree between the inner and outer motor can be evaluated accurately and conveniently, which lays a foundation for the high reliability operation and flexible controllability of the BDR-FSPM motor. II. MOTOR TOPOLOGIES AND MAGNETIC FIELD DISTRIBUTION In this paper, four topologies are presented and investigated for low magnetic coupling, as shown in Fig. 1. From Fig. 1 (a) to (d), among the four motor topologies, the common grounds are the same pole-slot combinations of 22-pole /12-slot /10-pole and the same locations of armature winding and PMs. Meanwhile, the differences of them are the various designs of the PM topology, flux barrier, magnetic bridge, and relative position between the inner and outer stators. Then the magnetic field distributions of the four motor topologies are depicted in Fig. 2. It can be seen from Fig. 2 (a) to (d) that the motors of type I, type II and type III present obvious serial magnetic path between the two air-gaps, while the majority of magnetic flux lines in Type IV motors is closed in the middle stator, enjoying a desired parallel magnetic path and indicating a lower magnetic coupling to some extent. Additionally, to quantitatively evaluate the flux density fluctuation caused by magnetic coupling, four referenced points are selected for calculating the flux density fluctuation, respectively setting in the outer rotor, outer stator, inner rotor, and inner stator, as illustrated in Fig. 2. III. SIMULATION AND EXPERIMENT Fig. 3 shows the no-load flux densities of the four points for the four motor topologies. When the inner motor works alone, the flux densities variations of point 1 in outer rotor and point 2 in outer stator are respectively depicted in Fig. 3 (a) and (b). Similarly, at the condition of outer motor working alone, Fig. 3 (c) and (d) respectively show the flux densities variations of point 3 in inner stator and point 4 in inner rotor. Obviously, under the four points, the type IV motor has the lowest flux density variation. For better presentation, Fig. 3 (e) illustrates the peak to peak (P-P) values of the flux densities in all points. And to present a fair comparison, the total flux density fluctuations of the four motors are further calculated, and it is defined as the average value of the flux density P-P values of the four points, as shown in Fig. 3 (f). As expected, among the four topologies, the type IV motor has the smallest flux density fluctuations, indicating that it possesses the lowest magnetic coupling degree between the inner and outer motors. Moreover, the partial performances of the type IV motor are given in Fig. 4. From Fig. 4 (a) and (b), the inner coupling-EMF accounts for 2.5% value of the outer back-EMF, while the percentage of the outer coupling-EMF on the inner back-EMF is also low, only accounting for 1.8%, manifesting a low magnetic coupling. Meanwhile, the steady torque of outer and inner motors is presented in Fig. 4 (c) and (d). Then a prototype motor with the type IV topologies is manufactured, as shown in Fig. 5(a). And Fig. 5 (b) depicted the measured back-EMF of outer motor and its coupling-EMF, which is agreed with the results in Fig. 4 (a). In conclusion, the simulation and experiment results shows that the BDR-FSPM motor with the topologies IV offers low magnetic coupling, providing the guarantee for the flexible controllability of the motor. More detailed performances analysis and experimental results will be presented in the full paper to verify the validity.

BS-11. Development of Differing Extent Mesh Adaptive Direct Search applied for Optimal Design of Spoke-Type PMSM.

D. Lee[2] and S. Jung[1]
1. Sungkyunkwan University, Suwon, The Republic of Korea; 2. Department electrical and computer engineering, University of Illinois at Urbana-Champaign, Champaign, IL, United States

Introduction The spoke type permanent magnet synchronous machines (PMSM) have a buried PMs on both sides of poles in rotor, which has characteristics of high torque density and high power density by concentrated magnetic flux [1,2]. However, torque ripple and cogging torque is generated higher than other type motors. Hence, spoke type PMSM is required for reduction design of torque ripple and cogging torque [3]. This paper presents newly differing extent mesh adaptive direct search (MADS) to minimize torque ripple and cogging torque for spoke type PMSM. MADS is a mesh-based approach for heuristic search methods and generates random trial points to search the best local minima [4]. Multistart strategy can be adopted in MADS to search the global optimum, which enables an algorithm to select the global optimum among several solution candidates. In conventional multistart scheme, each solution starts to search for a local optimum after a convergence of the previous one. This consumes excessive function calls at local regions that are irrelevant to the global optimum. This study aims to solve these problem by introducing Differing Extent MADS, which it is an intelligent method that conducts parallel multistart methods and shares information between each solution in the same search step. It can distinguish whether the points are close to the global optimum and stops the search if not, to reduce the computation time. Furthermore, each solution is classified as three group (p1~3), which have distinct characteristics as: p1 has large searching flame and mesh size, which can strengthen the searching performance for a global optimum. p3 has small of that, which can convergence fast to local optimum than others. p2 have intermediate feature between these, which can complement both global optimum and speed. Also, three group search to share an information each other for effective searching. Fig.1 show the concept of proposed algorithms. In full paper, the performance of proposed algorithm would be verified by benchmark function and electric machine in terms of global searching and a computation time, which it compared with other algorithms. For rotating machine with high speed, PMs get centrifugal force and it causes serious damage to the rotor core. Also, changed slot sharp and current density by optimal design causes temperature rising. In accordance, it is recommended to include mechanical stress according to modified designs. In this paper, the proposed optimization algorithms have been applied for optimal design of spoke type PMSM for multi-objective with reducing the torque ripple and cogging torque considering mechanical stress. The performance is analyzed for reliable accuracy based on nonlinear FEA as shown Fig. 2. In the process for optimal design, rotor dimension is designed for mechanical stress from optimization algorithms and it is evaluated for safety factor according to maximum rotor speed. Electromagnetic analysis starts until satisfying a safety factor iteration on. Second, average torque is calculated by electromagnetic field. If it is not satisfied, input current is increased one until average torque is satisfied. 'The results will be presented at full paper.

Abstract This paper mainly investigates two axial field flux-switching memory (AFFSM) machines with serial and parallel permanent magnets (PMs) configurations. Hysteresis model is adopted to present the flux regulation principle in both configurations. Finite element method is used analyze influence of design parameters on the working of hybrid PM.The flux regulation characteristics are obtained and compared. Results show that both configurations can obtain a good flux regualtion capacity by coordinating two PMs. Introduction Memory machines using low coercive force (LCF) nonlinear permanent magnets (PMs) for flux regulation are attracting great research interests [1-6].The LCF PMs in memory machines can be demagnetized and re-magnetized by short pulse current with negligible energy dissipation. As a result, it shows benefit in improving the efficiency and extending the speed range of PM machines when magnetization levels of LCF PMs are controlled at the optimal levels [1], [2]. However, some advantages of PM machines such as high torque density may disappear due to the lower energy product of LCF PMs. Another drawback is that LCF PMs can get easily demagnetized by armature field even under normal load [3]. To take the advantages of the flux controllability of LCF PMs and overcome the disadvantages, additional high coercive force (HCF) PM is introduced into memory machine to assist the LCF PM. By incorporating two types of PM in parallel or serial to provide hybrid excitation, the PM memory machines can not only provide magnetic flux controllability but also maintain the high torque/force density [4-6]. However, interactions between two types of PMs in two PM configurations exist and are different. LCF PM can be either magnetized or demagnetized by HCF PM even without magnetization control current [4], [6]. Thus, working of both PMs must be coordinated and carefully evaluated. The purpose of this paper is to develop the hybrid PM memory machines based on axial field flux-switching (AFFS) machines. Two axial field flux-switching memory (AFFSM) machines with different hybrid PM configurations, i.e. series PM (SPM) and parallel PM (PPM) types are proposed and compared. Hysteresis model coupling magnetic circuit is proposed to present the flux regulation principle of the SPM and PPM. For simplicity, the main specifications of two investigated memory machines such as the inner diameter, outer diameter and axial length are the same. The total usage of hybrid PM and the ratio between HCF PM and LCF PM are adjusted in order to achieve the same torque when LCF PMs are at fully magnetization state. The impacts of different PM dimensions on the magnetization requirement are also investigated. In particular, flux regulation characteristics and maximum flux regulation capacities of two memory machines are analyzed and compared. Machine Configuration and Operating Principle of Hybrid PM Fig. 1 a) and c) shows the 3-D views of the proposed double stator single rotor SPM- and PPM-AFFSM machines. Two stators are symmetric along the axis and have a 12/10 pole combination. Two PMs are arranged adjacent to each other and are tangential magnetized. Each stator adopts the same armature winding arrangement. To change the magnetization state of LCF PM, an additional DC excitation winding is introduced into the stator. By imposing pulse current with different amplitudes in the DC excitation winding, the LCF PMs can be magnetized and demagnetized. The working processes of LCF PM in two configurations during magnetizing and demagnetizing process are shown in Fig. 1 b) and d) respectively. As can be seen, the load line of LCF PM in SPM configuration moves towards the first quadrant, which means LCF PM can be magnetized by adjacent HCF PM. In contrast, LCF PM will be demagnetized by adjacent HCF PM, moving its load line towards the second quadrant. Comparison of Flux regulation characteristics Fig. 2 shows the minor loops of LCF PM in SPM and PPM configurations from different initial magnetization states. As shown in Fig.2 a) and b), magnetic flux of LCF PM in SPM configuration can be decreased up to 40% of its fully magnetized value. As two types of PMs are connected in series, variation range of total magnetic flux will be directly determined by the change of magnetic flux in LCF PM. One thing should be notice is that maximum demagnetizing current is almost identical with fully magnetizing current due to the magnetizing of HCF PM. By contrast, LCF PM can be total demagnetized from the completely magnetization in PPM configuration. However, total flux regulation capacity will be smaller as HCF provides part of fixed magnetic flux. Since LCF PM produces magnetic field opposing that of LCF PM, demagnetizing of LCF PM will be easier compared with SPM configuration. However, fully magnetizing LCF PM in PPM configuration will be more difficult. Conclusion In this paper, two AFFSM machines with SPM and PPM configurations are proposed and investigated. Flux regulation characteristics are presented. Results show that by adjusting the usage of PMs both configurations can obtain good flux regulation capacity. Working of LCF PM in SPM configuration is more stable. However, larger demagnetizing current is required. By contrast, fully demagnetizing current is much smaller in PPM configuration.

BS-13. Magnetic and Mechanical Characteristics of Electric Motor according to the Weld-laminated Core and the Bond-laminated Core.

D. Kim[1], M. Park[1], M. Yoon[1], J. Sim[1] and J. Hong[1]
1. Automotive engineering, Hanyang University, Seoul, The Republic of Korea

Today, electric motors are used in a variety of fields such as automotive, consumer electronics, and industrial applications. The demand for these motors is also increasing [1]. Especially, we have come closer to everyday life, such as automotive (e.g., traction, EPS, and ISG), household appliances (e.g., refrigerators, washing machines and elevator motors). Because the vibration and noise caused by the motor cause anxiety and discomfort to people, studies are being actively carried out to clarify and reduce the cause of motor vibration and noise. The factors that affect the vibration and noise can be largely divided into magnetic, electronic, aerodynamic, and mechanical sources [2]. First, the magnetic source generates excitation force through the magnetic field that passes through the airgap to create deformation in a stator, and if the frequency of this force matches the natural frequency, resonance occurs, and the sound vibrations are amplified. The studies on the vibration and noise created by the magnetic source are as follows. In [3-5], the vibration and noise were analyzed in accordance with the stator shape, pole angle, skew, overhang, and barrier of the rotor. In [6-10], the vibration orders by pole and slot combination were compared, optimization for vibration and noise reduction was performed, and the unbalanced magnetic forces were analyzed according to the winding method used to compare and analyze the vibration and noise. As a result, these studies helped reduce the vibration and noise by controlling the spatial harmonics of the airgap magnetic flux density in the motor design. Second, the vibration and noise caused by electronic sources occur as the input (including the harmonics) rather than the sinusoidal input is applied during the motor control. Especially, when the force generated by the harmonic input is generated near the natural frequency, the vibration and noise are further increased. In related studies [11], the vibration and noise were reduced through a method of avoiding the natural frequency of the stator by adjusting the magnitude and frequency of the PWM voltage. In [12, 13], harmonics were injected into the current to generate additional forces of the same magnitude and frequency as those that cause the vibration and noise in the opposite phase, thereby offsetting the two forces and reducing the vibration and noise. Most of these studies analyzed the vibration and noise for their design and control, but as mentioned earlier, the mechanical property of the stator is one of the main factors affecting the vibration and noise. Also, the stacking of the stator affects its mechanical characteristics [14-15]. The effects of lamination have been studied steadily. A study on the change of magnetic properties when welding lamination was performed [16-17], and a study on the change of magnetic properties due to mechanical stress applied during lamination was also studied [18]. However, further studies on the change of mechanical properties by lamination are needed In this regard, this paper presents the differences in the magnetic and mechanical characteristics depending on the stator lamination method used during the manufacturing process of the motor, and we propose a lamination method to improve the vibration of an electric motor based on the analysis of magnetic and mechanical characteristics of weld-laminated core and bond-laminated core. In Section II, the B-H curve and iron loss of an electric steel sheet according to two lamination methods are measured and the output characteristics of the induction motor are compared using finite element analysis (FEA). In Section III, modal tests of weld-laminated core and bond-laminated core are performed to compare the mode shape, stiffness and damping ratio, and the influence of this on the vibration of the motor is verified through FEA. Fig. 1 is a comparison of the frequency response function (FRF) of a weld-laminated core and a bond-laminated core through a modal test. The difference in the natural frequency of the two models is approximately the same at 0.51% based on circumferential mode shape 2. However, the attenuating band at the FRF peak is wider, ie, gradually attenuated, in the bond-laminated core. This means that the damping ratio is larger than the weld-laminated core. In section IV, the vibration reduction effect mentioned above is verified experimentally at a load of 4Nm, the rated output of the target motor, and a rotational speed of 3500rpm. As can be seen in Figure 2, the overall vibration of the bond-laminated motor at the same load was reduced by 2.5 dB. Finally, Section V concludes this paper.

BS-14. A Novel Demagnetization Fault Detection Technique for IPMSM using Voltage angle.

Z. Ullah[1] and J. Hur[1]
1. Department of electrical engineering, Incheon National University, Incheon, The Republic of Korea

Owing to its high efficiency and torque density interior permanent magnet synchronous motor (IPMSM) is widely used [1]. However, IPMSM has a critical issue of irreversible demagnetization fault (IDF). It is among the most frequently occurred fault in PM motors. IDF means that the strengths of PM in IPMSM decrease, and it generates a low output torque. Various reason can cause IDF, such as high temperature, uneven magnetization, aging, and the reverse magnetic field [2].It has a very intensive effect on the operation of the motor. It severely decreases the back electromotive force of the PMSM.Furthermore, it causes variations in the air gap flux density, stator voltages, currents, and the output torque. Consequently, the vibrations and the acoustic noise in the motor also increase. A higher input current for the constant torque and speed, rise in winding temperature, and drop in magnetic flux are results of this fault [3].Several strategies are proposed for the diagnosis of IDF. Stator current Frequency-based [4], Frequency-time distribution based [5], [6], coil sensing based [7], and electromagnetic analysis based [8], techniques are proposed. However, these methods lack accuracy and are too complex. Furthermore, the frequencies used in mentioned techniques can also be caused by other faults such as eccentricity [9].In addition, in the nonstationary condition, the frequency domain analysis is extremely difficult to extract. This paper proposed a new method, which is very simple and relatively faster way for the detection of IDF.The reduction in magnetic flux due to weaken-magnet change the dq-axis voltages and hence the angle (δ) of the voltage vector also change. We exploit this property of δ for the detection of IDF. The proposed method is verified by conducting simulation and experiments on a 400-watt IPMSM (rated parameter: 10.32A, 1.1Nm, 3500rpm). To maintain the accuracy and avoid false alarm the data obtained at several operating conditions is processed using linear discriminant analysis (LDA) and quadratic discriminant analysis (QDA) method. The IPMSM model in the d-q frame is given by the following equation: $V_d=R_ai_d+d\lambda_d/dt-\lambda_q\omega_e$ (1) $V_q=R_ai_q+d\lambda_q/dt+\lambda_d\omega_e$ (2) $\lambda_d=\lambda_{PM}+L_di_d$ (3) $\lambda_q=L_qi_q$ (4) In steady state, the derivative terms are zero. Hence we can write the eq. (1) and (2) as follow: $V_d=R_ai_d-\lambda_q\omega_e$ (5) $V_q=R_ai_q+\lambda_d\omega_e$ (6) Here V_{dq}, i_{dq}, L_{dq}, and λ_{dq} represent the dq-axis voltages, currents, inductances, and flux. λ_{PM}, R_a, and ω_e are PM flux, stator resistance, and angular speed. When the IDF occurs the IPMSM draw more current for the same load at constant speed. Furthermore, L_d and L_q get bigger with the severity of IDF because the reluctance of the IPMSM become smaller. The decrease in λ_{PM} cause reduction in total λ_d.The effect of demagnetized region is similar as an air gap, forcing the magnetic flux towards q-axis and this phenomenon causes an increase in λ_q and hence the V_d in (5) increase on negative side while V_q in (6) decrease. The variation of flux and voltage vectors under healthy and IDF for an IPMSM is shown in Fig. 1(a). It is shown that as a result of IDF the δ_h (healthy) increase to δ_f (IDF). Thus, this increase in δ can be utilized as a signature of IDF. If the condition $\delta>\delta+\Delta\delta$ is true, so we can conclude that IDF has occurred. Where $\Delta\delta$ is a threshold value decided by the variation of δ in the healthy condition by noise factor. During analysis of δ, the change in magnitude and angle (β) of the stator current is kept under consideration. Because δ is proportional to β. A practical problem of the detection of reversible demagnetization exists. However, this fact is already verified that the IDF does not arise under steady state [10], [11]. To verify this idea simulation and experiments are performed. The magnetic flux density of single pole demagnetized model in Finite element method (FEM) is shown in Fig. 1(b). A 6 poles / 9 slots IPMSM for the experiment can be seen in Fig. 1 (c). To realize the different severities of IDF different size of magnets are used in each pole of the rotor, Fig. 1(d). Each pole has 14mm width. Therefore, 14mm (0% IDF), 11mm (21% IDF), 8mm (42% IDF), 5mm (64% IDF), and 2mm (86% IDF) wide magnets are used in each pole to realize the fault. FEM simulation is conducted on different operating points to get the values of the dq-axis inductances. It is impossible to obtain and process the data on all operating points. Therefore, the operating points exist within our calculated one are obtained using interpolation. The simulation and experiment are carried out for the constant load and speed (1.1 Nm, 3500 rpm) and observed the effect of DF on dq-axis current, flux and voltages. Fig. 2(a) shows the λ_{dq} on full load and 50% load with different severities of DF.The V_{dq} for the healthy and faulty motor can be seen in Fig. 2(b) with rated load and two different speeds. The corresponding change in δ is shown in Fig. 2(c). It is clear that as the DF increases the value of δ also increase. Fig. 2(d) shows the result of LDA and QDA based analysis. A generalized expression for the δ valid for every motor model, variation stator resistance, uniform magnetization and more detail of operating conditions will be added in full paper.

BS-15. Design of IPMSM for Minimization of Electromagnetic Vibration.

I. Jang[1]
1. Hyundai Mobis, Yongin-si, The Republic of Korea

1. Introduction The vibration occurring in an electric motor can be largely divided into mechanical vibration due to nonaligned bearings and shafts, and electromagnetic vibration by the electromagnetic force. For existing industrial electric motors, the mechanical vibration associated with the life of the motor was the most important concern. However, in recent years, electric motors—such as the ones used for electric cars and hybrid cars—have high-torque density by using the rare-earth permanent magnet. Thus, the relative importance of electromagnetic noise and vibration is increasing. Electromagnetic vibration and noise affect people emotionally, so it has become very important to reduce vibration when designing a motor. The electromagnetic vibration can be predicted by analyzing radial force as a vibration source when designing the electromagnetic field of an electric motor. Thus, analyzing the spatial and time harmonics of the radial force enables us to find the harmonic that most influences the vibration. In this study, the optimum design of a 10-pole, 12-slot IPMSM for vibration reduction was performed. The optimum design was created by analyzing the radial force and finding the design variables that affect vibration. Additionally, to verify the validity of the design results, the results were compared using an electromagnetic-vibro coupled analysis. 2. Review of Electric Motor Design Parameters (Variable Selection Process) In an electric motor, torque is affected by the fundamental frequency components of the airgap flux density. Electromagnetic vibration is affected by the fundamental frequency component of the air gap flux density, as well as by time harmonics and spatial harmonics of the same density. The velocity of the vibrations generated in a motor is a function of the magnitude of the vibration source and mechanical geometry of the motor. The vibration caused by the electromagnetic force has the radial force density as a vibration source, and is calculated by squaring the airgap flux density, as shown in equation (1). The airgap flux density can be expressed as a function of the magnetomotive force generated in the stator and rotor, and the slot relative permeance is given as shown in Equation (2). Fig. 1(a) shows the airgap flux density of the 10-pole, 12-slot motor and 10-pole, slotless motor. The results of the FFT analysis are shown in Fig. 1(b). The absence of the stator slot demonstrates that only the 5th, 15th, and 25th harmonics exist, which are the multiple orders of the pole pair number. But the presence of the stator slot shows that the harmonics of other orders also exist. If the variable geometries of the rotor and the stator change, the magnitude of harmonic components of the flux density also changes. Therefore, to achieve the optimum design while considering vibration, the shape parameters should be selected. This affects the harmonic factors of the air gap magnetic flux density. 3. Optimum Design (Design Elements, Objective Function) In this chapter, the optimum design was found by selecting the design variables that minimize the vibration velocity for the initial design model. Table I shows the specification of the 10-pole, 12-slot IPMSM used for the optimum design. Fig. 2 shows the 10-pole, 12-slot IPMSM and design variables. For the design variables, the barrier angle $\theta_{barrier}$ that affects the harmonic waveforms of the magnetic flux density due to a permanent magnet was selected, along with the slot opening width W_{so} that affects the harmonics of the stator slot relative permeance. The objective function was designed to minimize vibration. The optimum design was created by maintaining the torque T and, at the same time, minimizing its vibration velocity V_m in the initial model. In this paper, vibration velocities were calculated by extracting the radial force densities for individual time steps from the results of an electromagnetic finite element analysis, and dividing those densities into a time harmonic and a spatial harmonic [1]. Table II shows the results on the torque and vibration velocity, and presents initial values and optimum values. For the 10-pole, 12-slot model, the 2nd spatial harmonics of the radial force density in the 2nd vibration frequency have the greatest impact on vibration velocity. As shown in Fig. 3, the 2nd spatial harmonics of the radial force density in the 2nd time harmonics of vibration velocity decreased 4.52%, and thus the overall vibration velocity decreased as well. 4. Verification Through Coupled Analysis During actual measurement of vibration velocity, it is also possible to identify a cause of electromagnetic force and to observe that mechanical vibration actually occurs. Thus, it is difficult to distinguish the mechanical vibration from the electromagnetic vibration by using tests. Therefore, in this study, the validity of the results was verified using an electromagnetic-vibro coupled analysis on the 10-pole, 12-slot model. Fig. 4 shows a comparison of vibration velocities by time harmonics in the initial model and the optimum model. 5. Conclusion In this study, an analysis was made to identify the shape parameters that affect the magnetic flux density of rotor and slot relative permeance in a permanent magnet motor. Using these parameters, optimal design was performed to minimize the vibration velocity in a 10-pole, 12-slot IPMSM initial model. As a result, vibration velocity was reduced by 5.5%. In addition, electromagnetic field-vibration interaction analysis was performed, and thus the results of the optimum design were verified.

Introduction Switched reluctance (SR) machines are attractive because they present relatively high efficiencies and torque densities but have no permanent magnets. Their limitations include high torque ripple, mitigated in large inertia applications such as electric vehicles. This digest focuses on the multi-objective optimization of an external rotor switched reluctance motor. The stator has concentrated coils and the rotor is configured with magnetically isolated modules. The experimental methodology tries to identify the variables affecting the objectives of loss and active mass. After this, differential evolution is used for optimization. The digest illustrates the optimal design process associated with the development of a prototype machine and its systematic comparison with a conventional SR motor design. Improvements with respect to the chosen objectives over a reference machine are quantified through finite element analysis. Further, a method for comparing the different designs on the Pareto front and identify the best compromise designs is proposed. *Background* Switched reluctance motors employing rotors with magnetically disconnected modules are shown to have higher specific torque and efficiency. This is primarily because of the shorter flux paths, which lead to a larger difference of aligned and unaligned position inductances for the same dimensions [1-2]. In such machines, the stator has wide main and narrower auxiliary stator teeth (Fig. 1 (a)). Only the main teeth are wound with concentrated coils, and the auxiliary teeth serve as return paths for the flux. The specific torque and efficiency increase with rotor module number in this type of machine. The machine considered in this study has 12 stator teeth and 26 rotor poles. A prototype demonstrator of this type was presented in [2] and is illustrated in Fig. 1(b). The increase in performance when a higher number of rotor modules is used is because of the reduction in the required volume of magnetic core material, which provides more room for the coils. This allows an increase in the ampere-turns for the same dimensions or the use of a larger split ratio, both of which contribute to a higher torque output. *Problem Formulation and Solution* A two-objective function unconstrained optimization is used in this study. The loss, including copper and core loss and active mass are considered as objectives to be minimized. The average torque output of the machine depends on geometrical parameters, and in this context, nine dimensionless independent variables are identified. The outer diameter is kept constant for all designs. For the better performing designs, the machine axial length is modified to ensure that all the studied candidates provide the same torque. A variation of ±20% from the dimensions of a reference design is considered for this study. The number of candidate designs that need to be studied to find an optimum solution if all nine design variables are considered would be very large, and therefore, the experimental methodology identifies which of the input variables have a significant impact on the objectives [3]. The variables that do not have a statistically significant effect on the outputs are fixed at their reference values and not considered in the optimization study. Multi-objective differential evolution (DE) is used in this study. *Systematic Method for Best Compromise Design Selection* Following an optimization study using DE, a method for systematically comparing the designs is proposed. The results of an example DE based study are shown in Fig. 2(a). The method allocates scores and ranks designs based on a directed graph, developed by representing each design with co-ordinates corresponding to the values of its objective functions; this is shown in Fig. 2(b). Arrows on the directed graph point towards designs with smaller co-ordinates. The score of each candidate design is evaluated by taking normalized weighted sums of the scores of other designs. The weight is calculated using the difference between the co-ordinates. If the difference is found to be against the direction of the arrows then the corresponding weights are set to zero. The scores are evaluated by the solution of an equation of the type Ax=x. To illustrate the capability of the algorithm, eleven designs marked in Fig. 2(a) are selected and compared. The proposed directed graph based technique eliminates the designs labeled x_6, x_7, x_8, x_9 and x_{11}, and retains the remaining six. The remaining designs are found to be on the Pareto front, which validates its successful operation. This method can be used to compare different designs on the Pareto front. Weighing factors can be included depending on which objective is more important, and this can be used to study different scenarios which aids the selection process.

I. Introduction Variable flux permanent magnet synchronous machine (VF-PMSMs) has drawn considerable attention due to the capability of operating in a wide speed range with overall high efficiency. The conceptual machine firstly proposed employs AlNiCo magnets characterized by low H_c and $(BH)_{max}$ as sole magnetomotive force (MMF) source [1]. Various topologies have been further developed to enhance the torque density by employing both low coercive-force PMs (AlNiCo) and high coercive-force PMs (NdFeB) [2,3]. The magnet configuration could be classified to parallel configuration and series configuration, as shown in Fig. 1(a) and (b). In parallel configuration, part of MMF generated by NdFeB magnets exerts on AlNiCo magnets, which leads to low working point and even unintentional demagnetization of AlNiCo magnets under on-load operation. Preceding defects could be avoided in series configuration due to the support of NdFeB magnets to AlNiCo magnets, but several times of demagnetizing current are required to fulfill the demagnetization process and the magnetization state variation range is usually limited. In this paper, a topology of VF-PMSM with quasi-series magnet configuration and passive flux barrier is proposed, which exhibits both advantages of high torque density of series configuration and easily achievable demagnetizing current of parallel configuration. II. Machine topology and operating principle A 48-slot/8-pole proof-of-concept machine is illustrated in Fig. 1 (c). AlNiCo magnets and NdFeB magnets are arranged in V type and spoke type, respectively. A flux barrier playing a crucial role of passively regulating magnetic flux during the demagnetization process is arranged between the NdFeB magnets and the shaft. The flux distribution under no-load operation, demagnetization regulation and after regulation are shown in Fig. 2 (a) to (c). In the case of no-load operation, most magnetic flux of NdFeB magnets flows through AlNiCo magnets to the airgap, while little magnetic flux of NdFeB magnets are short circuited through the passive flux barrier. The support of NdFeB magnets as existing in series configuration enables AlNiCo magnets to keep a high working point to enhance the torque density of the proposed machine. During the demagnetization process, 1 p.u. d-axis current pulse (J=5.24 A/mm^2) is applied to demagnetize AlNiCo magnets. In contrast to no-load operation, most magnetic flux of NdFeB magnets yields to flow through the passive flux barrier due to the applied opposite MMF. The flux barrier acts as a passive closed path of NdFeB magnets' flux during the demagnetization process. There is no need for the demagnetizing MMF to overcome the magnetizing MMF generated by NdFeB magnets and hence AlNiCo magnets are more easily demagnetized than the traditional series configuration. After the demagnetizing pulse is removed, most magnetic flux of NdFeB magnets flows through AlNiCo magnets again. However, the proportion of this part magnetic flux decreases when compared with that before demagnetization. This results from the decrease of working point as well as magnetic flux of AlNiCo magnets, and thus the magnetic flux of NdFeB magnets in series with AlNiCo magnets decreases. Such effect benefits extending the magnetization state variation range. III. Comparative study between different magnet configurations To further demonstrate the merit of the proposed machine, a quantitative study between three configurations is carried out. As shown in Fig. 1, same volumes of both AlNiCo magnets and NdFeB magnets are consumed in three configurations. Working point variations of AlNiCo magnets during demagnetization process are shown in Fig 2(d) to (f). A moderate demagnetization from 0.89 T to 0.52 T is obtained in the proposed topology by employing 1 p.u. demagnetizing pulse. In the parallel configuration, AlNiCo magnets are demagnetized reversely at -0.24 T by the same amplitude of demagnetizing pulse. What's more, the working point of parallel configuration with 1 p.u. load current locates at -0.06 T demonstrating the unintentional demagnetization at load operation. In the series configuration, it can be seen that the working point of AlNiCo magnets is demagnetized from 1 T to 0.96 T in a fairly tight range. IV. Influences of passive flux barrier on demagnetization and torque capability Demagnetization ratio and torque capability with different thicknesses of passive flux barrier ranging from 0 mm to 3 mm are summarized in Fig. 2(g). Demagnetization ratio used to evaluate the magnetization state variation range is defined as $k=|B_r-B_{ave}|/B_r\times100\%$, where B_r is the remanence of AlNiCo magnet, B_{ave} is the average flux density of AlNiCo magnet after being demagnetized. When 1 p.u. demagnetizing pulse is employed, demagnetization ratio increases with the thickness of flux barrier decreases. However, the torque with small thickness of flux barrier decreases due to the leakage flux, and particularly the torque with 2 p.u. load current is very limited in this situation. The thickness of passive flux barrier ranging from 1.5 mm to 2 mm is preferred, which could obtain about fifty percent demagnetization ratio at 1 p.u. demagnetizing pulse and exhibit overload capability. V. Conclusion The proposed topology of VF-PMSM could accomplish the demagnetization manipulation with an achievable level of demagnetizing pulse. Meanwhile, the quasi-series magnet configuration enables the proposed machine to offer a high torque density and overload operating capability.

BT-02. Torque Improvement of External-Rotor Permanent Magnet Machine Using Flux Concentrated Rotor.

Q. Li[1] and T. Fan[1]
1. Institute of Electrical Engineering, Chinese Academy of Sciences, Bei-Jing, China

I.Introduction In recent decades, due to high specific torque, external rotor permanent magnet synchronous machines (ER-PMSM) have been widely applied for in-wheel direct-driving electric vehicle (EV) [1]. The torque enhancement of the external rotor SPM becomes research hotspot and has been discussed intensively [2]-[3]. Ref. [2] investigated the effect of the stator tooth width, magnet depth and Halbach array to the external rotor motor, through analyzing the torque and the efficiency characteristic. In [3], the influence of the motor design parameters on the characteristics of the external rotor PMSM was researched. The relationships of pole number and teeth height ratio on the torque, losses and winding temperature rise are derived from analytical calculation method. In this paper, an external rotor PMSM using flux concentrated rotor is proposed to enhance the output torque. The output toque characteristic of the proposed motor is compared with the conventional motor, calculated by the finite element analysis (FEA). To evaluate the peak torque capacity, the instantaneous temperature contour of the proposed motor under the peak torque condition is also compared with the conventional external rotor motor. II.Introduction Topology of ER-PMSM with Flux Concentrated Rotor Fig.1(a) illustrates a conventional ER-PMSM, which is optimized for peak torque 240Nm by the method proposed in [3], under the effective weight limitation for 6 kg and the space constraints. The outer diameter of the rotor core is limited to 220mm, and inner diameter of the stator core is constrained to 150 mm, while the length of the core is fixed to 45mm. In order to enhancing the specific torque, the flux concentrated rotor is used by spoke magnet, and this proposed motor is shown as Fig.1(b). Both of these two motors have 48 slots, and almost the same stator diameters and winding, except the slot opening. It means these two motor have the same phase resistance and same copper losses with the same current excitation. The conventional motor has 40 poles with surface mounted permanent magnet, while the proposed motor has 56 poles with spoke permanent magnet utilizing flux concentrated character. III. Electromagnetic and Thermal Analysis The electromagnetic characteristics of the two motor are calculated by the finite element analysis (FEA). For the proposed motor, the fundamental component of the no-load induced voltage increases 32% than that of the conventional motor, because of the flux concentrated rotor. Therefore under the same current excitation, the output torque of the proposed motor is obviously bigger than the conventional motor. Considering the temperature constraint of the peak torque, which is should operating 30 second, the peak current is limited to 105 Arms. The peak torque of the conventional motor is 240.1 Nm, while using flux concentrated rotor, the peak torque of the proposed motor is enhanced to 309 Nm, increase nearly 29%, shown as Fig2. (a). To evaluate the peak torque capacity, the temperature contour of the two motor under peak torque condition with operating 30s are predicted by the FEA. As a water jacket with a coolant temperature of 40 °C is assumed to be mounted in the candidate machines and the winding insulation is C-class (220°C), so the maximum winding temperature under peak torque condition should be under 190°C. As the two motor have same phase resistance, so the copper losses are the same and the winding hottest points of the two motor under peak torque condition are almost equal to 188°C, shown as Fig.2(b) and (c). IV. Conclusion In this paper, an ER-PMSM with flux concentrated rotor is proposed to improve the output torque. A conventional ER-PMSM is optimized as baseline motor under 6 kg effective weight limitation. By utilizing flux concentrated rotor, the no-load air-gap flux density can be obviously increased, compared with that of the conventional ER-PMSM. Therefore, the peak torque the proposed motor increases about 29% than the prototype motor, and the temperature contour of the two motor under peak torque condition are also evaluated by FEA. The specific torque of the proposed motor under effective weight is up to 50 Nm/kg under effective weight, It can be found that using flux concentrated rotor can obviously enhance the torque capacity.

BT-03. Robust hybrid type permanent magnet traction motor against irreversible demagnetization at high temperature.

C. Jeong[1] and J. Hur[1]
1. Incheon National University, Incheon, The Republic of Korea

Permanent magnet (PM) motors have been applied for a traction motor, because they have great efficiency, high power density, and wide power-speed range. Despite of these advantages, in case of all motors using PM, there is a common concern, which is irreversible demagnetization generated by current armature reaction. This is because the demagnetization has directly a bad effect on performance, reliability, and safety. Although many studies have already analyzed the demagnetization phenomenon [1]-[3], the risk of irreversible demagnetization in the traction motor is still remained, since the traction motor should endure at high temperature over 180°C, which can lead to irreversible demagnetization. Therefore, it is necessary to develop a robust PM motor to withstand at high temperature. For developing the PM traction motor, neodymium PM has been generally applied, because of its advantages such as high flux density per PM volume, durability, and downsizing. Nevertheless, various researches are currently studying the ways to decrease the dependence on neodymium PM in order to reduce the cost of electrical and hybrid vehicles and ensure reliability of material supply. As a result, the motors with less- or non-rare earth material are suggested in [4]-[6]. Especially, a hybrid type PM motor is recently considered to substitute for neodymium PM motor [7], [8]. Here, the hybrid type PM denotes that both of neodymium and ferrite PMs are simultaneously used in a rotor. This is because, comparing the output characteristics per identical rotor volume at same operation condition, the hybrid type PM motor is better than ferrite PM motor. In this paper, it is proposed that the hybrid type PM motor employed in a traction motor is robust against the irreversible demagnetization at high temperature, compared with neodymium PM motor. First, a novel motor using hybrid type PM is demonstrated and suggested to be an alternative motor, as the output characteristics between neodymium PM and hybrid type PM motors are compared by using results through finite element analysis (FEA). Furthermore, the irreversible demagnetization of each motor at high temperature is analyzed for verifying reliability of proposed motor. Fig. 1 shows the performance comparison of neodymium PM and proposed hybrid type PM motors. In case of the hybrid type PM, all length of stator, rotor, and stack is maintained, compared with that of neodymium PM motor, as shown in Figs. 1(a) and (b); whereas, the volume of neodymium PM in motor using hybrid type PM is only used about 60% of neodymium PM motor. Comparing Fig. 1(c) with Fig. 1(d), even though the amount of neodymium PM is decreased, the back electro motive force (BEMF) of motor using hybrid type PM is higher than that of motor using neodymium PM, because of assisted ferrite PMs. As a result, when input current of both neodymium and hybrid type PM motors is identical, the average torque of hybrid type PM motor is higher than that of neodymium PM motor. Consequently, it is evaluated for hybrid type PM motor to be appropriate for replacing the neodymium PM motor as a traction motor. In case of traction motor, it is essential to analyze irreversible demagnetization, since the traction motor have to be able to withstand high temperature in accordance with operating environment. The demagnetization aspects according to magnet type embedded in PM motor are changed in spite of same input current and temperature, because neodymium and ferrite PMs have different characteristic of BH curve about temperature. Therefore, for comparing the demagnetization aspects at each motor, the irreversible demagnetization of two motors is analyzed, as shown in Fig. 2. When beta angle, temperature, and input current are 90°, 140°C, and 240A_{rms}, the severity of irreversible demagnetization is demonstrated through demagnetization ratio in PM, as shown in Figs. 2(a) and (b). In case of neodymium PM motor, the average demagnetization ratio at overall magnets is enhanced about 15%; on the other hand, in case of hybrid type PM motor, the demagnetization ratio at PM corner is partially increased about 35%. At that time, comparing the change of BEMF value between two motors, the BEMF of neodymium PM motor is decreased about 7.6%, but that of hybrid type PM motor is almost constant, as shown in Figs. 2(c) and (d). Moreover, Fig. 2(e) shows that the reduction rate of BEMF value by increasing temperature is indicated. As a result of this analysis, it is verified that the hybrid type PM motor can endure at higher temperature than neodymium PM motor. In future work, detail information of each motor and the fluctuation of radial flux density by armature reaction leading to irreversible demagnetization will be described. Furthermore, the analysis of irreversible demagnetization according to various beta angles will be discussed.

BT-04. Elimination of Sub-harmonic in Stator MMF of 18-slot/10-pole PM Machines by Employing Unequal Slot and Uneven Turns per Coil.

H. Sun[1] and X. Chen[1]

1. Electrical Engineering, Nanjing University of Areonautics and Astronautics, NanJing, China

I.Introduction Surface-mounted permanent magnet (SPM) machines with fractional-slot non-overlapping windings offer several key features, such as high torque density, high efficiency, and low cogging torque, and have been widely used in these high performance applications [1]. However, the associated parasitic effects, i.e., significant rotor loss (rotor core loss and PM loss), high localized stator saturation and large noise and vibration, have always been obstacles, which are mainly due to the non-sinusoidal stator magnetomotive force (MMF), especially the sub-harmonic and super-harmonic [2]. Recently, SPM machines with fractional-slot overlapping windings (FSOW), for example, 18-slot/10-pole machines, have been paid lots of attention since they prove to be competitive in reducing rotor eddy current loss resulting from the harmonic in MMF [3]-[4]. For 12-slot/10-pole machine, the winding factors of 1st (sub-harmonic), 5th (working harmonic), and 7th (super-harmonic) are 0.067, 0.933, and 0.933, respectively, whilst for 18-slot/10-pole machines, they are 0.061, 0.945, and 0.139, respectively. It is clear to see that by employing the 18-slot/10-pole FSOW machine, the 7th harmonic can be suppressed significantly, whilst the 1st harmonic can still be large whose rotating speed is high, which will induce large rotor loss especially at high speed. The purpose of this paper is to reduce the sub-harmonic in stator MMF of 18-slot/10-pole FSOW machine by employing novel stator with unequal slot and uneven coil turns while the torque density is not effected. The comparison of electromagnetic performance including the back-EMF waveforms, cogging torque, average torque, torque ripple, rotor eddy current loss between the conventional and novel 18-slot/10-pole FSOW machines are carried out, which will be shown in full paper. II.Structures and Features of Conventional and Novel 18-Slot/10-Pole SPM Machines Fig. 1 (a) shows the conventional 18-slot stator with coil pitch equal to 2. Each slot shares the same areas and the coil turn number N is identical. The mechanical angle between adjacent teeth is 20 degree. Fig. 1 (b) depicts the structure of novel 18-slot stator. Tooth 1, 4, 7, 10, 13, 16 are shifted by 1 degree clockwise whilst Tooth 3, 6, 9, 12, 15, 18 by 1 degree anti-clockwise. During the shifting, the slot opening width keep unchanged, being 2mm. The slot area of novel stator slot is no longer the same, which is beneficial for designing coils belonging to one phase with different turns for reduction of stator MMF space harmonic. Take one of the coil groups of phase A for example, which consists of coil A_1, coil A_2, and coil A_3. The number of turns of coil A_1, A_2, and A_3 is N for conventional stator, whilst for the novel stator, turns of coil A_1 and A_3 is N_2 and turns of coil A_2 is N_1, whose values are set for reduction of the sub-harmonic in stator MMF. Fig. 1 (c) shows a part of the novel 18-slot stator with only the coils of phase-A drawn. Tooth 1 and tooth 4 are shifted by b to the right side, whilst tooth 3 and tooth 6 are shifted by β to the left side. Fig. 2 shows the stator MMF and torque comparison between 18-slot/10-pole machines with conventional and novel stator. It can be seen that compared with the conventional stator, the novel stator can reduce the 1st harmonic of stator MMF to zero with the 7th harmonic increasing about 40%. The average torque of the two is about the same. III.Conclusion This paper proposes a method for elimination of the sub-harmonic in 18-slot/10-pole FSOW SPM machine. The subharmonic in stator MMF can be total eliminated by employing the novel stator with unequal slot and uneven coil turns. Rotor eddy current loss can be reduced and the torque density of the novel machine can maintain to be the same as that of the conventional one.

1. Institute of Electrical Engineering,Chinese Academy of Sciences, Beijing, China; 2. Beijing First-rate New Energyedrive Technology, Beijing, China

I.Introduction Since the growing shortage of energy and environmental problems, electric vehicle (EV) is getting increasing attention of researchers. In China, the number of EV has double during the past six years from 2010 to 2015 [1]. In particular, [2], [3] and [4] researched and developed the in-wheel motor technology for electric vehicles. However, the motor requirements of the in-wheel driving EV are not only high peak torque and small size, but also high continuous torque density, which is limited by the winding temperature. In this paper, a new cooling method is proposed for the external rotor SPM to improve the continuous torque capability, by enhancing heat dissipation at the end-winding. The finite element analysis (FEA) is used to evaluate the effect of the proposed cooling method. Two motors are manufactured, one is used the proposed cooling method, another motor is conventional motor. The experiment results of the two motors show that the continuous torque increased by 28.5% after using the proposed cooling method, under the same winding temperature constraint, and basically consistent with the simulation results. II.The proposed cooling construction For the conventional external rotor SPM, the winding is cooling by the water jacket, and the water jacket is fixed to the stator inner diameter. Therefore the hottest point is in the end-winding. So to improve the continuous torque, decrease the end-winding temperature is an attractive approach. In this paper, new cooling method is proposed for the external rotor SPM to improve the continuous torque capability. Fig.1(a) illustrates the proposed cooling construction. For the motor with the proposed cooling construction, the path of the heat transfer at the end winding is changed from the "the end winding – the winding – the stator – the water jacket" to "the end winding – the water jacket", which reduces the heat transfer resistance. III.electromagnetic and thermal characteristics To evaluate the proposed cooling method, a conventional external rotor SPM is optimized for a micro-EV, which continue torque is 70 Nm and Dimension is constrained. The outer diameter of the rotor core is limited to 220mm, and the inner diameter of the stator core is limited to 150mm, while the length of the core is limited to 45mm. the optimization method proposed in [5] is carried out, and the maximum winding temperature under continuous torque condition should be under 140°C, while the water jacket with a coolant temperature of 20 °C. Two motor models are built, one is the conventional motor, and another is the proposed motor using the new cooling construction. The design parameters of the two motor are the same, which cooling constructions are different. The Computational fluid dynamics (CFD) was used to evaluate the thermal characteristics of the two motors, under the same temperature limitation on continuous torque condition. The simulation results show that the continuous current of the proposed motor increase 30% compared with the conventional motor, as well as continuous torque. IV.Experiment and validation Two prototype motors are manufactured, the proposed motor is shown as Fig.1(b). As the experimental results in Fig.2 shows, the final winding temperature of the conventional motor is 134.2 °C with continuous torque 70 Nm during 600 rpm, while the final winding temperature of the proposed motor is 136 °C with continuous torque 91 Nm during 600 rpm. The winding temperature of the proposed motor calculated by CFD is quiet agree with the experimental results, shown as Fig.2. V.Conclusion This paper proposed a new cooling method, by enhancing heat dissipation at the end-winding. Utilizing the new cooling construction, the continuous torque increased by 30%. Both numerical simulation and experiment results validate the proposed cooling method.

BT-06. Design and Analysis a New Wide Speed Range Permanent Magnet Motor Capable of High Efficiency Over Wide Speed Ranges.

X. Zhu[1] and L. Ge[1]

1. School of Electrical and Information Engineering, Jiangsu University, Zhenjiang, China

I. Introduction. Permanent magnet (PM) motors have attracted considerable attention for their advantages of high torque density and high efficiency [1]. However, it is difficult to regulate the air-gap field, thus the narrow speed range of the PM motor limits their application especially in electric vehicles, where wide speed range is often needed [2]. Currently, several methods have been proposed to achieve the capability of flux adjustment, including applying a negative *d*-axis current or introducing extra DC field windings to PM motor [3], and yet additional losses may lead to degraded efficiency especially under the deep flux-weakening region. In this paper, a new wide speed range permanent magnet motor with special flux barriers design in rotor core is proposed, where a new design concept of variable main flux and leakage flux are both obtained at different load conditions successfully. The key novelty lies in that the saturation level of the leakage flux path can be controlled by applying different level of *q*-axis load current and thus the *d*-axis magnetic field can be controlled without any additional *d*-axis current and copper losses. So the proposed motor can achieve a high efficiency over wide speed and torque ranges. II. Topologies and Principles. Fig. 1 shows the proposed motor with leakage flux controllable characteristics. For comparison, the similar characteristics of a conventional PM motor are also proposed in Fig. 1. As seen from the figure, the leakage flux branch in the proposed motor is skillfully designed to be two arc-shaped bridges. Generally, to make full use of main magnet flux and to obtain high torque, the leakage flux is expected as small as possible. However, in this proposed motor, a leakage flux branch between two adjacent magnets is designed for a wider speed operation range. In high speed region, magnet flux has a trend of flowing through the leakage flux branch rather than into the air-gap, naturally forming a flux-weakening effect without additional *d*-axis current, thus the motor can realize magnetic field self-controlling under various conditions. Due to the decreasing of magnet flux, efficiency in high speed region can be advanced along with the reduction of iron losses. Moreover, the extra arc-shaped flux barriers can not only guarantee the output capability of the motor, but also make saliency ratio large, resulting in decreasing back electromotive force (EMF) at high speed operation. On the other hand, in low speed region, the leakage flux in the rotor core can be passively reduced by the *q*-axis current effect and more flux gets into the stator for high torque capability. III. Performance analysis. To confirm the unique characteristic, the relationship between *q*-axis current and *d*-axis flux is evaluated in Fig. 2 (a). Compared with the conventional PM motor, the *d*-axis flux variation of the proposed motor is fairly large, which is about 20%. From Fig. 2 (b), it can be obtained that the conventional motor has large saliency ratio, however, the proposed motor has relatively small saliency ratio due to the large *q*-axis reluctance by the extra arc-shaped flux barriers design. The corresponding motor torque distribution with motor speed is described in Fig. 3 according to a driving cycle. It can be seen that the motor works mainly at low torque operation and high-speed region. Hence efficiency characteristics of both the proposed motor and the conventional motor are investigated. In Fig. 4, the 95% efficiency contour line of both two motors is illustrated to protrude the high efficiency area. The high efficiency area of the conventional motor is mainly concentrated in the low-medium speed and large torque area, whereas the proposed new motor is mainly concentrated in the middle-high speed and low torque area. In order to verify the wider high efficiency region performance, iron loss and copper loss properties of both two motors are evaluated. Fig. 5 shows the iron loss difference map. It can be seen that the proposed motor achieves smaller iron loss property all over the operation ranges. This feature can be explained by the smaller magnet flux linkage under flux-weakening control due to the leakage flux property. Fig. 6 shows the copper loss of the proposed motor in high speed region is relatively reduced compared to the conventional motor when the speed is over 2500rpm. Under high speed operation with flux-weakening control, the magnetic flux can be passively decreased by up to 20% caused by leakage flux property, resulting in achieving small amount of flux-weakening current i_d. From these results, the proposed motor is suitable for high speed application in terms of improving average efficiency. More detailed analysis will be presented in the full paper.

BT-07. Design method of permanent magnetic loop return magnetic system and application in vehicle relay.

H. Liang[1], *H. Yu*[1], X. Ye[1] and G. Zhai[1]
1. Harbin Institute of Technology, Harbin, China

1 Preface Lots of vehicle relay is used to realize the function of signal transmission and logic control in high speed rail and urban rail transit. A certain type of traditional clapper type relay started running on the locomotive for a few months, the contact point is closed, however, the test results showed that the contact was broken, which greatly affected the normal operation of the locomotive. The SEM test results show that the contact is in the disconnected state, the moving contact surface is worn and polluted, C and O contents are lot. Therefore, the main failure mode failure mechanism leads to high contact surface film growth caused by contact resistance. Reducing the contact resistance is an effective way to solve this problem. Approaches to reduce the contact resistance divide in two, one is the seal of the relay contact surface in order to inhibit the growth of surface film, but it is not good for heat dissipation, high temperature will affect the service life of electronic components nearby; the other one is to increase the contact pressure, to decreases the contact resistance. The sealed coil has large power consumption and high temperature rise, which will reduce the service life of the surrounding electronic components. Therefore, the only solution of the problem is to increase the contact pressure. 2 Solution based on permanent magnet return circuit The static characteristics of fault traditional patted relay are shown in Figure1(a), when the contact pressure increases, the counter force increases (in Fig. 1(b) in force increases from the black line to the red dotted line), in order to ensure the regular operating (actuation: attractive force greater than the counter force; release: counter force greater than attractive force), needs the increasing of the electromagnetic attractive force (attractive force characteristic in Figure 1 increased from the solid black curve to red dotted curves), it is necessary to improve the current in the coil in order to obtain large attractive force, which will cause the rise of coil power consumption. In order to keep the power consumption of the coil constant and increase the contact pressure DFj at the same time, as shown in Figure 1(b), the counter force characteristics can be moved downward (black dotted broken line in Figure 1(b)) and then increased contact pressure, however, the holding force DFb of the relay at the release position (DFb is the difference between the counter force and the electromagnetic force at 0V, and the electromagnetic force at 0V is zero for the conventional clapper magnetic system) will decrease at this time, so that the relay vibration index is affected. If the electromagnetic force at 0V is a negative value besides zero. DFb can keep the original value unchanged, so that the contact pressure is increased and the coil power consumption and anti-vibration index is unchanged. If the reaction force characteristics continue to move down to obtain the expected absorption characteristics shown in Figure 3, the relay power consumption won't rise, while the contact pressure increases, DFb remains unchanged, and it can still meet the requirements of vibration resistance. Figure 1(c) shows the static characteristics is the typical suction characteristic curve shape of the permanent magnetic loop return magnetic system. In the existing relay products, the Balance Force relay magnetic system from Leach is the typical representative of this magnetic system. The characteristics of the permanent magnet loop return magnetic system are: (1) three working air gaps; (2) a permanent magnetic flux gap smaller closure path at the release location; (3) a permanent magnetic flux gap bigger closure path at the suction location. According to the characteristics of permanent-magnet-loop-return magnetic-system, combined with the structure of traditional clapper type magnetic system, a new type of magnetic system with permanent magnetic loop return magnetic circuit structure is showed. Carry out the static characteristic simulation of the new permanent magnetic loop return clapper magnetic system, and compared with the traditional type, see table 1. As can be seen from it, the contact pressure is increased, the rated power consumption of the new magnetic system is unchanged, the power consumption of the absorbing part is reduced, and the retaining force of the releasing side remains constant, which achieves the goal of improvement. Contact pressure(N) Retention(N) Act consumption(10-3J) Power rating(W) Fault relay 0.3 7.4 8.69 1.78 Improved relay0.4 7.44.12 1.77 3 conclusion (1) Three characteristics of the permanent magnet loop return magnetic system are presented: three working air gaps, a permanent magnetic flux gap closed path at the release location, and a permanent magnetic flux gap closure path at the suction location. (2) Based on the characteristics of the permanent magnet loop return magnetic system, a method of constructing a new permanent magnet loop return magnetic system is presented. This method can also be used in other permanent magnet magnetic systems. (3) Proposed a new type of permanent magnet loop back clapping magnetic system, the simulation results show that this kind of magnetic system of relay with high contact pressure, low power consumption, pull off the electrical characteristics of permanent magnet coil on loop back, solves the traditional capping relay fault due to high contact resistance failure problems.

BT-08. Analysis on the starting and Synchronization Capabilities for a Novel 6/8 Pole Changing Line-Start Permanent Magnet Synchronous Motor.

M. Tian[1], X. Wang[1], W. Zhao[1] and C. Li[1]
1. School of Electrical Engineering, Shandong University, Ji'nan, China

I. Introduction Line-start permanent magnet synchronous motor (LSPMSM) has been widely used in applications such as pumps, fans and compressors for its high torque and power density, efficiency and power factor [1]-[2]. However, it suffers from the poor starting and synchronization capabilities, and always a compromise between the starting and synchronization capabilities is adopted because of the conflict with each other [3]-[4]. So far, several different rotor configurations, such as squirrel-cage rotor, solid rotor, slotted solid rotor, two-part rotor geometry and so on [5]-[7], and different magnet, cage bars shapes [8]-[9], were presented and discussed to improve the starting and synchronization capabilities. But the starting capability cannot get fundamentally improved for the existence of the braking and pulsating torques. In [10]-[12], the pole changing method was presented, and the drawbacks of PMSM got overcame. However, more switches were used, and the reliability was reduced for the proposed 2/4 pole changing winding. In addition, the turn numbers cannot be adjusted to balance the starting and running performance. In this paper, a 6/8 pole changing LSPMSM is designed based on the novel 6/8 pole changing stator winding. As the different pole numbers between stator winding and rotor PMs during 6-pole starting process, the inherent braking torque and pulsating torque for conventional LSPMSM can get effectively eliminated, and the starting capability can be fundamentally improved. Furthermore, as the effective improvement of the starting capability, the rotor resistance can be optimized to be smaller to improve the synchronization capability simultaneously. II. The Structures of the Motor and 6/8 Pole Changing Winding Fig.1(a) and (b) show the structures of a 380V, 30kW, 8-pole LSPMSM and the proposed 6/8 pole changing winding respectively. At the beginning of the starting, 1U, 1V, 1W are connected with the applied source, and the winding is 6-pole. When the motor reaches a certain speed, 1U, 1V, 1W are disconnected and 2U, 2V, 2W are switched on, the winding is switched to 8-pole. Keep the 8-pole state until the motor runs stably. The structure of the proposed winding is more simple and easier to control because of the less use of switches, the reliability is also get higher and service life is longer. Meanwhile, the performance of the starting and steady running can also get balanced by adjusting the winding turns of the two pole states. III. The Analysis of the Starting Process Firstly, the no-load back electromagnetic force (EMF) of the proposed 6-pole and 8-pole winding are calculated respectively. The results show that the value of the 6-pole winding is nearly zero, which can fundamentally explain the reason for the elimination of the braking torque. Then the comparison of the locked-rotor torque with two winding shows that the values are 900 Nm and 909 Nm respectively, but the torque fluctuation rate is reduced by 40.4% for the 6-pole winding. Finally, the speed, current and electromagnetic torque during the entire starting process between the proposed pole changing and conventional LSPMSM are compared. The results show that the starting time is shorter, speed and torque fluctuation is smaller, and even the time to pull into synchronization is also shorter for the proposed one. IV. The Improvement of the Synchronization Capability Under the premise that the starting capability has been effectively improved, the rotor resistance R can be appropriately reduced to improve the synchronization capability simultaneously. Fig.2(a) shows the torque-speed (T-s) curve with two different rotor resistance R_1 and R_2, and R_1>R_2. As the starting torque T_{st} is proportional to R, so T_{st1}>T_{st2}. The maximum torque T_{max} and the corresponding critical slip s_m are, $T_{max}\approx m_1U_1^2/(2\Omega_s(X_{1\sigma}+X'_{2\sigma}))$, $s_m\approx R/(X_{1\sigma}+X'_{2\sigma})$, where m_1, U_1, Ω_s, $X_{1\sigma}$, $X'_{2\sigma}$ are phase numbers, input voltage, angular velocity of rotation, stator leakage reactance and rotor leakage reactance, respectively. So T_{max1}=T_{max2}, s_{m1}>s_{m2}. And during the synchronization process, for an arbitrary slip s_0, the smaller rotor resistance corresponds to the larger torque, T_1<T_2, which is more advantageous for pull-into synchronization. To reduce the rotor resistance, the cross-sectional area of the cage bar is designed larger. And then the comparison of the synchronization capability between the original and the new proposed 6/8 pole changing LSPMSM is analyzed by comparing the maximum inertia of moment J_{max} (the rated inertia of moment is J_r) that motor can pull into synchronization. The speeds of two motors with different J is shown in Fig.2(b), and the results show that J_{max} is 15J_r for original 6/8 motor while for the proposed new designed 6/8 pole motor, J_{max} is 19J_r. The synchronization capability gets well improved. V. Conclusion This paper has proposed a novel 6/8 pole changing LSPMSM. Based on the pole changing starting method, the starting capability gets fundamentally improved. Furthermore, under the premise of guaranteeing the starting capability, the synchronization capability is considered by reducing the rotor resistance. Through processing, both the starting and synchronization capabilities have been improved.

BT-09. Investigation of a Transverse-flux Flux-reversal Motor with Consequent-pole Configuration.

B. Kou[1], *X. Yang*[1], Y. Zhou[1], J. Luo[1] and H. Zhang[1]
1. Harbin Institute of Technology, Harbin, China

I. INTRODUCTION With the advantages of high torque/power density and high feasibility for multi-pole/multi-phase design, the transverse flux motor has been widely investigated for low-speed large-torque direct-drive applications [1][2]. Nevertheless, the previous transverse flux motors always face the problem of high manufacturing cost that is caused by using of a large amount of expensive rare-earth permanent magnet and complex motor core structure. For avoiding those shortcomings, a transverse-flux flux-reversal motor (TF-FRM) is proposed in [3]. Both stator and rotor of the TF-FRM can be fabricated by silicon steel sheet that simplifies the manufacturing of core, meanwhile, the total volume of PMs used in TF-FRM is fewer and the provided torque density is considerable. In this paper, a transverse-flux flux-reversal motor with consequent-pole configuration (TF-CFRM) is proposed based on the forgoing TF-FRM, which can further reduce the volume of PMs and provide high torque density. Firstly, the basic structure and working principle are introduced. Secondly, the analytical expression of the electromagnetic torque is derived by a 3-D equivalent magnetic circuit model. Then the influences of structural dimensions on torque density is analyzed by finite element method. At last, the torque performance of the proposed TF-CFRM is compared with TF-FRM and flux reversal motor [4]. *II. BASIC STRUCTURE AND WORKING PRINCIPLE* The fundamental structures of traditional flux reversal motor, forgoing TF-FRM and proposed TF-CFRM are shown in Fig.1. The proposed TF-CFRM is a three-phase machine which is combined by three single-phase units along axial direction. The stator radial-flux cores have tooth-slot configuration in the inner surface, the center line of 'tooth' in one core is aligned to the center line of 'slot' in another core in one single-phase unit. The PMs are fixed in the 'slot' area of stator radial-flux cores, all PMs of the same polarity and they are magnetized along radial direction. Like the traditional flux reversal PM motor, the proposed motor works on the principle of variable flux linkage, inducing a back electromotive force that interacts with an alternating armature current in torque generation. *III.PRELIMINARY ANALYSIS BY 3-D EQUIVALENT MAGNETIC CIRCUIT MODEL* A 3-D equivalent magnetic circuit model is built for preliminary analysis of TF-CFRM. Since the magnetic field of different phases of TF-CFRM are decoupled, and the model has a periodicity along rotational direction, the magnetic circuit model under two pole-pitch is built for simplify the calculation. Then the analytical expressions of flux linkage in coil, no-load back electromotive force and electromagnetic torque are divided. *IV. INFLUENCE OF KEY DIMENSIONS AND TORQUE PERFORMANCE COMPARISON* Since the length of PM in the rotational direction, the thickness of PM in the magnetized direction and the rotor core length in rotational direction (l_{pm}, h_{pm} and l_{rt} respectively) have significant effects on the magnetic reluctance of TF-CFRM, then resulting in the influences on the torque performances. The ratio of PM rotational length on pole-pitch k_{pm} (l_{pm}/τ_{pm}), the radio of rotor core rotational length on pole-pitch k_{rt} (l_{rt}/τ_{pm}) and the PM thickness h_{pm} are listed as three key dimensions. The analysis of key dimensions are done by finite element method, and the results are shown in Fig.2a and 2b. From the results, the optimal value range of the three dimensions are selected as 1.1~1.2, 0.6~0.7 and 3~4mm. The torque performance such as cogging torque, electromagnetic torque and torque ripple of the proposed TF-CFRM is compared with TF-FRM and flux reversal motor which have same dimensions, the results are shown in Fig.2c. *V. CONCLUSION* A transverse-flux flux-reversal motor with consequent-pole configuration is introduced in this paper. The expressions of electromagnetic torque is derived by equivalent magnetic circuit model. The influences of three key dimensions on torque performance are investigated by finite element method, the optimal value ranges of key dimensions are presented which provides useful information for future design process. And the torque performance of proposed motor is compared with TF-FRM and FRM by FEM. The torque density per volume of TF-CFRM is 8.07kN.m/m^3 when the RMS current density is 4.3A/mm^2, which is similar to the ones of TF-FRM and FRM. Meanwhile, the total volume of PMs used in TF-CFRM is 77% of TF-FRM and 57% of FRM. That means TF-CFRM is a considerable solution of direct-drive motor which can reduce the manufacturing cost and provide acceptable large torque density.

BT-10. Torque Improvement of Five-Phase Halbach Permanent Magnet Machines Considering Third-Harmonic Flux Density.

L. Zhang[1] and L. Liu[1]
1. Nanjing University of Aeronautics and Astronautics, Nanjing, China

I. INTRODUCTION Multi-phase machines have obtained wide applications in aerospace, rail transient, electric vehicle, etc. due to the advantages of high torque density, high efficiency, and high reliability [1]-[2]. The five-phase permanent magnet (PM) machines, as one of such machines, can improve the torque density by injecting third-harmonic current into the fundamental one. This is mainly due to the additional output torque can be contributed by the interaction of third-harmonic back-EMF and injected third-harmonic current [3]. Therefore, the third-harmonic component in phase back-EMF is the basic conditions of torque density improvement by third-harmonic current injection. The Halbach PM array technique, which can provide approximate sine air-gap flux density to suppress the torque ripple, has been widely applied to obtain excellent static and dynamic performance in the PM machines [4]-[5]. However, due to the lack of third-harmonic component in phase back-EMF for this structure,it is no of effect to improve the torque density by injecting third-harmonic current in the five-phase PM machines. Therefore, this paper proposes a third-harmonic Halbach PM array structure based on the conventional Halbach PM array, in which the more third-harmonic contents in phase back-EMF can be provided. The torque characteristics of the five-phase PM machines with the proposed structure and the conventional structure are compared by finite element method, when the sine with third-harmonic (SIN+3rd) current is supplied under the current constraints of the same amplitude (AMP) and the same root-mean-square (RMS), respectively. II. MACHINE STRUCTURES AND FINITE ELEMENT ANALYSIS The proposed third-harmonic Halbach PM array structure consists of two sets of conventional discrete Halbach PM array for one pole, and the evolution schematic of the proposed structure is shown in Fig.1 (a). The analogous saddle shaped air-gap flux density can be produced in the proposed structure, and the corresponding back-EMF is induced, which can improve the contents of third-harmonic component in the phase back-EMF. Therefore, the output torque can be improved by the additional torque contributed by the third-harmonic components. In order to verify the torque improvement of the proposed structure compared to the conventional structure, the 10-slot/8-pole five-phase PM machines with unequal teeth and single-layer non-overlapping winding are employed. The two five-phase PM machines structures are shown in Fig.1 (b) and (c). The output torque waveforms of the two five-phase PM machines are given in Fig. 2 (a) and (b). It can be observed that the average torque of the five-phase PM machines with proposed third-harmonic Halbach PM array can be improved by 6.57% compared to that of the conventional Halbach PM array five-phase PM machines, when the SIN+3rd current is supplied under the same AMP constraint. For the same RMS constraint, the average torque can be improved by 5.99% of the conventional Halbach PM array five-phase PM machines. Meanwhile, it should be noted that the corresponding torque ripple is hardly deteriorated.

BT-11. A High Power Factor Vernier Machine with Coil-Pitch of Two Slot Pitches.

Y. Liu[1], H. Li[1] and Z. Zhu[1]
1. The University of Sheffield, Sheffield, United Kingdom

Abstract--In this paper, an 18-slot/26-pole Vernier permanent magnet synchronous machine (VPMSM) with coil-pitch of two slot pitches is proposed based on a 9-slot/18-flux-modulation-pole/26-pole VPMSM with concentrated tooth-coil windings. Compared with the original VPMSM, the number of slots is doubled and the phase winding connection is adjusted to reduce the space harmonic content, the phase inductance and hence, improve the power factor. The study shows that the proposed VPMSM has a higher power factor of 93% with a torque improvement. Moreover, a series of VPMSMs with high power factor is proposed from the same design principle. 1. Introduction Vernier permanent magnet synchronous machine (VPMSM) has become a promising candidate in direct drive application because of its high torque density [1] and low torque ripple [2]. However, different from traditional PMSMs, Vernier machines suffer from low power factor which increases the cost of power converters [3] and hinder their application. Compared with the traditional PMSM with higher power factors, the low power factor of VPMSM is caused by the increased number of rotor PM poles and the relatively large phase inductance. There are some papers trying to improve the power factor of VPMSMs by using Halbach PM rotor [3] or dual-rotor structure [4]. However, special techniques or complicated structures are needed, hindering their application to common VPMSM designs. In this paper, an 18-slot/26-pole VPMSM with coil-pitch of two slot pitches is evolved and proposed based on a 9-slot/18-flux-modulation-pole (FMP)/26-pole VPMSM with concentrated tooth-coil windings. Compared with the original machine, the slot number is doubled and the phase winding connection is adjusted in the proposed one to reduce the space harmonic content, and hence, decrease the phase inductance. The study shows that such design can effectively decrease the phase inductance and improve the power factor from 73% to 93% with a torque improvement. Moreover, a series of VPMSMs with high power factor will be proposed from the same design principle. 2. Machine structure and performance comparison A 9-slot/26-pole VPMSM with 18 FMPs and concentrated windings is shown in Fig. 1 (c). This is a typical VPMSM with concentrated tooth-coil windings [5] since it satisfies p_r=N_f-p_s, where p_r is the number of PM pole-pairs in the rotor, N_f is the number of FMPs in the stator and p_s is number of the armature winding pole pairs in the stator. This machine suffers from low power factor as a result of high PM pole number and relatively large phase inductance. In this paper, an 18-slot/26-pole VPMSM with coil-pitch of two slot pitches is proposed based on the 9-slot/26-pole VPMSM. The proposed machine is evolved from the original machine via the following steps: (1) Double the number of slots so that in the proposed machine the number of stator slots N_s equals to N_f in the original machine, as shown in Figs. 1 (a) and (b). (2) Divide the windings of phase (A, B, C) in Fig 1 (c) into two groups denoted as (A1, B1, C1) and (A2, B2, C2) in Fig. 1 (d). (3) In the proposed machine, configure (A1, B1, C1) in the same way with (A, B, C), with the coil spanning two slot pitches. (4) In the proposed machine, configure (A2, B2, C2) 180 mechanical degree away from (A1, B1, C1), with opposite polarity. By doing this, the armature reaction space harmonics of even orders can be effectively eliminated without affecting the fundamental harmonic [6], as shown in Fig. 1 (e). The reduction of armature reaction space harmonic content can directly reduce the phase inductance per turn, and hence, improve the power factor. Both the 9-slot and the 18-slot/26-pole VPMSMs are globally optimised under the same overall size, same copper loss considering the end windings and PM volume. The performance of the optimised machines are shown in Table 1. It shows that the proposed machine increases the power factor from 73% to 93%, with a torque improvement. 3. Design principle and guidelines It is proved that for the VPMSM with concentrated windings, as long as it satisfies $1/2N_f = N_s = 2(N_f - p_r) \pm 1$, it can be evolved into a VPMSM with $N_s = (4p_r \pm 2)/3$ and coil-pitch of two slot pitches. In this way, the space harmonic content as well as the inductance will be reduced, and hence, the power factor will increase. Detailed design principle and guidelines will be presented in the full paper. 4. Experiment validation The prototype of the 18-slot/26-pole machine with coil-pitch of two slot pitches will be manufactured and tested. 5. Conclusion In this paper, an 18-slot/26-pole VPMSM with coil-pitch of two slot pitches is proposed from a 9-slot/18-FMP/26-pole VPMSM with concentrated windings. Compared with the original VPMSM, the proposed design reduces the armature reaction space harmonic content and phase inductance without affecting the fundamental harmonic, and hence increases the power factor with a torque improvement. The study also shows that a series of VPMSMs with coil-pitch of two slot pitches can achieve high power factor based on the same design principle.

BT-12. A study on hall sensor fault signal compensation algorithm to prevent irreversible demagnetization by hall sensor faults.

D. Lee[1], B. Kim[1], S. Lee[1], J. Lee[1] and D. Kang[1]
1. Convergence System Engineering, keimyung university, Daegu, The Republic of Korea

BLDC motors are similar to DC motors, but they use semiconductor switches to implement commutator and brush functions. Therefore, it is the motor that solves the disadvantages of the mechanical structure of DC motor. BLDC motors have a simple structure and high torque and high speed operation.[1][2] In order to realize this function, it is essential to know the position of the permanent magnet. Normally, a permanent magnet motor uses a Hall sensor. The three Hall sensors are arranged at intervals of 120 ° of the machine angle to detect the position of the rotor.[3][4] From the detected signal, the position of the rotor can be divided into six sections. In the six sections, two phases should be selected to excite current. So that the rotor continually rotates in one direction. However, this hall sensor has frequent faults according to the usage environment and has a disadvantage that an error signal can be generated due to the influence of an external magnetic field. The magnetic field sensing capability may be degraded in a high temperature environment. In addition, an error signal may be generated by the leakage magnetic flux generated by the magnetic saturation of the iron core.[5] Fault of a position sensor such as a Hall sensor in a permanent magnet synchronous motor drive system rotating at high speed is an important factor that lowers the reliability of the control system.[6] In addition, the fault of the hall sensor may generate an overcurrent in each. The overcurrent increases in proportion to the speed of the motor. The overcurrent generated in each phase is one of the fatal factors that can cause Irreversible demagnetization in the permanent magnet synchronous motor. Failure analysis studies are under way to solve these problems. Sensorless control switching studies in the event of faults are also underway. A sensorless position estimator is usually used to compensate for the failure signal of the position sensor. The sensor output value is compared with the output value from the sensorless controller. If the error is over a certain range, the sensor is judged to be faulty and switched to sensorless control. If the error range for judging the failure of the sensor is small, an error is determined to be a failure even in a normal state. On the contrary, if the error range for judging the failure of the sensor is too large, a large current ripple occurs when switching to the sensorless control. In this paper, we use the method of comparing and analyzing the interval data from the first triggered point in real time. Therefore, the failure of the hall sensor can be detected immediately, and the hall sensor in which the failure has occurred can also be grasped. In this paper, the signal of the failed Hall sensor is compensated by using two Hall sensors operating normally. Therefore, it has higher reliability than sensorless control by using a normal sensor. The circuit that compensates the signal uses a logic circuit and a phase shift circuit. Two normally operating Hall sensors are input to the logic gate circuit to generate an inverted waveform of one hall sensor. The phase shift circuit is constructed using resistors, capacitors, and op amps. The inverted waveform from the logic gate circuit is input to the phase shift circuit to generate two waveforms delayed by a specified angle. The delayed two waveforms are used to generate the faulty hall sensor waveform through the op amp. The simplorer circuit consists of a motor, a controller, and an inverter. And the Hall sensor was forced to generate a fault at 200[ms]. We have detected the fault by constructing the algorithm as described above. Identify the failed hall sensor and enter the remaining normal operating Hall sensor into the phase shifting circuit. The signal generated through the phase shift circuit compensates the signal of the failed Hall sensor. As a result, we confirmed that the motor operates normally through the compensated Hall sensor and two normally operating Hall sensors. Irreversible demagnetization of the permanent magnet is also reduced when the Hall sensor fails.

BT-13. Efficiency Optimization for IPMSM Considering Hysteresis Loss.

T. Ishikawa[1]
1. Electronics and Informatics, Gunma University, Kiryu, Japan

1. Introduction It is very important to maximize the efficiency of electric motors, because electric motors consume more than 50 % of total energy produced in the world. One way to achieve this goal is to apply control techniques to reduce the motor losses. Interior permanent magnet motors (IPMSMs) exhibit better efficiency than induction motors. Therefore, this paper treats IPMSMs. IPMSMs have two types of loss such as copper loss due to the winding resistance and iron loss due to eddy current and hysteresis losses in the core and permanent magnet materials. However, the references which treated loss minimization of IPMSMs take into account a constant core-loss resistance only [1] [2]. This paper proposes d- and q-axis equivalent circuits which take into account eddy-current-loss resistance and hysteresis-loss resistance. The characteristics of an IPMSM are clarified when the loss minimization algorithm is used. 2. Loss minimization algorithm In order to use a vector control strategy, three-phase stationary frame is transformed to a two-phase synchronously rotating d-q frame. Figure 1 shows the d-q axis equivalent circuits of IPMSMs including copper, eddy-current and hysteresis losses. In this figure, R_a: stator resistance, R_e: eddy-current-loss resistance, R_h: hysteresis-loss resistance, ω: electrical rotor speed, ϕ_f: magnetic flux linkage, L_d, L_q: d-q axis self-inductances, R_{h0}: R_h when $\omega=\omega_0$, v_d, v_q: d-q axis stator voltages, i_d, i_q: d-q axis stator currents, i_{od}, i_{oq}: d-q axis magnetizing currents, i_{ed}, i_{eq}: d-q axis eddy-current-loss currents, i_{hd}, i_{hq}: d-q axis hysteresis-loss currents in the synchronous rotating frame. In the equivalent circuit shown in references [1] and [2], hysteresis-loss resistance R_h is omitted. The terminal voltage ignoring stator resistance is expressed as at a steady state, V_o=sqrt($v_{od}^2+v_{oq}^2$)=ω*sqrt(($L_d*i_{od}+\phi_f)^2+(L_q*i_{oq})^2$)=ω*ϕ. Therefore, copper loss is given by $P_c = R_a*(i_d^2+i_q^2)$. Eddy current loss is given by $P_e = V_o^2/R_e = \omega^2*\phi_f^2/R_e \propto f^2*B^2$. Hysteresis loss is also given by $P_h = V_o^2/R_h = \omega^2*\phi_f^2/(R_{h0}*\omega/\omega_0) \propto f*B^2$. It is noted that if hysteresis-loss resistance $R_h = R_{h0}*\omega/\omega_0$, hysteresis loss is proportional to frequency f times the square of flux density B. The d-axis magnetizing current iod for minimizing loss is given by $d(P_c+P_e+P_h)/d(i_{od}) = 0$. As a result, iod is represented as a function of ω and torque T_e, and then ioq, id, iq, and the efficiency can be represented as a function of ω and torque T_e. 3. Characteristics at loss minimization situation As derived in the previous section, i_d, i_q, and efficiency become a function of only iod when load torque and speed are considered to be constant. The stator current id and iq of a IPMSM producing minimum loss are plotted in Figure 2 for three different speeds and four different torque, in which ω0 is set to 1000 min^{-1}. The stator current id and iq without considering the hysteresis-loss resistance are also plotted to clarify the effect of hysteresis loss resistance, in which R_h is set to be infinite and Re is set to be half. It is found from figure 2(a) that id becomes large when speed is high and becomes a little bit small when speed is low by considering the hysteresis-loss resistance. Figure 2(b) shows that motor efficiency becomes low when speed is high and becomes low when speed is high by considering the hysteresis-loss resistance. Therefore, the hysteresis-loss resistance should be taken into account when the loss minimization algorithm is used. 4. Conclusions This paper has proposed d- and q-axis equivalent circuits which take into account eddy-current-loss resistance and hysteresis-loss resistance, which is proportional to the speed. It has been clarified that the hysteresis-loss resistance should be taken into account when the loss minimization algorithm is used.

BT-14. Comparison of the Power Factor of SMPM and SM Vernier Outer Runner Machines for Traction Applications.

D. Thyroff[1], C. Hittinger[1] and I. Hahn[1]
1. Institute of Electrical Machines and Drives, University of Erlangen-Nuremberg, Erlangen, Germany

1. Introduction In traction applications high torques at low speeds and in standstill are required. Therefore, often a high speed machine is combined with a gear to adapt torque and speed of the machine [1, 2]. However, gears need maintenance and lubrication, while creating noise and increasing the inertia of the machine. Using direct drives instead of high speed drives allows removing the gear. Yet, the used direct drives need a very high standstill torque and a high torque density [1, 2]. Besides the PM machine, the Vernier machines, a group of the flux modulation machines, offer machine topologies with higher torque densities [4]. In comparison to the PM machine, a very low power factor of the Vernier machine is reported [5 - 7]. The power factor of both machine types is mostly compared in the corner speed point. But in traction applications it is not sufficient to focus on a single point and on a single objective, as the drive is dynamically driven over the whole torque and speed range. Therefore, this paper investigates on a performance comparison of both machines designed as outer runner machines with surface mounted magnets [3], while applying the same objectives and requirements. The calculation method bases on FEM and includes the evaluation of iron losses by the IGSE model [8]. The final paper will include pictures and data of the machines geometry *2. Control strategies and machine design objectives* The control of an electrical machine splits into the base speed region and into the field weakening area. In the base speed region the machine is driven following the MTPA (= maximum torque per ampere) control strategy, while the MTPA is found by following the trajectory of maximum torque per current amplitude through the Id- and Iq-map [9, 10]. Figure 1 shows the Id- and Iq-map for the investigated Vernier machine. The MTPA connects the zero point and the current limit circle in the Id- and Iq-map, as shown in figure 1. In the field weakening area the machine is operated following the MTPV (=maximum torque per voltage) control strategy, while the MTPV is found by following the maximum torque per voltage amplitude trajectory through the Id- and Iq-map [9, 10]. The MTPV connects the current limit circle and the ideal short circuit point (= SCP) by a nearly vertical trajectory, as shown in figure 1. Only if the machine is operated following the MTPV a constant power output in the field weakening area is possible. Therefore, it is necessary that the ideal SCP lies inside the current limit circle of the machine. Otherwise the output power of the machine will decrease in the field weakening area [9, 10]. However, offering constant power at higher speeds is a significant objective in traction applications, therefore it is an important design objective to locate the ideal SCP inside the current limit circle. Doing so also allows a safe runout with tolerable currents in case of an inverter failure. Both trajectories are connected by traveling on the current limit circle, resulting in the Id and Iq limit curve. The resulting speeds and torques along the limit curve are shown in figure 2. The final paper will also include the MTPA and MTPV Id- and Iq-map plots for the PM machine. *3. Power factor comparison of the PM and Vernier Machine* As it is mandatory for traction applications to locate the ideal SCP point inside the current limit circle, the design of both machines needs to fulfil this requirement. It is fulfilled, if the winding is able to fully compensate the magnet flux linkage. Due to the theory of flux modulation the amplitude of the flux linkage in the Vernier machine is smaller than in the PM machine, since not the whole flux is linked. However, due to the speed difference between stator and rotor the back-EMF and the torque are higher, which is the known as the magnetic gearing effect. In summary, the Vernier machine achieves a higher torque and a higher back-EMF compared to the PM machine, while developing a smaller flux linkage [7]. During the design of both machines it is noticeable that the magnet volume in the PM machine needs to be decreased to locate the ideal SCP point inside the current limit circle. Due to the necessary reduction of magnet volume in the PM machine it is obvious that the power factor is strongly reduced. However, to achieve acceptable power factors with the Vernier machine the machine current needs to be reduced. Nevertheless, the Vernier machine accomplishes nearly twice the torque of the PM machine with only 60% of the current, while both machines locate the ideal SCP point inside the current limit circle. The power factor of the Vernier machine at the corner point is 0.65, see figure 2, and the power factor of the PM machine at the corner point is 0.7. Finally, the power factor of the Vernier machine is in a similar range when it comes to traction applications, while the Vernier machine shows significant improvements in torque. The power factor plot for the PM machine will be included in the final paper. Furthermore equations supporting the named arguments will be included in the final paper. *4. Conclusion* The general claim, that Vernier machines exhibit poor power factors is not true if it comes to traction applications and the objective is to locate the ideal SCP point inside the current limit circle. As in this case, the power factor of the PM machine is in a very similar range as the one of the Vernier machine. It even is shown that Vernier machines are advantageous as the flux linkage is smaller, wherefore it is easier to fulfill the design objective.

BT-15. Comparative Parameters Investigation of Composite Solid Rotor Applied to Line-Start Permanent-Magnet Synchronous Motors.

B. Yan[1], Y. Yang[1] and X. Wang[1]
1. School of Electrical Engineering, Shandong University, Ji'nan, China

I. INTRODUCTION Besides the desirable properties of high power factor and high power density, the line-start permanent-magnet synchronous motor (LSPMSM) features another capability of self-starting due to the cage embedded in the rotor. However, the starting behavior of such motors remains sensitive to heavy loads, and the braking torque caused by the permanent-magnets (PMs) constitutes the main reason for the load sensitivity [1]. Decreasing the PMs content will surely restrain the braking torque, whereas the motor steady-state performances, such as the working efficiency and synchronous torque, will be worsened by the PMs decrement. To solve this conflict, a composite solid rotor (CSR) applicable for the LSPMSM is designed in [2] by the authors. As shown in Fig. 1(a), the solid steel rather than laminated one is used in the designed rotor for its inherently high starting torque [3]. Meanwhile, a squirrel cage and some narrow slots are attached on the rotor surface, by which the rotor energy conversion is strengthened [2] and the motor starting capability is hence improved. II. PARAMETERS DETERMINATION BASED ON EEC Aimed at a further research on the cage and slots covered in the CSR, a parameters comparison between the CSR and three other rotors (named as I-III) is performed in this paper. Fig. 1(b) gives the cross-sectional views of rotor I-III. In contrast to the CSR, rotor I and II are not equipped with the slots and cage, respectively. Rotor III embraces neither cage nor slots on its surface. Parameters determination of the CSR and rotor I-III relies on an electric equivalent circuit (EEC) established for the motors. Configuration and parameters definition of the EEC are depicted by Fig. 1(c). It should be noted that all of the compared rotors exhibit heavy structural unbalance due to the solid steels split by PMs. Consequently, the rotor parameters of the EEC are divided into the *q*- and *d*-axis components, and the rotor unbalance is reflected in detail by the parameters division. A two-dimensional (2-D) finite element method (FEM) is utilized to calculate the circuit elements covering the rotor parameters. During the calculation, the PMs are treated as air blocks since the rotor parameters are merely dependent on the conductive rotor segments. However, the effects of the PMs on the reluctivity distribution are kept unchanged by the frozen-permeability method [4], [5]. III. PARAMETERS COMPARISON AND ANALYSIS The rotor parameters derived from the EEC are compared in Fig. 2(a). Based on the comparison, two remarkable value relations can be concluded as: (1) the *q*-/ *d*-axis resistances and leakage reactance of the CSR and rotor I are smaller than those of rotor II and III, (2) the *q*-axis resistance of the CSR is smaller than that of rotor I, and the *q*-axis resistance of rotor II is smaller than that of rotor III. The upper half of Fig. 2(b) gives reasons for relation (1). Compared to rotor II and III, both of the CSR and rotor I additionally contain a cage on the surface. The added cage carrying eddy currents makes up a branch in parallel with the solid steel, and the resistance and leakage reactance of the whole rotor is decreased due to the parallel connection. The lower half of Fig. 2 (b) provides explanations for relation (II). Compared to rotor I and III, both of the CSR and rotor II furtherly include the slots on their surface. The added slots located on the *d*-axis central lines enlarge the eddy-current area of the *q*-axis rotor region and hence reduce the *q*-axis rotor resistance. By using the parameters given in Fig. 2(a), the induction torques of the LSPMSPMs with the four compared rotors are calculated and then displayed in Fig. 2(c). It can be found that the highest torque value is involved by the motor with the CSR, which is generated by its smaller rotor parameters than those of motors with rotor I-III. A further comparison among the motors with the CSR and rotor I-III is carried out through the FEM calculations of start-ups under heavy load conditions. As shown in Fig. 2(d), only the motor with the CSR reaches synchronization under 1.2 times of normal load torque and 6.5 times of rotor inertia. The above comparisons of rotor parameters (Fig. 2(a)), induction torques (Fig. 2(c)) and start-ups (Fig. 2(d)) validate the rotor parameters decrement and the resultant torque enhancement by attaching the cage and slots on the CSR, and thus the starting performance improvement by applying the CSR in the LSPMSM.

BT-16. Multi-sensor Fusion Based Permanet Magnet Demagnetization Detection in Permanet Magnet Synchrounous Machines.

M. Zhu[1], W. Hu[1], *S. Mukundan*[1] and N. C. Kar[1]
1. Electrical and Computer Engineering, University of Windsor, Windsor, ON, Canada

I.Introduction Most of the demagnetization detection techniques are based on single sensor diagnosis such as analysis of stator current [1], acoustic noise [2], or torque [3]. However, single sensor demagnetization detection has inherent uncertainties due to fault models and motor operating environments. Hence, multi-sensor information fusion is an effective way to solve such uncertainties and improve demagnetization detection accuracy and improve motor control stability. This paper explores the use of acoustic noise and torque ripple for on-line PM demagnetization detection by using the multi-sensor information fusion method. Both noise and torque signals are first analyzed and processed by wavelet transforms for de-noising and feature value extraction. Moreover, multi-sensor information fusion is applied to estimate the demagnetization ratio based on the support vector machine (SVM) training set. The proposed demagnetization detection approach is experimentally verified on a laboratory PMSM and compared with single-sensor detection method. II.Multi-Sensors Information Fusion Multi-sensors information fusion technology is based on the idea that sensors with different information have complementary characteristics and results in more accurate estimation than a single source. The multi-sensors fusion method can effectively improve the robustness of diagnostic decision-making. The information can be fused at different levels such as signal-level, feature-level and decision-level. For a medium-sized permanent magnet synchronous machine (PMSM) in electric vehicle (EV), there is not much choice in terms of sensor accuracy or feature extraction. So, in this paper, decision-level fusion is more suitable and efficient and hence a human artificial network based fusion method is implemented. III.Multi-Sensors Information Fusion Based Demagnetization Detection During motor operation, the rotor magnet demagnetization distorts the magnetic flux distribution resulting in noise, vibrations and torque ripple in the machine. In order to use those multi-source information as the demagnetization indexes, a demagnetization detection model is proposed and shown in Fig. 1(a). The detailed procedure is explained as follows. A. Signal Pre-process The measured noise and torque from individual sensors are non-stationary and are generally disturbed by the noises from inverter and flux linkage harmonics. To eliminate or reduce those electromagnetic noises and interferences, the initial signals should be filtered first. The example of torque measurement processing is shown inFig.1 (b). B. Feature Extraction Power spectral density (PSD) is chosen as the characteristic which shows the strength of the variations as a function of frequency and calculated according to (1), where $R_X(\tau)$ is the auto-correlation function. The example of torque PSD is shown in Fig. 2(a). C. Initial Demagnetization Diagnosis via Individual Sensor The process of individual sensor classification can be implemented by support vector machine based on LIBSVM algorithm. In order to analyze the ability of classification association, the training sample set for the rotor demagnetization is divided into three types: health, demagnetization 1 (17% magnets loss) and demagnetization 2 (33% magnets loss). The data samples are first transformed to [-1,1] through scaling transformation, and then optimal penalty factor C and parameter γ of the kernel function is optimized by performing grid search. The posterior probability of each classifier can be determined according to (2), where $p_i(x)$ is the normalized posterior probability of x to the i^{th} class. D. Fusion analysis After the posterior probability of each classifier is combined to construct the decision profile for decision-level fusion, a BP NN is applied for decision-level making based on the decision profile. Then the demagnetization detection results are diag nosed consistently with the corresponding decision rules. IV.Demagnetization Detection Model Validation A laboratory 12.5 kW PMSM shown in Fig. 2(b), with rated torque of 50 Nm and rated speed of 3,000 rpm, is employed for validating the performance of the proposed method. The test motor was demagnetized by increasing the motor internal temperature through long period of operation. After a series of testing, a look-up table has been established, based on which the PM demagnetization ratios can be referred to the relevant motor internal temperature. By applying the proposed method, the SVM result is shown in Fig. 2(c), and the demagnetization result can be estimated from decision-level fusion. Fig. 2(d) shows the BPNN training performance. More results will be shown in the full paper. V.Conclusion This paper presents a non-invasive approach to detect the PM demagnetization based on multi-sensor fusion. Two sensors information are measured to evaluate the rotor flux linkage individually at first. Then fusion method is employed to detect the PM demagnetization at the decision-level. The experimental results have demonstrated that the detection accuracy is significantly improved by fusing the individual detection on decision-level compared with single sensor methods. If there is a priori knowledge of demagnetization, detection can be achieved without the need for data fusion. However, due to the complexity of the motor, many environmental conditions affect the certainty of the diagnosis. Therefore, under constant load condition, the diagnostic accuracy can be achieved up to 100%, while under variable load conditions, the diagnostic accuracy drops to 90.24%.

BU-01. PLD-fabricated Nd-Fe-B film magnets on Si substrates with Si oxide layer.

Y. Yamaguchi[1], D. Shimizu[1], A. Yamashita[1], T. Yanai[1], M. Nakano[1] and H. Fukunaga[1]
1. Nagasaki University, Nagasaki, Japan

Although a sputtering method is one of promising methods to obtain an anisotropic Nd-Fe-B film magnet on a Si substrate with a Ta buffer layer [1][2], the maximum thickness of the films is mainly 20 microns because peeling phenomenon occurred during a deposition or an annealing process, and an increase in thickness is required in order to apply them to various miniaturized devices. On the other hand, we reported an isotropic Nd-Fe-B film magnet deposited on a Si substrate with a 500 nm-thick thermal oxide layer using PLD (Pulsed Laser Deposition) method and succeeded in enhancing the thickness up to approximately160 microns [3]. In our previous experiment, the exfoliation of a Nd-Fe-B film couldn't be confirmed and mechanical destruction occurred from the inside of a Si substrate. In this report, we investigated the adhesion between a PLD-fabricated Nd-Fe-B film and a Si substrate with a Si oxide layer such as a natural and a thermal oxide one. It was clarified that the sufficient thickness of the oxide layer is indispensable to avoid the peeling phenomenon. We also paid attention that a glass has an intermediate thermal expansion coefficient (10.0×10^{-6} K^{-1}) between a Si substrate (2.6×10^{-6} K^{-1}) and a $Nd_2Fe_{14}B$ phase (14.7×10^{-6} K^{-1}), and therefore the fabrication of a thick glass film instead of the use of a Si oxide layer was carried out. Resultantly, we could improve the magnetic properties of a Nd-Fe-B film deposited on a Si substrate. A rotated target was ablated using a Nd-YAG pulse laser (wave length=355 nm, frequency : 30 Hz) in the vacuum atmosphere of approximately 10^{-5} Pa. The deposition of a Nd-Fe-B film magnet on a Si substrate was carried out using a $Nd_XFe_{14}B$ (X=2.0~3.5) target. Four Si substrates with a 1 nm-thick natural oxide layer together with three thermal oxide layers with the thickness 20, 100 and 500 nm, respectively, were used. Moreover, in order to prepare a glass film on a Si substrate using a Nd-YAG pulse laser in the vacuum atmosphere, a glass plate on a bulk metal was used as a target. The glass film was deposited followed by a Nd-Fe-B film on a Si substrate. A flash annealing (PA) method followed the deposition to crystallize an as-deposited Nd-Fe-B film with amorphous structure. The magnetic properties of the samples were measured with a vibrating sample magnetometer (VSM) under the maximum applied magnetic field of 2.5 T after magnetizing each sample with a pulsed magnetic field of 7 T. All the films had isotropic magnetic properties, therefore in-plane ones were only shown in the paper. The thickness of each film was measured with a micrometer or estimated by measuring each weight. The compositions of glass films together with Pr-Fe-B films was analyzed with an X-ray photoelectron spectroscopy (XPS) and an energy dispersive X-ray spectrometry (EDX), respectively. Figure 1 shows the obtained maximum thickness of PLD-fabricated Nd-Fe-B film magnets without mechanical destruction deposited on Si substrates with various thicknesses of Si oxide layers. Here, Nd content (Nd / (Nd + Fe)) in each Nd-Fe-B film was fixed at approximately 20 at. %. As the thickness of the oxide layer increased, the thickness of the film magnets could be enhanced after an annealing process. In addition, the peeling of a Nd-Fe-B film occurred in the case of each Si substrate with a natural oxide together with a 20 or 100 nm-thick thermal oxide klayer. On the other hand, mechanical destruction from the inside of a Si substrate was always observed as the thickness of a Si oxide layer became 500 nm. It is considered that the dependence of the thickness of an oxide layer on the adhesion is attributed to the existence of a Fe-Si-O compound. We have already reported that an increase in Nd contents of a Nd-Fe-B film compared with a stoichiometric composition enabled us to enhance the thickness of the film deposited on a Si substrate without a mechanical destruction [3]. The phenomenon is considered to be attributed that Nd element precipitated around a Nd_2Fe_4B grain boundary has an intermediate linear expansion coefficient between a Si and a $Nd_2Fe_{14}B$ phase. On the other hand, the reduction in Nd contents of a Nd-Fe-B film is required because a large amount of Nd degraded the values of residual magnetization and $(BH)_{max}$. Here, we focused on the linear expansion coefficient of glass and prepared a glass film with the thickness range from 20 to 130 microns, which is thicker than that of the previously mentioned thermal Si oxide layers. Figure 2 shows the M-H loops of two Nd-Fe-B films deposited on each Si substrate with a 500 nm thick thermal oxide layer and a 64 µm-thick glass film, respectively. The thicknesses of the both Nd-Fe-B films were almost 60 µm. It was clarified that the use of a thick glass film is effective to decrease the Nd amount and $(BH)_{max}$ value of a Nd-Fe-B film deposited on a Si substrate could be improved by approximately 20 kJ/m^3.

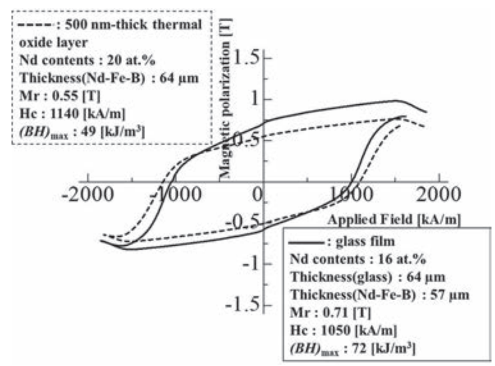

Fig. 2. Two M-H loops of Nd-Fe-B films deposited on each Si substrate with a 500 nm thick thermal oxide layer and a 64 µm-thick glass film, respectively. The use of a glass film enabled us to enhance the values of residual magnetization and $(BH)_{max}$.

BU-02. Increase in nucleation field of nanocrystalline Nd-Fe-B magnets due to strengthening of exchange interaction - computer simulation –.

T. Harada[1], T. Yanai[1], M. Nakano[1] and H. Fukunaga[1]
1. Nagasaki University, Nagasaki, Japan

An improvement in coercivity H_c is strongly needed for N-Fe-B magnets, because their H_c values deteriorate remarkably at high temperatures and this deterioration raises difficulty in their applications at high temperatures. As H_c is affected by a microstructure of a magnet, effects of microstructures on H_c have been reported. Previously, we carried out micromagnetic simulation of demagnetization process for nanocrystalline Nd-Fe-B magnets with non-magnetic inclusions with varying the size of the inclusions and reported that the nucleation field H_N is affected by not only the strength of local demagnetizing field but also the spatial size of the region where the local demagnetizing field exists [1]. It was also clarified that the nucleation of the reversal domain occurs when the above size exceeds a critical value depending on the exchange length, L_{ex} (= $\sqrt{(A/K_u)}$), where A and K_u are the exchange stiffness coefficient and the anisotropy constant, respectively. The above results strongly suggest that A as well as K_u affect H_N. In this contribution, the effect of A on H_N was investigated with varying temperature for nanocrystalline Nd-(Fe,Co)-B magnets by computer simulation, and it was found that strengthening of A effectively increases H_N of nanocrystalline Nd-Fe-B magnets. The simulation model was shown in the inset of Fig.1. We assumed a model magnet composed of $Nd_2Fe_{14}B$ grains (48 or 96 nm in size), a tetrahedral non-magnetic multi-junction phase, and non-magnetic grain boundary phase covering the $Nd_2Fe_{14}B$ grain. The periodic condition was adopted for three directions, and resultantly a tetrahedral non-magnetic multi-junction phase contacts with neighboring four $Nd_2Fe_{14}B$ grains. The grain was divided into 64×64×64 cubic elements, and micromagnetic simulation of demagnetization process was carried out with varying A, the size of the tetrahedral non-magnetic multi-junction phase, T, and temperature. Details of the calculation method were described elsewhere [1]. The non-magnetic multi-junction generated a local demagnetizing field and H_N decreased with increasing T. The calculated decrease in H_N corresponds to the increase in the effective demagnetizing factor N_{eff}, because H_N is described as $H_N = aH_A - N_{eff} J_s / \mu_0$ [2], where a, H_A, J_s, and m_0 were the microstructure factor, the anisotropy field, the saturation polarization, and the permeability of vacuum, respectively. Therefore, we calculated N_{eff} with varying T, L and temperature, and the results are shown in Fig.1 as a function of T/L_{ex}. As seen in the figure, N_{eff} was plotted on one curve independently of L and temperature, and increased with the increase in T/L_{ex}. The increase in N_{eff} corresponds to the decrease in H_N. This result clearly suggests that the effect of demagnetizing field is determined by the ratio of T and L_{ex}, and that the effect of demagnetizing field can be suppressed by decreasing T/L_{ex}. Therefore, for fixed T and K_u values, an increase in A is expected to decrease N_{eff} and resultantly to increase H_N. To confirm the above idea, H_N was calculated for the model Nd-Fe-B magnet with L = 96 nm, T = 60 nm and K_u = 4.5 MJ/m^3 with varying A. Consequently, it was confirmed that the increase in A from 8.7 to 17.4 pJ/m results in the increase in H_N from 4.46 to 4.82 MA/m. The above results strongly suggest that the enhancement in the exchange interaction is one of effective methods for improving H_N of Nd-Fe-B magnets composed of fine grains. The replacement of Fe with Co is effective in increasing A and it has been reported the replacement up to 10 at. % does not decrease K_u remarkably [3]. Therefore, we simulated H_N for the magnet composed of $Nd_2(Fe_{0.9}Co_{0.1})_{14}B$. Figure 2 shows H_N and N_{eff} for L = 96 nm and T = 60 nm as a function of temperature. H_N is reduced by the anisotropy field H_A. It is clearly seen that the replacement decreases N_{eff} and increases H_N/H_A. In conclusion, strengthening of the exchange interaction is effective in increasing H_N and resultantly improving H_c.

I. INTRODUCTION The hot deformed Nd–Fe–B permanent magnets have drawn widely attention due to their high magnetic performance[1]. It is important to understand the relevance between the local magnetic properties and the local orientation texture features in hot deformed Nd–Fe–B magnets. Detailed investigation have revealed that its magnetic performance was inhomogeneous along axial directions which are parallel with the press directions[2]. However, the systematic investigations on the inhomogeneities of the magnetic performance in hot deformed Nd–Fe–B bulk permanent magnet along the radial directions are insufficient. In this paper, hot deformed Nd–Fe–B bulk magnets have been prepared by spark plasma sintering (SPS) method. The relationship between magnetic properties and inhomogeneities of orientation texture in the different locations along radial directions in hot deformed Nd–Fe–B magnet has been investigated. II. EXPERIMENTS Commercial Nd–Fe–B magnetic powders (MQP-F) were used as initial materials. The magnetic powders were poured into a tungsten carbide (WC) mold and fast consolidated into columnar samples by using the spark plasma sintering (SPS) method. The temperature and pressure of sintering were 650°C and 500 MPa, respectively. The size of compaction isotropic magnet is 7.5 mm in radius and 15 mm in height. After compaction, the columnar samples were hot-deformed into disc-shaped samples with a height reduction of 60% via SPS in 750°C. The size of final anisotropic bulk magnet is 12 mm in radius and 6 mm in height. From the hot-deformed magnet, three samples were selected by their distances to the center in radial directions, named "center region", "subcenter region", and "edge region". The crystal structure and microstructure were characterized by X-ray diffractometry (XRD, Bruker D8 ADVANCE) and scanning electron microscopy (SEM, FEI NANO200), respectively. The magnetic properties at room temperature were measured by vibrating sample magnetometry (VSM, Lakeshore 7410) with a magnetic field up to 30 kOe. The electron back-scattered diffraction (EBSD) measurements were performed using a high-speed detector (EDAX Hikari camera) incorporated in the scanning electron microscope. III. RUSULTS AND DISSUSION XRD patterns of the three samples are shown in Fig. 1(a). The magnets were examined with the surface perpendicular to the radial direction of the disc. All diffraction peaks could be indexed to the standard patterns of $Nd_2Fe_{14}B$. The intensity ratios of (0 0 6) and (1 0 5) peaks which indicate the degree of texture of c-axis crystallographic alignment are 3.13, 1.90 and 0.66 for "center region", "subcenter region" and "edge region" magnet, respectively. The XRD patterns of the "edge region" are similar to that of the isotropic magnets. However, the intensity ratio is obviously increased in the "center region". The changes of intensity ratios reveal that the degree of crystal alignment along the easy c-axis is different in the various locations of radial directions. The magnetic hysteresis loops of the three samples are shown in Fig. 1(b). For all samples, the high remanence ratio indicates that c-axis texture forms throughout the whole sample via hot deformation, leading to strong magnetic anisotropy in the entire magnet. However, the maximum energy product sharply increases to 43.72 MGOe, while coercivity slightly decreases to 12.06 kOe from the edge to the center along the radial direction, which illustrates that the magnetic performances are heterogeneous at different locations in the bulk magnet. The quantitative texture analysis is carried out based on the calculation of pole figure (PF) and inverse pole figure (IPF) of the normal direction (ND). Fig. 2 shows the {001} PFs and the IPFs obtained from the EBSD data of the three samples. The maximum intensities of the "center region" sample is the highest which is approximately 48.0 MRD (Multiple of a Random Distribution) in PF and 47.7 MRD in IPF, while those of the "edge region" sample are the lowest. The low MRD values suggest a weak texture in the sample. IV. CONCLUSION In summary, anisotropic Nd–Fe–B magnets were prepared by hot deformation methods. The hot deformed permanent magnets exhibit inhomogeous magnetic performance in radial directions along which the maximum energy product increases obviously from the "edge" to the "center", while coercivity decreases slightly. The XRD and EBSD characterizations suggest that the enhanced c-axis texture in "center region" results in the stronger magnetic anisotropy and increased maximum energy product.

It is well known that the magnetic properties of Nd-Fe-B sintered magnets are microstructural sensitive. Post-sintered annealing is an important process to improve magnetic properties, and appropriate post-sintered annealing can effectively enhance coercivity without HRE elements introduction[1-4]. So, many researches have been carried out to explain the change in coercivity during the post-sintered annealing in order to further improve coercivity, including the evolution of rare earth oxides [1, 2]and Cu-rich phase[3, 4]. Ambient pressure has huge influence on the microstructure, but the relationship of ambient pressure between microstructure and magnetic properties has never been revealed. Therefore, it is meaningful to investigate the effect of ambient pressure on microstructure and magnetic properties. The original magnets with the nominal composition of $Nd_{31.5}Fe_{bal}B_{0.91}Cu_{0.2}$ (wt. %) was prepared by traditional metallurgy route. As shown in Fig. 1(a), the as-sintered magnets were divided into two groups, one group was annealed at 900 °C for 2 h in 0.2 MPa Ar atmosphere, marked as Sample A, while another group treated in vacuum, marked as Sample B, then two groups both annealed at 500 °C for 2 h. Fig. 1(b) shows the demagnetization curves of Sample A & B. It can be clearly seen that the coercivity of the Sample A, 10.79 kOe, is 0.51 kOe higher than that of Sample B, 10.28 kOe, without any difference of remanence. Fig. 2 expresses the secondary electron (SE) SEM images of the magnets surface. From the Fig. 2(a), we can find that the $Nd_2Fe_{14}B$ grains are still obviously visible and a small amount of granular material appears on the grains. Moreover, we can distinguish that the granular material is agglutinated with another phase. On the contrary, in Fig. 2(b), the whole magnet surface of Sample B is wrapped by a newly formed phase and no distinct $Nd_2Fe_{14}B$ grains can be found. According to the EDS analysis (not show here), the chemical composition of the granular matter and surrounding gelatinosa matter is closed to NdO and $Nd_6Fe_{13}Cu$. These two phases are common part of the grain boundary phase, so we can conclude that the grain boundary phase volatilize during 1st post-sintered annealing and the higher ambient pressure is beneficial to suppress the volatilization. Furthermore, the relationship between the quantity of volatilization, microstructure and magnetic properties is comprehensively investigated.

High thermal stability and enhanced coercivity (H_{ci}) of sintered Nd-Fe-B permanent magnets have attracted a lot of research interest driven by the demand for motor applications in hybrid electric vehicles (HEV) and generators such as wind turbines. The heavy rare earth (HRE) Tb and Dy substitution for Nd has been developed as a common method for the H_{ci} enhancement, but it leads to the decrease in magnetization saturation and their criticality impedes the application in the long term. To solve the problem, grain boundary diffusion process (GBDP) has been developed as a more efficient method. By GBDP, the grains were magnetically hardened by the $(Nd,HRE)_2Fe_{14}B$ shell with higher anisotropy field and the surface region was magnetically hardened by such grains. However, the high amount of Tb in the outermost surface grains lead to the substantially reduced remanence compared to the initial state prior to GBDP and thus has to be removed. To improve HRE efficiency, a method to reduce the Tb enrichment in the near surface region without detrimental effect on H_{ci} is desired. In this study, the influence of TbH_2 powder GBDP with Al powder aiding (TbH_2-Al) through dip-coating 30 at.%TbH_2 and 70 at.% Al in alcohol on the magnetic properties and the microstructure of sintered Nd-Fe-B magnets were investigated. The H_{ci} was enhanced from 13.70kOe to 22.26 kOe and 23.29 kOe for the magnets GBDP by TbH_2 and TbH_2-Al, respectively, as shown in Fig. 1(a). The increase in H_{ci} enhancement with Al aiding was 1.03 kOe though the TbH_2 amount in the source was reduced. The distribution of Tb concentrations of the GBDP magnets versus depth are shown in Fig. 1 (b). For both the TbH_2 and TbH_2-Al GBDP magnets, Tb concentrations in the near surface area were higher than that in the inner area. The accumulation of Tb in the near-surface region was substantially reduced with Al aiding. The improved H_{ci} enhancement and the reduced accumulation in the near surface region indicate highly effective GBDP by TbH_2 with Al aiding. Compared to the microstructure of a typical sintered Nd-Fe-B magnets GBDP by TbH_2 as shown in Fig.2(a) which consist of $(Nd,Tb)_2Fe_{14}B$ shell and the less visible grain boundary phases (GBs), the TbH_2-Al GBDP magnets exhibit distinct differences. First, the grains are surrounded by the uniform Nd-rich phase along the GB. Secondly, the thickness of the shell structure was reduced. Analysis of the domain pattern by Kerr microscopy combined with the uniform Nd-rich phase along the GB and the core-shell structure is of importance for the understanding of the mechanism for H_{ci} enhancement. The Al and Tb distribution in the grains and the GBs is helpful for understanding the phase evolution during GBDP by SEM with EDS and TEM.

Due to the excellent magnetic properties of Nd-Fe-B magnets, the usage of the magnets has been spread in various applications, such as sensors, motors and generators. However, because of the poor thermal stability of $Nd_2Fe_{14}B$ magnets, the expansion of application field is largely limited. The most effective ways to solve this problem are considered to be the additions of Co or heavy rare earth (HRE) elements of Dy or Tb to increase the Curie temperature or coercivity of magnets, respectively. However, the cost of the magnets would be increased because of the scarcity and shortage crisis of Co and RE elements. Besides, the excessive addition of Co elements will deteriorate the magnetic properties. So at present days, the enhancement of coercivity is considered to be the most popular methods to optimize the thermal stability. For now, the optimization of grain boundary is the most economically feasible method, such as grain boundary diffusion process, to obtain high coercivity magnets without abundant usage of HRe. In hot-deformed Nd-Fe-B magnets, the coercivity of magnets could be largely enhanced by covering low eutectic RE-rich alloys and then annealing. However, in this way, the remanence and maximum energy product are decreased simultaneously. In this paper, the melt spun powders mixed with $Pr_{70}Cu_{30}$ powders are hot pressed to obtain fully density precursor. And then the hot-deformed magnet is obtained by die-upset process with a height reduction of 70%. The coercivity of the magnets with 1 wt.% and 2 wt.% $Pr_{70}Cu_{30}$ addition is 20.3 and 22.7 kOe while the remanence is 13.45 and 13.32 kGs, respectively. The coercivity and remanence coefficients of temperature of the specimen with 2 wt.% $Pr_{70}Cu_{30}$ addition are β=-0.537%/^{o}C and α=-0.108 %/^{o}C slightly better than that of sintered HRe-free magnets which are β=-0.617%/^{o}C and α=-0.12 %/^{o}C. The irreversible flux losses of the hot-deformed magnets and sintered magnets with and without HRe are also obtained as shown in Fig.1. It can be seen that the irreversible flux loss of the hot-deformed magnets with Pr-Cu addition is comparable to that of sintered-HRe magnets while is much better than that of sintere-HRe free magnets. In order to analysis the thermal stability of the hot-deformed magnets with Pr-Cu addition, the temperature dependence of magnetic domain structure is also carried out using the Magneto-optic Kerr microscope.

BU-07. Enhanced coercivity of Nd-Ce-Y-Fe-B sintered magnets by adding (Pr, Nd)-H powders.

B. Peng[1], Y. Liu[1], J. Jin[1] and M. Yan[1]
1. Department of Materials Science and Engineering, Zhejiang Unviersity, Hangzhou, China

Incorporating cheaper and more abundant rare earth (RE) elements Ce, La or Y into the Nd-Fe-B based magnets has stimulated considerable research efforts [1-2]. Among them, one promising candidate is the Y/Ce co-substituted Nd-Ce-Y-Fe-B sintered magnet, for which the Y-rich 2:14:1 phase with positive temperature coefficient of magnetocrystalline anisotropy can improve the thermal stability of magnetic properties. However, the inferior anisotropic field (H_A) of $Ce_2Fe_{14}B$ and $Y_2Fe_{14}B$ to $Nd_2Fe_{14}B$ leads to low coercivity of the Nd-Ce-Y-Fe-B magnets when Y/Ce substitution for Pr/Nd exceeds 25 wt%. To further enhance the coercivity, in this work, $(Pr_{20}Nd_{80})$-H_x powders were introduced into the $(Nd,Pr)_{22.8}(Y,Ce)_{7.7}Fe_{bal}B_1$ sintered magnets. Fig. 1 shows the room temperature coercivity H_{cj} and remanence B_r for the starting Y/Ce co-substituted magnet and the magnets added with 1, 2 and 3 wt% (Pr, Nd)-H powders, respectively. The coercivity can be effectively enhanced with the increase of (Pr, Nd)-H powders amount, for example, H_{cj} is 10.3 kOe when added with 3 wt% (Pr, Nd)-H, which is 10.8% higher than that for the starting magnet. The coercivity increment is accompanied with very slight reduction in B_r and $(BH)_{max}$. After (Pr, Nd)-H powders is added, the intergranular RE-rich phase becomes clearer and more continuous when compared to the starting magnet, isolating well the adjacent grains. As shown in Fig.2, the grain boundary layer is ~10 nm, which may play an important role to decouple the adjacent 2:14:1 phase grains during magnetization reversal. Meanwhile, the dehydrogenation of (Pr, Nd)-H during sintering promotes the diffusion of Nd and Pr towards the 2:14:1 phase grains. The formation of (Nd, Pr)-rich shell with locally enhanced magnetocrystalline anisotropy also contributes to the coercivity enhancement.

BU-08. Spin reorientation, magnetic viscosity and exchange coupling effects of the Nd-Ce-Fe-B sintered magnets prepared by single-main-phase and dual-main-phase alloy methods.

Z. Jiang[1], *Y. Fang*[1], R. Han[1], T. Liu[1], M. Zhu[1] and W. Li[1]
1. Functional Materials Research Institute, Central Iron and Steel Research Institute, Beijing, China

Introduction Achievement of high performance Nd-Fe-B magnets is highly dependent on Nd and Pr elements, which are only occupied small quantity in the natural rare earth resources. From commercial and resource utilization consideration, low cost compounds with tolerable less or same magnetic properties are generally welcomed. Ce element, which is abundant in rare earth ore, is considered as a potential substitute [1-3]. In 1991, D. Li *et al.*[2] reported magnetic properties of $(Ce_{1-x}Nd_x)_{13.5}(Fe,Co,Si,)_{80}B_{6.5}$ sintered magnets. Zhou *et al.* [3] have investigated the influence of Si, Co and didymium oxide on the magnetic properties of 40%Ce-50%Nd-10%Pr magnets. These previous magnets were prepared by a single-main-phase alloy method. Recently, Zhu *et al.*[4] have reported $(Nd_{0.7}Ce_{0.3})(Fe,TM)_{bal}B$ sintered magnets with the maximum energy product of over 43 MGOe by a dual-main-phase alloy method. More recently, Susner *et al.*[5] have discussed Ce-substituted $Nd_2Fe_{14}B$ single crystals, showing only small decrease with increasing Ce content in intrinsic magnetic properties. To further reveal the influence of Ce on the magnetic properties of Nd-Ce-Fe-B sintered magnets, the temperature dependence of magnetic properties were investigated systematically, especial for a wide temperature range from 50K to 360K. The effect of heat-treatment conditions on the magnetic properties (spin reorientation, magnetic viscosity, exchange coupling) were discussed for the magnets prepared by single-main-phase alloy method and dual-main-phase alloy method as well. Experimental Magnets with nominal composition of $(Nd_{0.8}Ce_{0.2})_{30}(Fe,TM)_{69}B_1$ were prepared by single-main-phase (SMP) alloy method and dual-main-phase (DMP) alloy method [4], respectively. In order to reveal the effect of annealing process on the magnetic properties of the magnets, two kinds of specimens were fabricated. One was as-sintered magnet only sintered at 1323K for 2h, the other was tempering magnet, which was obtained for the as-sintered magnet tempered at 773K for 2-5h. Magnetic measurements were performed using Physical Property Measurement System with the maximum field of 9T. Results and Discussion The temperature dependence of magnetic properties of the SMP and DMP specimens were measured in the range of 60K to 360K for the as-sintered and tempering states (Fig.1). The saturation magnetization M_s and remanent magnetization M_r of all the specimens decreases gradually with increasing temperature. Moreover, the M_s and M_r of the as-sintered specimens are more than that of tempering one whatever it is SMP or DMP method. As shown in Fig.1(b), It is found that the curves take on peak around 100K, indicating an abnormal temperature coefficient of M_r, which is related to be the spin orientation discussed bellow. For intrinsic coercivity H_{cj}, it show different story. As for SMP specimen, the as-sintered one shows higher H_{cj} than that of the tempering one. However, for DMP specimen the as-sintered state has lower H_{cj} comparing to tempering state. Taking the room temperature H_{cj} as example, from as-sintered to tempering state, H_{cj} decreases from 7.51 to 3.90kOe for SMP specimens, and increases from 4.96 to 7.34kOe for DMP specimens. The enhanced coercivity for the DMP tempering state specimen maybe due to the smooth transition between grains to intergranular phase reduced the exchange coupling interaction between the matrix grains with different magnetocrystalline anisotropic field. The temperature dependence of ac susceptibility χ_{ac} of the specimens with perpendicular c-axis direction was shown in Fig. 2. The χ_{ac} peak represents minimum magnetocrystalline anisotropy. It is the temperature of easy-magnetization direction turning point, or spin reorientation temperature (T_{sr})[7]. The anomalies in the χ_{ac} curves reflect T_{sr}. Compared the specimens prepared in different methods, the T_{sr} of SMP specimens is about 80K, while the T_{sr} of DMP specimens is relatively higher, about 90K, indicating that the anisotropy field of the specimens has changed, and their grains real composition should be different. The SMP specimens should make a cerium substitution of Nd in the Nd-Fe-B main phase. Time dependence of the magnetization was furthor investigated. The specimens are kept in an magnetic field H_0 equal to H_{cj} for 2400 seconds. Time dependent of magnetization follows the expression $M(t)=M_0-S\,ln(t+t_0)$, where S is the magnetic viscosity parameter, M_0 a constant and t_0 a fitting parameter to establish a reference time. From 0 to 120 seconds, the M/M_0 curves show a non-linear change, indicating that the M rapidly decreases at the initial stage of time and then reaches a steady state. The magnetic viscosity parameter of DMP as-sintered specimens is the highest among the specimens, which is 4.23emu/(g.s); while DMP tempering specimen is only 2.07 emu/(g.s), indicating that tempering reduces magnetic viscosity, which is related to exchange coupling interaction between grains. Conclusions Magnetic measurements indicate that the M_s and M_r represent different temperature dependence comparing to intrinsic coercivity H_{cj} for SMP and DMP specimens. The ac susceptibility χ_{ac} investigation shows that the spin reorientation changes from 80K in SMP specimens to 90K in DMP specimens, which is lower than Nd-Fe-B sintered magnets. Moreover, the magnetic viscosity characterization indicates that tempering could reduce exchange coupling interaction between grains.

Recently, the abundant and inexpensive RE elements like La and Ce have been employed for developing high performance/price permanent magnets. Ce is the only RE element which not only has trivalent (3^+) $4f^1$ and tetravalent (4^+) $4f^0$ electronic states but also exhibits phases with enormous (15-17%) volume differences[1, 2]. Although the intrinsic magnetic properties of $Ce_2Fe_{14}B$ are inferior to those of $Nd_2Fe_{14}B$, they are sufficient for producing the magnets with hard magnetic properties higher than ferrites. Herbst[3] et al. obtained the appropriate magnetic properties in melt spun $Ce_{17}Fe_{78}B_6$ alloy with intrinsic coercivity ${}_iH_c$=429.9 kA/m, remanence J_r=0.49 T, and energy product $(BH)_{max}$=33 kJ/m^3. To further improve their performance, it is essential to modify the composition, control the phase constitution, and refine the microstructure. Our previous work suggested that in ternary Ce-Fe-B alloy, $Ce_2Fe_{14}B$ phase precipitates first during rapid quenching, while α-Fe phase precipitates first from the amorphous matrix during annealing[4]. The $CeFe_2$ phase behaves as a soft magnetic phase below 230(±2) K[5] and its presence is thought to be harmful to the hard magnetic properties but beneficial to the wettability of 2:14:1 phase when the magnets are sintered [6]. For composition modification, Co substitution for Fe was used to increase the curie temperature T_c of $Ce_2Fe_{14}B$ phase[7]. Zr, Hf doping could refine grain size and optimize the microstructure. Jiang et al. [8] reported that Ga doping could also improve the magnetic properties and curie temperature (T_c) attributed to the increase of Ce^{3+} ratio. On the other hand, another transition metal Ta has been frequently employed in soft magnetic materials for improving thermal stability and glass formability. However, the effects of Ta doping on the structure and magnetic properties of RE-Fe-B alloys received little attention. Liu et al.[9] showed that Ta plays an important role in producing an appropriate combination of magnetic properties in $Nd_9Fe_{86-x}Ta_xB_5$ alloys. In this work, the effects of Ta element doping and Ce reduction on the phase constitution, microstructure and magnetic properties of melt spun $Ce_{17}Fe_{78}B_6$ alloy were systematically investigated. The XRD refinement results for the optimized $Ce_{17-y}Fe_{78-x+y}Ta_xB_6$ alloys indicate that the alloys composed of $Ce_2Fe_{14}B$ phase and $CeFe_2$ phase. With the Ta substitution for Fe, the lattice constants *a* and *c* of 2:14:1 phase keep constant, but a decreasing trend is observed for grain size of 2:14:1. The volume fraction of $CeFe_2$ phase decreases by reducing Ce content in $Ce_{17-y}Fe_{77.25+y}Ta_{0.75}B_6$ alloys and only 2:14:1 phase can be detected in y=5 alloy. The *x* dependent magnetic properties are shown in Fig. 1. The highest H_c of 553 kA/m obtained in $Ce_{17}Fe_{77.25}Ta_{0.75}B_6$ alloy is attributed to the increase of RE/Fe ratio and the grain refinement. Further substitution of Fe by Ta deteriorates the magnetic properties perhaps due to the formation of an unknown phase. The deterioration of thermal stability (temperature coefficient of coercivity β and temperature coefficient of coercivity α) is observed in the Ta substituted alloys in the temperature range between 300 K and 400 K, which is inconsistent with the effects shown in Ta substituted (Nd,Dy)-(Fe,Co)-B alloys reported by Chin et al.[10].The reason could be attributed to the decreasing Curie temperature T_c from 424 K for x=0 alloy to 416 K for x=0.75 alloy. As Ta element does not enter 2:14:1 phase, the decrease of T_c might because of the increase of vacancies in the Fe sublattices for higher Ce content and low Fe content reported by Li et al.[11]. By reducing the Ce content in the $Ce_{17-y}Fe_{77.25+y}Ta_{0.75}B_6$ alloys, H_c value decreased monotonously, but the remanence (J_r) was significantly enhanced by increasing Fe content, as shown in Fig. 2. The H_c value of y=5 alloy is quite low since the decoupling effect between $Ce_2Fe_{14}B$ grains was weakened due to its low amount of intergranular phase. As a result, good magnetic properties i.e. H_c=514 kA/m, J_r=0.49 T, $(BH)_{max}$=36 kJ/m^3 and 448 kA/m, 0.54 T, 41 kJ/m^3 were obtained in the $Ce_{15}Fe_{79.25}Ta_{0.75}B_6$ and $Ce_{14}Fe_{80.25}Ta_{0.75}B_6$ alloys, respectively, which are superior to those of recently reported $Ce_{17}Fe_{78-x}M_xB_6$ (Zr, Ga and Hf) alloys. The present work shows that a minor substitution of Ta could further improve the magnetic properties of Ce-Fe-B alloys, which is beneficial for composition design.

$Nd_2Fe_{14}B$-type magnets have attracted considerable attention and widely used in many fields due to the highest magnetic energy product ($(BH)_{max}$) among all the developed permanent magnetic materials. The hot deformation method is a potential and simple method to obtain anisotropic Nd-Fe-B magnets with high $(BH)_{max}$ [1]. However, the intrinsic coercivity ($_iH_c$) of hot-doformed Dy-free Nd-Fe-B magnets is normally smaller than 15 kOe, $_iH_c$ enhancement is crucial and necessary for the applications at high temperature. In order to enhance the coercivity, a noticeable amount of heavy rare earth (HRE) element, such as Dy or Tb, is added to obtain $(Nd, HRE)_2Fe_{14}B$ phase with a higher magnetocrystalline anisotropy field (H_a) [2]. In addition, Ga addition into the hot deformed magnets is also effective in coercivity enhancement [3]. In this work, $R_{80}Ga_{20}$ (R=Pr, Dy and Tb) alloy powders were adopted to be mixed with the commercial NdFeB MQU-F powders as the raw material to make hot deformed NdFeB magnets for the purpose of improving the coercivity especially. $R_{80}Ga_{20}$ (R = Pr, Dy, and Tb) alloys powders were prepared by arc-melting and subsequently melt spun at wheel speed of 30 m/s. Two weight % of the crushed $R_{80}Ga_{20}$ powders with size of about 200 μm were mixed with the commercial NdFeB MQU-F powders. The as-mixed powders were pressed at 650 °C under 250 MPa in vacuum to form a dense disk, and then deformed at 810 °C under 100 MPa with 70% reduction in thickness. Furthermore, the hot deformed magnets were post-annealed at various temperatures for 2 hours to optimize the microstructure and magnetic properties. The magnetic properties were measured by a B-H loop tracer. To understand phase distribution and microstructure, X-ray diffraction (XRD), scanning electron microscopy (SEM), and transmission electron microscopy (TEM) were employed, respectively. Magnetic properties of the hot deformed NdFeB magnets by doping $R_{80}Ga_{20}$ (R=Pr, Dy and Tb) powders are studied. As shown in Fig. 1(a), the magnet made from pure MQU-F powder exhibits good magnetic properties of remanence (B_r) = 13.0 kG, $_iH_c$ = 15.0 kOe, and $(BH)_{max}$ = 41.5 MGOe. Coercivity are enhanced by doping $R_{80}Ga_{20}$ (R=Pr, Dy and Tb) powders. Coercivity enhancement (Δ_iH_c) of the magnets doped with $R_{80}Ga_{20}$ (R=Pr, Dy and Tb) powders is highly related to H_a of $R_2Fe_{14}B$ phase. For hot deformed $Pr_{80}Ga_{20}$ and $Dy_{80}Ga_{20}$-doped magnet followed by 600 °C annealing, Δ_iH_c are 2.2 kOe and 2.7 kOe, respectively, but B_r and $(BH)_{max}$ are decreased to 12.0 kG and 34.1-35.5 MGOe. Especially, $Tb_{80}Ga_{20}$-doped magnet exhibits larger Δ_iH_c of 3.7 kOe with higher $_iH_c$ = 18.7 kOe and slightly decreased B_r (= 12.5 kG) and $(BH)_{max}$ (= 39.4 MGOe). Quite importantly, increasing annealing temperature to 700 °C could remarkably enhance the coercivity to 24 kOe (Δ_iH_c =9 kOe) and slightly reduce $(BH)_{max}$ to 37.5 MGOe. As shown in Fig.1 (b) and (c), the platelet-shape grains observed in studied samples contribute to high B_r and $(BH)_{max}$. The size of magnetic grains approached to single-domain size results in coercivity enhancement and the improvement of the squareness of demagnetization curves shown in Fig. 1(a). Figure 2 shows XRD patterns of the studied NdFeB magnets. All diffraction peaks of the studied samples belong to 2:14:1 phase, and no other phase is detected. In addition, all studied magnets show a good (00L) texture. High I(006)/I(105) of 1.7 for the hot deformed magnet made from pure MQU-F powders results in higher B_r and thus $(BH)_{max}$. The reduced I(006)/I(105) value to 1.2 for the samples with R = Pr and Dy, and 1.5 for the magnet with R= Tb leads to the decrease of B_r to 12.0 kG and 12.5 kG, respectively. TEM and EDX analysis show that Tb and Ga prefer to appear at grain boundary for the $Tb_{80}Ga_{20}$-doped magnets post annealed at 600 °C, while Tb diffuses into grain interior and Ga also prefer to stay at grain boundary with increasing annealing temperature to 700 °C. The appearance of Ga decreases Fe content at the grain boundary phase, and therefore reduces number of nucleation sites and also increases pinning strength of the domain wall movement. H_a of 2:14:1 phase is improved by Tb diffusion into 2:14:1 grains. Both above effects lead to remarkable coercivity enhancement. This study provided economic way for mass production a thicker MQ 3 magnets which are suitable for the application at high temperature.

Doping HRE-rich powders has been proved to be an effective way to improve coercivity in sintered bulk Nd-Fe-B magnet. Dy-Fe-Ga powders with a fine grain size were prepared though hydrogenation–disproportionation–desorption–recombination and a further jet-milling. The powders were added in conventional Dy-free powders and a high increase rate of coercivity for adding Dy-rich additives is achieved by 3.59 kOe/wt. % Dy. During sintering, redistribution of liquid phase leads to distinctive Dy diffusion behaviors. A model is proposed to explain the process. In order to acquire fine grain size, HDDR is introduced in processing Dy-Fe-Ga powder. The initial alloy with a composition of $Dy_1(Fe_{0.8}Ga_{0.2})_2$ was prepared through high-frequency induction melting. The alloy was directly processed in hydrogen furnace and the disproportionation condition is set as 800°C in 2 hours. After HDDR, the powder was further refined through jet milling. By blending the refined Dy-Fe-Ga power in conventional Dy-free powder, the coercivity of the sintered magnet increased 7.17kOe, which equals 3.59kOe increase for 1% Dy adding. The demagnetization curves are shown in Fig. 1. The detailed microstructure changes during sintering was investigated via observation in samples quenched at 800°C, 1000°C and 1030°C which corresponds to different sintering stages till achieving final sintering temperature. SEM images of samples processed at 800°C and 1000°C both show a relatively denser area containing less holes and more Nd-rich phase. SEM areal composition analysis shows the dense areas in the sample of 800°C contains more than 36 wt.% Nd, and the area outside contains much less Nd of 28 wt.% which is closed to the stoichiometric Nd content of 26.68 wt.% in $Nd_2Fe_{14}B_1$, however, the Dy and Ga content shows opposite distribution tendency as follows: in the dense area, less than 2.5 wt.% of Dy is recorded compared with more than 3.5 wt.% outside, more than 1.3 wt.% of Ga is recorded compared with less than 0.7 wt.% outside. The sample processed at 1000°C shows a much more homogenized elemental distribution but with the same tendency of the sample processed at 800°C. The sample processed at 1000°C showed a more obvious core-shell structure outside the dense area, detailed compositional analysis of points also reveals this. Through investigating the sample without adding Dy-Fe-Ga powder, no agglomerated liquid phase was detected though the whole sintering process. Based on this, The liquid phase which contains less than 5 wt.% Dy and more than 50 wt.% Nd forms as the diffusion of Dy into the 2:14:1 phase. Excessive Nd-rich phase liquidifies and agglomerates, which prompt the diffusion of Dy deep into the 2:14:1 phase. To be noticed that Dy content outside the dense area is much higher than that in the dense area, the uneven mixing of powder, which might be conceivable, do not directly leads to the agglomerated liquid phase. The whole diffusion process is schematically shown in Fig 2. It is interesting though, comparing with the grains in the porous area, dense area features a much lower Dy concentration difference between the inner and outer parts of the grains than the dense area. The excessive liquid phase should be the cause of that considering the liquid sintering process accompanied in 1000 °C. Study reveals that dissolution and re-precipitation of $Nd_2Fe_{14}B$ reaction with the RE-rich liquid phase features the liquid sintering process [1]. The ternary eutectic reaction, $L \leftrightarrow Nd + Nd_2Fe_{14}B + Nd_{1+\varepsilon}Fe_4B_4$, reacts at 655 °C, which is much lower than 1000 °C, so the dissolution and re-precipitation process should be violent in the dense area. The reaction causes not only reshape of grains but also exchanges of large amount of atoms, [2] as for the main phase grain, prompting Dy atoms diffusing deep into the center part of grain. Besides the solid-liquid reaction, diffusion follows the Fick's second law, but the diffusion constant without liquid phase at 1000 °C should be relatively low, so for the porous area, a much more obvious core-shell structure is observed.

I. INTRODUCTION Since the discovery of NdFeB in 1983 by Sagawa [1], permanent-magnet materials develop rapidly and become the heart of modern technology, such as wind power generators and electric cars. Misch metal (MM) is mined as raw ore with a composition of $La_{25}Ce_{55}Pr_5Nd_{15}$, but Pr and Nd are overused which causes idle of La and Ce. It must also be mentioned that sintered magnets made using of MM can greatly reduce costs. Yu et al. reported the $MM_{33}Fe_{66}B$ alloys yield M_s of 11.3 kG, H_A of 48.4 kOe, and T_c of 502.9 K[2]. The intrinsic magnetic properties of MM-Fe-B are not very low, but it has a lower price. In some researches [3-4], $CeFe_2$ phase exists in the magnet as harmful phases and decreases the magnetic properties. In our study, alloy ingot with nominal composition of $(La_xMM_{1-x})_{33}Fe_{66}B$ were prepared, the effects of La substitution on the crystal structure and intrinsic magnetic properties of MM-Fe-B alloy were investigated. It is found that the addition of La could suppress the $CeFe_2$ phase. II. EXPERIMENTS Alloy ingot with nominal composition of $(La_xMM_{1-x})_{33}Fe_{66}B$ (x=0, 0.025, 0.05, 0.075, 0.1, 0.15) was prepared by induction melting, and the ingots were then homogenized by annealing at 1273 K under Ar for 24 h. Misch-metal containing about 23.8 wt.% La and 55.2 wt.% Ce and 4.1 wt.% Pr and 16.6 wt.% Nd with a purity of about 99.7 wt.% was used in this experiment. The crystal structure and phase relations of the $(La_{1-x}MM_x)_{33}Fe_{66}B$ system were investigated by X-ray powder diffraction (XRD), scanning electron microscopy (SEM) equipped with energy dispersive X-ray spectroscopy (EDS). Measurements of magnetization-field curves (M-H) along both magnetically easy and hard direction of the alloy and magnetization-temperature curves (M-T) were carried out in a vibrating sample magnetometer (VSM) (Quantum Design) with a maximum magnetic field of 3 T. III. RESULTS AND DISCUSSIONS Fig. 1 shows the XRD diagram of the $(La_xMM_{1-x})_{33}Fe_{66}B$ ingots. It can be found that there are the peaks of $CeFe_2$ phase at 21 degrees, 34.6 degrees and 40.8 degrees when the substituted amount of La is 0-7.5 wt.%. With the increase of La to 10 wt.% in $(La_xMM_{1-x})_{33}Fe_{66}B$, the peaks of $CeFe_2$ phase disappear. Therefore, it is concluded that the addition of La can inhibit formation of $CeFe_2$ phase. The addition of La will consume some Ce to preferentially form La-Ce solid solution, and then it would suppress the formation of 1:2 phases. As a result, the massive $CeFe_2$ phase disappears when La replaces 10 wt.% MM. This is consistent with the observation from SEM–EDS. There is no denying that $(La_xMM_{1-x})_{33}Fe_{66}B$ alloy have four main phases including $Nd_2Fe_{14}B$, $Pr_2Fe_{14}B$, $La_2Fe_{14}B$ and $Ce_2Fe_{14}B$. Another interesting finding is that La substitution would cause the change of Nd, Pr, La and Ce content in main phase, which means the four main phases ratio changes with the La substitution. The Pr+Nd/La+Ce ratio as function of La substitution is shown in Fig.2(a). With increase of La content, the Pr+Nd/La+Ce ratio decreases first, peaks at 7.5 wt.% La substitution, and then increases. At 295 K, the M_s of $Nd_2Fe_{14}B$, $Pr_2Fe_{14}B$, $La_2Fe_{14}B$ and $Ce_2Fe_{14}B$ alloy is 16, 15.6, 13.8 and 11.7 kG. Therefore, the M_s of $(La_xMM_{1-x})_{33}Fe_{66}B$ alloy would be determined by the different main phase ratio. As a result, it exhibits the same tendency to Pr+Nd/La+Ce ratio as shown in fig. 2(b). It should be pointed out that the Pr+Nd/La+Ce ratio in the alloy with 15 wt.% La is less than that of the alloy without La substitution. However, M_s of $(La_{0.15}MM_{0.85})_{33}Fe_{66}B$ alloy is bigger than that of $MM_{33}Fe_{66}B$ alloy. Given that $CeFe_2$ phase disappears in the $(La_xMM_{1-x})_{33}Fe_{66}B$ alloy with La substitution more than 7.5 wt.%, and the $CeFe_2$ phase has low M_s, $(La_{0.15}MM_{0.85})_{33}Fe_{66}B$ alloy with higher M_s is reasonable. To further explore this concept, the M_s of $(La_xMM_{1-x})_{33}Fe_{66}B$ alloy was calculated according the M_s of four main phases and $CeFe_2$ phase, the Pr+Nd/La+Ce ratio and the $CeFe_2$ content. As shown in fig.2(c), the calculation data is in accord with experimental results. IV. CONCLUSIONS The alloy with nominal composition of $(La_xMM_{1-x})_{33}Fe_{66}B$ were prepared, and the rule of La substitution on the crystal structure and intrinsic magnetic properties of MM-Fe-B alloy were obtained. It is found that La substitution could suppress the $CeFe_2$ phase and cause the change of Pr+Nd/La+Ce ratio in main phase of $(La_xMM_{1-x})_{33}Fe_{66}B$ alloy, therefore, reflect in the M_s of $(La_xMM_{1-x})_{33}Fe_{66}B$ alloy. With increase of La content, the M_s decreases first, peaks at 7.5 wt.% La substitution, and then increases. The M_s of $(La_{0.15}MM_{0.85})_{33}Fe_{66}B$ alloy is bigger than that of $MM_{33}Fe_{66}B$ alloy due to restrain of the $CeFe_2$ phase. ACKNOWLEDGEMENT This work was supported by the National Key Research and Development Program of China (2016YFB0700902).

BU-13. Effects of (Nd,Pr)H_x intergranular addition on the mechanical properties of Nd-Pr-Ce-Fe-B sintered magnets.

J. Jin[1], Z. Qian[1], G. Bai[1], B. Peng[1], Y. Liu[1] and M. Yan[1]
1. material science and engineering, Zhejiang University, Hangzhou, China

Incorporating Ce into the $Nd_2Fe_{14}B$-type sintered magnet has attracted growing attention due to its high crustal abundance and low material cost [1-3]. The inferior intrinsic magnetic properties of $Ce_2Fe_{14}B$ to $Nd_2Fe_{14}B$ compound, however, pose a big challenge for the Nd-Ce-Fe-B permanent magnets to exhibit equivalent magnetic properties. Fortunately, the multi main phase (MMP) magnet, by mixing the Ce-free and Ce-rich 2:14:1-type components has been demonstrated to possess preferable magnetic performance recently [4-6]. For instance, maximum energy product $(BH)_{max}$ of 36.7 MGOe has been obtained upon a high level of Ce substitution for Nd (45 wt. %) [6]. Considering that the gap in the coercivity between Nd-Fe-B commercial magnets and Nd-Ce-Fe-B MMP ones still exist, Nd hydrides have been introduced as intergranular additives into the Nd-Ce-Fe-B sintered magnets. Results revealed that the coercivity can be significantly enhanced from 8.3 to 12.2 kOe upon 3 wt.% (Nd,Pr)H_x additives. Besides the magnetic performance, other properties including the mechanical performance of 2:14:1-type permanent magnets also determine the end-product application in various areas, such as high-speed motors. As the introduction of (Nd,Pr)H_x into Nd-Pr-Ce-Fe-B magnets may exert complex influences on the traditional intergranular fracture behavior, whether the mechanical properties suffer severe deterioration or not is still left unknown. Understanding the relationship between (Nd,Pr)H_x content, microstructure and mechanical properties changes is of great significance in mass production of Nd-Pr-Ce-Fe-B sintered magnets and hence requires detailed investigations. In the present work, 20 wt.% $(Nd,Pr)_{30.8}Fe_{bal}M_{1.39}B$ and 80 wt. % $[(Nd,Pr)_{0.5}Ce_{0.5}]_{30.8}Fe_{bal}M_{1.39}B$ magnetic powders have been mixed to prepare the MMP magnet with 40 wt. % Ce substitution. Here 0~3 wt.% (Nd,Pr)H_x has been added before compressing, sintering and annealing. Dependences of fracture toughness K_{IC} and bending strength σ_{bb} on the (Nd,Pr)H_x addition are shown in Fig. 1. Clearly, the increasing (Nd,Pr)H_x content from 0 to 3 wt.% can gradually enhance both the fracture toughness and the bending strength. At 3 wt.% (Nd,Pr)H_x incorporation, high value of 2.0 $MPa \cdot m^{1/2}$ and 229 MPa can be obtained for the 40 wt. % Ce-containing MMP magnets. It suggests that the Nd-Pr-Ce-Fe-B MMP magnets with (Nd,Pr)H_x intergranular addition are promising to be new substitutes for low-to-medium Nd-Fe-B commercial magnets. The enhanced mechanical properties can be attributed to the increased volume fraction of the intergranular regions upon (Nd,Pr)H_x addition and the modified distribution of RE-rich intergranular phases, as shown in Fig. 2a and b. Additionally, thick grain boundary layers can also be found in the fractograph of Nd-Pr-Ce-Fe-B MMP magnets after (Nd,Pr)H_x addition (Fig. 2d). It is in good agreement with the aforementioned results that (Nd,Pr)H_x intergranular additives can enhance both the fracture toughness and the bending strength simultaneously.

BU-14. Study on recycling technology for waste MQ bonded Nd-Fe-B magnets.

M. Liu[1], Y. Zhang[1], W. Liu[1], D. Zhang[1] and M. Yue[1]
1. Beijing University of Technology, Beijing, China

I. INTRODUCTION Nowadays, the Nd-Fe-B bonded magnets are playing a crucial role in many aspects, such as hard disk drive magnet (HDD), optical disk drive magnet (ODD) [1]. So more and more waste Nd-Fe-B bonded magnets are produced and filled into land due to their short lifetime and difficult recovery techniques. Recent increasing prices of rare-earth elements and concerns over the security of supply are making it highly attractive to recycle these magnets. However, those available techniques for recovering sintered magnets cannot be applied to bonded magnets due to different contaminants in two kinds of waste magnets [2]. Therefore, a novel recovering technique is adopted to remove the epoxy resin in waste bonded Nd-Fe-B magnets in this paper. II. METHOD Firstly, the waste magnet bulks were demagnetized in the vacuum environment. Then, the demagnetized magnet bulks were swelled in the mixed solvent of acetone, N-butyl alcohol, Dimethyl Formamide in the ratio of 1.43:1:1.47 to obtain MQ magnetic powders. Acetate acetone and mixed solutions of acetone, N-butyl alcohol, Dimethyl Formamide were used to remove oxides impurities and the epoxy resin by water bath heating and stiring, respectively. Finally, recycled magnetic powders were obtained by vacuum drying at 40°C after being washed in acetone. The microstructure and phase of the samples were examined by scanning electron microscopy (SEM) and X-ray diffraction (XRD), respectively. Magnetic properties at room temperature were measured using a physical property measurement system (PPMS) with a magnetic field up to 3T. III. RUSULTS AND DISSUSION After waste bonded magnets are treated by above process, the main phase is still $Nd_2Fe_{14}B$ with no being destroyed. However the content of carbon and oxygen are reduced to 54%,25.7%, respectively, because the large amount of epoxy resin are removed. It can be seen from Fig.1.(a) that a large amount of epoxy resin (white part) are agglomerated on the surface of the waste magnetic powders. Contrarily, the surface of the recovered powders is clear and smooth due to epoxy resin particles disappearing. The magnetic hysteresis loops of three magnetic powders are shown in Fig.2. The recycled magnetic powders possess the best magnetic properties with M_r of 98 emu/g, M_s of 151.5 emu/g, H_{cj} of 7.139 kOe, and $(BH)_{max}$ of 13.741 MGOe, which were greatly improved compared to those of the waste magnetic powders. When compared with the commercial magnetic powder, the M_r, M_s, H_{cj} and $(BH)_{max}$ of recycled magnetic powder reached 102%, 107%, 102%, 105% of commercially powder, respectively, which are satisfied to the standard of commercial application. IV. CONCLUSION A method for recycling the magnetic powder from the waste MQ bonded Nd-Fe-B magnets has been proposed, which does not destroy the magnetic particles itself. The obtained recycled magnet powders have attained the demand of commercial application and can be applied to the preparation of bonded magnets, such as hard disk drive magnet, automotive motor and magnetic sensor products.

BV-01. Negative spin Hall magnetoresistance effect in Pt/GdIG.

H. Zhao[1] and D. Wu[1]
1. Physics, Nanjing Unversity, Nanjing, China

We fabricate high-quality ferrimagnetic thin film Gd3Fe5O12 (GdIG) via pulsed laser deposition and study the spin Hall magnetoresistance effect (SMR) in Pt/GdIG. GdIG has a minimal magnetization below Curie temperature, called magnetic compensation temperature (T_{comp}). We study the magnetoresistance of Pt around and far away from T_{comp} of GdIG thin film. In comparison to the positive SMR, a negative SMR is observed around T_{comp}. In this unique temperature range, magnetic moment of Gd approaches to net magnetic moment of two different Fe which are tetrahedrally and octahedrally coordinated with oxygen atom. The antiferromagnetic exchange coupling no longer dominates, leading to canted phase between Gd moments and Fe moments. Therefore, the negative SMR is explained by the changes of magnetic moment obliquity in size around T_{comp} on account of weak antiferromagnetic exchange coupling.

Spin Hall nano-oscillators show great promise for future communication technologies. Recently, the experimental and theoretical fundamental research yielded different geometries and ways to synchronize them mutually or to an external stimulus for increasing coherency and output power [1,2,3,4]. Here, we report on the injection locking in constriction based spin Hall nano-oscillators measured by μBLS. Auto-oscillations of the magnetization are excited within a 150 nm wide constriction of a 1 micron wide wire consisting of a double layer of Pt(7)/Co40Fe40B20(5). Due to the constriction, the generated pure spin current via the spin Hall effect in the Pt reaches its highest value within a laterally confined area. This pure spin current is injected in the CoFeB layer where the magnetization is aligned under an angle of 170° with respect to the spin current polarization by an external magnetic field of 50 mT. There, the spin current density exceeds the critical value and creates a torque on the magnetization which compensates the intrinsic Gilbert damping stabilizing a certain precession trajectory of the magnetization. As a consequence, for a fixed direct current a certain auto-oscillation amplitude and frequency is achieved. With the injection locking experiment we were able to influence the frequency, line width and amplitude of the auto-oscillations for fixed values of the direct current. We added an alternating current (12 dBm) to the direct charge current leading to a spin current modulation and effective field modulation due to the generated alternating Oersted field. The alternating current was swept from a frequency below the auto-oscillation frequency to a frequency above the autooscillation frequency (Fig 1). Coming closer to the auto-oscillation, a significant frequency pulling of the auto-oscillations towards the external stimulus was observed indicating the interaction. Within the locking range the frequency of the auto-oscillation was synchronized with the external stimulus and the amplitude was strongly amplified. The line width of the auto-oscillations was decreased significantly below the value of the free running state indicating an increase of coherency of the oscillating magnetization volume. Fig. 1. Plot of the auto-oscillation frequency measured by μBLS. Outside the locking range the auto oscillations have a frequency of about 5.63 GHz (black line). The frequency of the alternating current is swept from 4.5 GHz to 6.5 GHz indicated by the dotted white line and a weak increase of the spin wave intensity. Within the locking range the auto-oscillation intensity is increased strongly and controlled by the external stimulus indicated by a shift of the auto-oscillation frequency (5.25 GHz to 5.75 GHz).

BV-03. Vectorial Observation of the Spin Seebeck Effect in $NiFe_2O_4$ Thin Films.

I. Introduction The spin Seebeck effect (SSE) can generate spin current by a temperature gradient and first observed by K. Uchida et al. in 2008. The longitudinal spin Seebeck effect (LSSE) refers to the generation of spin current from an out-of-plane temperature gradient. The generated spin voltage can be detected in two perpendicular in-plane film dimensions, which depends on the orientation of spin polarization vector, magnetic anisotropy and magnetic domain state. We show how magnetization reversal process can be understood by analyzing the voltages from LSSE in two perpendicular in-plane directions. This method may present an alternative to vectorial magnetometry using the magneto-optic Kerr effect. II. Experimental Nickel ferrite ($NiFe_2O_4$, NFO) films were prepared on (110) or (100) oriented MGO and CGO substrates ($5 \times 5 \times 0.5$ mm^3) by PLD technique in an oxygen environment with a background pressure of 10 mTorr. The temperature of the substrates was kept constant at 700 °C during the film growth. For LSSE measurements, a 5 nm thick Pt film was deposited *in-situ* on top of the PLD grown NFO films by DC sputtering at 20 W power and 5 mTorr Ar pressure. All films were structurally characterized using a Philips X′Pert diffractometer with a Cu-Kα source and their thicknesses were determined from X-ray reflectivity (XRR) measurements. Magnetization hysteresis loops of the samples were also measured by VSM in a PPMS® DynaCool™ system (Quantum Design). For four-point vectorial LSSE measurements, it is shown in Fig. 1. III. Results & Discussion Magnetization measurements were performed on 450 nm thick NFO film grown on (110)-oriented MGO and CGO substrates to examine the magnetic in-plane anisotropy. As shown in Fig. 2(a), we observe a sharp switching of the magnetization when the external magnetic field is applied along the magnetic easy axis [1 -1 0] direction with a squareness of approximately one. With the external magnetic field applied along the hard axis [0 0 1] direction, we obtain a switching behavior with magnetic hard axis and an anisotropy field of about 2000 Oe, with squareness far lower than one. Similar with magnetization measurements, we measured the V_{LSSE} signal in two perpendicular configurations. In the first configuration (in Fig. 2(b)), we measure the voltage signal along the magnetic hard axis ([0 0 1]). When the magnetic field is applied along the magnetic easy axis ([1 -1 0]), the magnetization of the NFO film also aligns along in the same direction. When the magnetic field direction changes polarity, the magnetization of the film also switches into the same direction. This results in a sharp switching in the V_{LSSE} signal (90° in Fig. 2(b)) and it is comparable to the corresponding magnetization measurement when the magnetic field in the [1 -1 0] direction (Fig. 2(a)). In saturation, the magnetization of the NFO film is aligned along the direction of external magnetic field for all θ angles. The direction of the voltage measurement is sensitive to detect the spin current that is spin polarized along the x-direction. The voltage generation due to the ISHE is caused by the projection of magnetization in the x-direction. Upon lowering the angle between the external magnetic field and the x-direction, the saturation voltage decreases in correspondence with cross product in the ISHE equation. In the second configuration (in Fig. 2(c)), we changed the position of voltage contacts to the magnetic easy axis direction and then measured the V_{LSSE} signal. When the external magnetic field is applied along the magnetic hard axis of NFO thin film, we observe a LSSE voltage curve similar to the magnetization curve along the magnetic hard axis direction ([0 0 1] direction in Fig. 2(a)). The voltage signal saturates at the highest applied external magnetic field. When the external magnetic field is reduced, the voltage signal does not show a sharp switching, but favors the curved shape of the magnetization measurement in the [0 0 1] direction with low remanence, which is very different from that from the first configuration (in Fig. 2(b)). The similar magnetization and LSSE measurements were done in NFO/CGO (110) film. From Fig. 2(d), we can see the magnetizations on two perpendicular directions are almost the same, since less lattice mismatch between the film and the substrate leads to weak magnetic anisotropy according to our analysis of samples' lattice structure data. Moreover, the voltage signals from LSSE measurement are shown in Fig. 2(e) & 2(f), and we can see the similar results from both directions if ignoring some misalignment during measurement. IV. Conclusions Two perpendicular LSSE measurements were carried out simultaneously for the first time. The lattice mismatch between the film and the substrate leads to strain anisotropy in the NFO thin film, which is higher for MGO substrate compared with CGO substrate. Moreover, the voltages obtained from two perpendicular LSSE measurements reveal the complete reversal process of magnetization, which shows potential application for a new alternative vectorial magnetometry for magnetization reversal.

Spin-orbit torque (SOT) produced by the Spin Hall effect (SHE) is currently considered as a promising mechanism for the excitation and control of the magnetization dynamics in magnetic nano-systems. The significant advantage of SOT for the emerging field of magnonics utilizing spin waves as a signal carrier in nano-circuits, is the possibility to exert spin-transfer torque over extended areas. In contrast to the spin transfer torque produced by spin-polarized electric currents, the SOT provides an opportunity not only to excite local magnetization oscillations, but also to control the propagation length of spin waves. Another important advantage of SOT is the possibility to implement spin-torque devices based on insulating magnetic materials, such as Yttrium Iron Garnet (YIG). In the past years, the applicability of this material was limited by the large micrometer-range thickness of high-quality YIG films. Only very recently, with the developments in preparation of high-quality nanometer-thick YIG films, the implementation of insulator-based spin-torque devices became practically feasible. We studied the effects of SOT on the propagation of spin waves in 1 micrometer wide waveguides prepared from a 20 nm thick YIG film grown by the pulsed laser deposition. The film was covered by an 8 nm thick layer of Pt deposited using dc magnetron sputtering and the YIG/Pt bylayer was patterned by e-beam lithography. Spin waves in the waveguide were excited by a broadband 3 micrometer wide microwave antenna made of 250 nm thick Au. A dc electrical current I flowing in the plane of the Pt film was converted by the SHE into the transverse spin accumulation. The associated pure spin current was injected into the YIG film resulting in a spin-transfer torque on its magnetization. Depending on the relative orientation of the current and the static magnetic field, the SOT either compensated or enhanced the effective magnetic damping in the YIG film. Propagating spin waves were detected with the submicrometer spatial resolution by using micro-focus Brillouin light scattering (BLS) spectroscopy, which allows the direct characterization of the spatial decay of propagating spin waves. The results of the measurements clearly demonstrated that, in the studied system, the propagation length of spin waves can be efficiently controlled by SOT. In particular, we observed an increase of the propagation length by nearly a factor of 10, when the electric current was applied. This variation corresponds to the SOT-induced increase of the spin-wave intensity at the output of a 10 micrometer long transmission line by three orders of magnitude. Additionally, the high efficiency of our system allowed us to study the regime, where the damping is overcompensated by SOT and the true amplification of spin waves is expected. We show that, in this regime, the spin system of the YIG film is strongly overdriven, which results in the suppression of the spin-wave amplification. Our observations should stimulate both the development of advanced magnonic devices and theoretical work to deepen the understanding of the interaction of spin currents with spin waves.

In-plane currents in a nonmagnetic/ferromagnetic bilayer nanostructure can generate a torque due to the spin-orbit coupling, known as the spin-orbit torque, which is sufficient enough to reverse the magnetization in the ferromagnetic layer [1]. Numerous studies have been conducted to identify the principal origin of the spin-orbit coupling as being either the spin Hall effect in the nonmagnetic layer [2] or the interfacial spin-orbit coupling—frequently referred to as the Rashba effect—at the nonmagnetic/ferromagnetic interface [3]. The precise analysis of the spin-orbit torque as a function of the magnetization angle can provide important information about the physical origin. Theoretically, the spin-orbit torque induced by the spin Hall effect is known to be independent of the magnetization angle of the ferromagnetic layer, whereas that induced by the interfacial spin-orbit coupling is dependent on the magnetization angle [4, 5]. In this study, an accurate method is developed to extract the spin-orbit effective fields, over a wide range of the polar magnetization angle, through an analysis of the results of harmonic Hall voltage measurements by deriving detailed analytical equations, in which both the *z*-component of the applied magnetic field and the second-order perpendicular magnetic anisotropy are taken into account [6]. The method is tested by analyzing the results of a macrospin simulation. The spin-orbit effective fields extracted from the proposed analytical method are found to be in excellent agreement with the input spin-orbit effective fields used for the macrospin simulation over the entire range of the polar magnetization angle and a wide range (0–2) of the ratio of the planar to the anomalous Hall voltage considered in this study. The accuracy of the proposed method is demonstrated more clearly via a systematic study involving a comparison of its results with those of the conventional analytical method (refer to Fig. 1) [6]. A further test of the proposed method, made by analyzing the experimental results for a stack with Si substrate (wet-oxidized)/Ta (5 nm)/Pt (5 nm)/Co (0.6 nm)/MgO (2 nm)/Ta (2 nm), also demonstrates the accuracy of the new analytical method (refer to Fig. 2) [6]. This research was supported by the Creative Materials Discovery Program through the National Research Foundation of Korea (No. 2015M3D1A1070465). I. INTRODUCTION Much effort has been dedicated to investigate the magnon transport in insulating magnetic films (such as yttrium iron garnet Y3Fe5O12 (YIG)) due to its long diffusion length and decay time. By means of the spin Hall effect (SHE) and the inverse SHE (ISHE) of heavy metal materials(such as platinum (Pt)), the magnon can be generated and detected in insulating magnetic layer/heavy metal layer hybrids. Recently, a magnon dragged magnetoresistance (R_{drag}) are discovered in the nonlocal YIG/Pt layers [1]. Most of the experimental studies of R_{drag} focus on a planar nonlocal YIG/Pt bilayer system with Pt as the injector and detector due to its strong SOC. It has been demonstrated that metallic antiferromagnets (such as IrMn) also exhibit spin Hall properties similar to that of Pt[2]. Thus, metallic antiferromagnets would be good candidates for investigation of magnon transport in insulating magnetic films. Here, we report a systematical study of R_{drag} and spin Seebeck effect (R_{SSE}) induced by DC current in nonlocal YIG/IrMn heterostructures. II. EXPERIMENT YIG (50 nm)/IrMn (5 nm) was grown by pulsed laser deposition and magnetron sputtering. After electron beam lithography and Argon ion etching, different gapped devices with the same injector (w_i = 600 nm, L_i = 150 μm) and detector (w_d = 600 nm, L_d = 120 μm) were prepared. DC current (I) was sent though the injector using a Keithley 6221 sourcemeter and the non-local voltage (V_{ISHE}) was recorded simultaneously by Keithley 2182A nanovoltmeters. By reversing the current, we can obtain $R_{drag} = [V_{ISHE}(+I)- V_{ISHE}(-I)] /2I$ and $R_{SSE} = [V_{ISHE}(+I) + V_{ISHE}(-I)] /2I$. The magnetic field is applied inplane with an angle θ to the current. III. RESULT AND DISCUSSION As shown in Fig. 1(a) and (b), the angular dependence of R_{drag} and R_{SSE} on the magnetic field exhibits $\cos^2\theta$ and $\cos\theta$ relationship since the former includes SHE and ISHE while the latter only involves ISHE in the detector. A clear linear R_{SSE} on current is observed which demonstrates the origin of SSE is the Joule heating effect. R_{drag} is almost the same with the current increasing for the drag effect is caused by spin accumulation at the interface. All the results confirm that IrMn could act as an ideal spin injector and detector. Fig. 2 (a) and (b) present the magnetic field dependence of V_{drag} and V_{SSE} in different gapped devices. All of them shown similar suppression by field. δV_{drag} = V(H=10 kOe)-V(H=0.1 kOe)/ V(H=0.1 kOe) increases from 40% to 70% with the injector-detector separation distance increasing, which is consistent with the diffusion model because the field will decrease the diffusion length of magnons [3]. The diffusion length can be obtained by fitting the signal with $V=V_0\exp(-d/\lambda_m)$ and we extracted λ_m = 1.2 μm at H = 0.1kOe which is within the values reported in YIG/Pt layers. The result is reasonable for our nano-thick YIG because the magnons scattering to the surface maybe enhanced due to the ultra-thin film. The same behavior of V_{SSE} is observed when the field increases from 1 kOe to 10 kOe. While a slight increase of V_{SSE} can be figured out when the magnetic field increases from 0.1 kOe to 1 kOe except for d = 1500 nm. The Joule heating in nonlocal structure is radical and maybe a local temperature appeared in the detector, therefore the thermally excited magnons are more complex than simple diffusive model which need to be explored in the future. Fig. 2 (c) shows the temperature dependences of R_{drag} and R_{SSE}. R_{drag} grows rapidly in nearly a $T^{2.3}$ trend with the temperature increasing from 125 K to 400 K while R_{SSE} saturated from 300 K to 400 K. Though electrically and thermally excited magnons both transport in the YIG channel, their distinct dependences on temperature indicate the spin accumulation for R_{drag} and R_{SSE} is very different. IV. SUMMARY We observed the magnon dragged magnetoresistance and spin Seebeck effect in YIG/IrMn nonlocal structures. According to their different dependences on applied current, R_{drag} and R_{SSE} can be separated as the antisymmetric and symmetric part of nonlocal inverse spin Hall voltages. The magnetic field and temperature dependences of magnon transport are systematically studied and the different temperature dependences demonstrate their distinct origin of spin Hall effect and spin Seebeck effect.

Spin-orbit torque (SOT) is conventionally realized by applying an in-plane current passes through the heavy metal (HM)/ ferromagnet (FM) multilayers. In order to enhance the magnitude of SOT, considerable experimental works have been devoted to studying HM material properties and thickness variation of HM and FM layer [1-4]. Recently, it was shown experimentally that the capping layer can strongly influence the SOT [1]. Hence, the objective of our study is to develop a model based on spin-drift-diffusion (SDD) theory to analyze the effect of capping layer on SOT in perpendicularly magnetized HM/FM/Cap systems (Fig. 1) and other experimentally observed trends. Our model shows close correspondence to experimentally observed trends. Here we considered two cases: i) capping layer only acts as a protective layer, e.g. normal metal (NM) with zero spin Hall angle (θ_{Cap}=0); ii) capping layer behaves as another HM or spin polarized current source, i.e., θ_{Cap}<0 (we have assumed HM possesses positive spin Hall angle, i.e., θ_{HM}>0). Firstly, we studied capping layer thickness dependence. For case i) θ_{Cap}=0, we get that SOT decreases with increasing capping layer thickness (t_{Cap}) in Fig. 2(a), which corresponds to the experimental results from [1] in which they use Cu as capping layer. In the same figure, we also plot the case with θ_{Cap}>0 (yellow dotted line) for comparison, the capping layer thickness dependence shows a similar trend to the case when θ_{Cap}=0 (the blue solid line), but with reduced magnitude. However, as can be seen from Fig. 2(b), in the case of ii) capping layer made of W which acts as another HM with opposite spin Hall angle (i.e., θ_{Cap}<0), SOT achieves a maximum value at t_{Cap}~2 nm, at which the general decreasing trend starts to overcome the second spin Hall source from the capping layer. This behavior corresponds closely to that observed from another experimental work [3], in which a torque maxima occurs at t_{Cap}~2 nm, as shown in the inset of Fig. 2(b). Comparing cases i) and ii), besides the presence of a torque maxima, it can also be seen that the magnitude of SOT has been generally enhanced by the presence of spin Hall effect in the capping layer. We also investigated FM layer thickness dependence for the above two cases in Fig. 2(c) and (d), both of them give similar trends: the spin torque decreases with increasing FM layer thickness (t_{FM}) after achieving a peak at t_{FM} that is comparable to transverse spin diffusion length of FM (l_{sf}^T). This trend corresponds to the experimental data [1] as shown in the inset, where MgO or Ru were used as capping layer. Note that the experimental measurements were done for thickness of t_{FM}=0.9 nm or thicker, because a FM layer is needed to realize magnetization switching. As a result, the decreasing trend seen experimentally to some extent corresponds to our simulation results for t_{FM} larger than 1 nm. In addition, by comparing the two curves in Fig. 2(d), it can be seen that a shorter l_{sf}^T (stronger spin relaxation in FM) results in increased magnitude of SOT. In addition to the thickness dependence, we also assessed how other physical properties of capping layer (i.e., spin diffusion length and resistivity) affect SOT, which may lead to further enhancement of SOT.

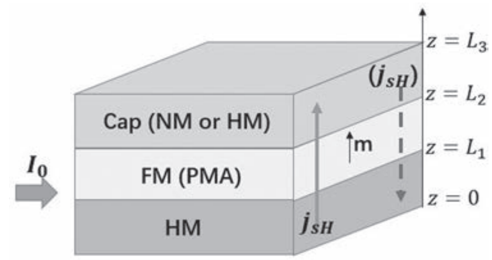

Fig. 1. Schematic diagram of the HM/FM/Cap multilayers discussed in this work. Here FM possesses perpendicular magnetic anisotropy (PMA), thus we assume the local magnetization direction is perpendicular to plane (i.e. along z direction) in FM. The charge current I_0 flows in-plane and introduces spin polarized current due to spin Hall effect (SHE) in HM. Here we will focus on transport perpendicular to plane or along z axis.

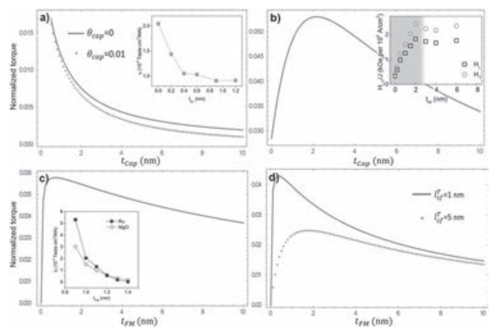

Fig. 2. Layer thickness dependence of SOT. The normalized torque as a function of capping layer thickness t_{Cap} from 0 nm to 10 nm with a) Cu as capping layer (i.e., θ_{Cap}=0), in which we also plot the case for θ_{Cap}>0 for comparison as the yellow dotted line shows; b) W as capping layer (i.e., θ_{Cap}<0). c) and d) plot of normalized torque as a function of FM layer thickness t_{FM} from 0 nm to 10 nm with Cu as capping layer (i.e., θ_{Cap}=0) and W as capping layer (i.e., θ_{Cap}<0), respectively. In (d), we also plot the case for longer l_{sf}^T (i.e., l_{sf}^T=5 nm) for comparison as shown by the yellow dotted line. The insets are experimental results with corresponding capping materials adapted from experimental works [1] and [3], which indicate close correspondence between our simulation results and experiments.

BV-08. Spin accumulation in asymmetric topological insulator thin films in out-of-plane magnetic fields.

Topological insulator (TI) thin films[1] differ from bulk TI in that the former possess both top and bottom surfaces where the states localized at different surfaces can couple to each other due to the finite thickness. In this work, we calculate the spin accumulation resulting from an in-plane electric field in the *y* direction to a TI thin film system with an adjoining ferromagnetic (FM) layer magnetized in the *x* direction on top, and a magnetic field in the *z* direction (Fig 1). The spin accumulation exerts a torque on the magnetization which may be utilized for magnetization switching. The inter-surface coupling and out-of-plane magnetic fields each has distinct effects on the physics of the system. The inter-surface coupling opens up a band gap in the dispersion relation. The gap size is reduced by the magnetization coupling. The out-of-plane magnetic field, on the other hand, collapses the continuum spectrum of stattes into discrete Landau levels. The asymmetry between the top and bottom surfaces of the TI due to the presence of the FM layer at only the top surface results in two possible effects - (i) the top surface experiences a contact potential with the FM layer absent in the lower surface, and (ii) the top surface is more strongly coupled to the FM magnetization. We model the system and these effects via the Hamiltonian $H = v(\pi_y\sigma_x-\pi_y\sigma_x)\tau_z + \lambda\tau_x + \Delta_z\sigma_z + (M_x + \delta M_x\tau_z)\sigma_x + E_z\tau_z$. Here the τs indicate whether the states are localized nearer the top or bottom surface ($<\tau_z>=\pm1$), the $\lambda\tau_x$ term represents the inter-surface coupling, $\Delta_z\sigma_z$ the combined effects of the Zeeman splitting and out-of-plane magnetization, $\delta M_x\tau_z\sigma_x$ the difference in magnetization between the upper and lower surface, and $E_z\tau_z$ the potential energy difference between the two surfaces. In the absence of asymmetry ($E_z=\delta M_x=0$), the spin y accumulation due to the electric field is equal and opposite between the top and bottom surfaces so the net non-equilibrium spin accumulation summing over both surfaces, $<\delta\sigma_y>$ vanishes. Introducing either a finite value of either E_z or δM_x breaks this antisymmetry and leads to a finite spin y accumulation (Fig 2). The features appearing in the variation of the spin accumulation with energy can be related to the features in the dispersion relation. We argue that this spin accumulation may be explained by Berry curvature effects[2] as illustrated in Fig. 2. The Landau levels in the presence of the field may be thought of as resulting from the collapse of the continuum of states in the absence of the field into discrete levels, so that the spin accumulation of each Landau level is the sum of the contributions of its constituent continuum states. For each of these continuum states, applying an electric field causes a momentum shift, and the spins of the states rotate along with the changing momentum-dependent spin-orbit interaction field. The rotation of the spins can be thought of as being due to an effective magnetic field (inset of panel b) that both provides the torque to rotate the spins as well as confers an out-of-plane spin accumulation. Our results suggest that the amount of spin torque hence exerted can thus be controlled by modulating both or either of the scalar potential difference or magnetization magnitude difference between the top and bottom surfaces of the film. This offers an additional avenue to control the spin torque exerted on the FM magnetization independent of the in-plane current.

In Recent years, the magnetization switching induced by spin-orbit torques (SOT) in ferromagnetic (FM)/Heavy metal (HM) structure has drawn much attention for their potential application in magnetic memory and logic devices. In general, when a current passes through the FM/HM structure, both a damping-like (DL) and a field-like torque can be present. However, theoretical and experimental work have verified that the DL torque, arising from the spin-Hall effect (SHE), is most relevant to magnetization switching. The transformation efficiency from charge current to spin current is normally expressed by the spin Hall angleθ_{SH}=j_s/j_e. Different values of θ_{SH} were reported for various HM films β-Ta (0.12), Pt (0.07), and β-W(0.4). However, in recent works, people found that the FM/HM interface also plays an important role to determine the spin torque efficiency.[1] The interlayers between the HM and FM layers can significantly alter the spin transmission and thereby lead to a change in the observed θ_{SH}. Therefore, from application viewpoint, it is more meaningful to express the transformation efficiency by "SOT efficiency", instead of an intrinsic "spin Hall angle". In addition, Dzyaloshinskii-Moriya Interaction (DMI) at the FM/HM interface is another important factor for SOT-induced switching. DMI is capable of stabilizing Neel-type domain walls, and thereby alter the required in-plane field for a deterministic switching. So a further investigation and control of interfacial DMI still requires for much work. Recently, Pai et al[2] developed an indirect way to estimate SOT efficiency and DMI simultaneously. In this work, we measured the DL torque efficiency and DMI with respect to the thickness of Pt (t_{Pt}) in Ta/Pt/CoFeB/MgO structures by this method. We find that both the DL torque and DMI decreases with t_{Pt} in the range between 0-1nm. It is supposed that opposite sign of spin Hall angle and DMI in Ta and Pt could lead to this behavior. Laterly, SOT-induced switching under different in-plane bias fields were studied. We find that small SOT efficiency and DMI may result in larger switching current and small required in-plane field for a deterministic switching. The experiments were carried out in Ta(5)/Pt(t_{Pt})/CoFeB(1)/MgO(1)/Ta(1) structures(thickness in nanometer), where t_{Pt} various from 0 to 4 nm. All the stacks were deposited at room temperature on thermally oxidized Si substrates by using a magnetron sputtering system. These film stacks were subsequently patterned into Hall bar devices. M-H hysteresis loops of stacks were obtained by VSM and it is found that when t_{Pt} is less than 1.0nm, all the stacks exhibit significant PMA. As schematically shown in Fig. 1(a), we measured the R_H *vs* H_z loops in the Hall-bar devices as a function of applied dc current density (J_{dc}) and in-plane bias field (H_x). Representative R_H vs H_z loops with H_x =600 Oe and J_{dc} = ±5.6MA/cm^2 are shown in Fig. 1(b) for Ta(5)/CoFeB(1)/MgO(1)/Ta(1). Current-induced effective field H_z^{eff}, the outcome of DL torque, push the AHE curve to deviate from the original symmetric form and shift it to the left or right according the polarity of J_{dc} and H_x. Since SOT is proportional to the current, larger current indicates more obvious AHE-curve shift, as shown in Fig.1(c). By reversing the polarity of H_x, the slope of H_z^{eff} /J_{dc} is also reversed and H_z^{eff}/J_{dc} is almost zero at H_x=0. This is consistent with the prediction from the SHE +DMI scenario [3]. In Fig. 2(d), we summarized the measured effective field per current density (χ= H_z^{eff}/J_{dc}) as a function of H_x. We find that χ increases quasi-linearly with H_x and saturates at H_x≈±500 Oe, at which the DW moment in the Néel-type walls realign parallel to H_x, and therefore the $|H_z^{eff}|$ attains a maximum. This facilitate us to estimate the intensity of DMI by D = $m_0 H_{DMI} M_S \Delta$, where D is the DW width obtained from Δ=$(A/K_{eff})^{1/2}$. The χ-H_x curves were measured for all the samples with t_{Pt}=0, 0.3, 0.7, 1nm, as shown in Fig.2(a). The maximum spin torque efficiency (χ_m) and H_{DMI} can be subtracted from the saturation value and saturation field in χ-H_x curves, which are plotted in Fig.2(b). We find that both the DL torque and DMI decreases with t_{Pt} in the range between 0-1nm. Becasue Ta and Pt have opposite spin Hall angle, the Pt layer partially cancelled out the spin current produced in the Ta layers and results in a small χ_m. We expect that the DMI should change sign when a thin Pt layer was inserted because DMI is an interface effect. However, this did not happen until t_{Pt}=1nm. Recently, S. Tacchi et al[4] has proved that several monolayers heavy metals near the interface of HM/FM play paramount role in DMI. As we know, Pt with fcc structure is of lattice parameter a=0.39nm; thus, if Pt is thinner than 1nm which is approximately equal to 3 monolayers, the bottom Ta layer will remarkably affect the interfacial DMI and its contribution will weaken with increasing t_{Pt}. In the other hand, while Pt is thicker than 1nm, Pt insertion layer will shield the influence of Ta, dominates the interfacial DMI and enhances D.

BV-10. Spin-Orbit Torque Induced Magnetization Switching In Co/Pt Multilayer-based Synthetic Antiferromagnets.

L. Zhu[1], X. Xu[1], K. Meng[1], Y. Wu[1], J. Miao[1] and Y. Jiang[1]
1. School of Materials Science and Engineering, University of Science and Technology Beijing, Beijing, China

Spin-orbit torques (SOTs) switching have been observed in Co/Pt multilayers with strong perpendicular magnetic anisotropy (PMA).[1] In bilayers system made of heavy-nonmagnetic metals (HMs) and ferromagnets (FMs), SOTs are derived from spin Hall effect (SHE) and interfacial Rashba spin-orbit coupling. However, in multilayers, SOTs arise from the global imbalance of the spin currents from the top and bottom interfaces for each Co layer.[1] Moreover, synthetic antiferromagnets (SyAFs) can be switched by SOTs, and the switching mechanism does not obey the usual SOTs switching rule[2] of the macrospin model[3]. Therefore, it is important to clarify the mechanism of SyAFs based SOTs switching. In this work, we report SOTs switching in Co/Pt multilayer-based SAFs with the stacking structure of Si/SiO_2/Ta (2)/Pt (5)/[Pt (1)/Co (0.4)]$_3$/Ru (0.8)/[Co (0.4)/Pt (1)]$_5$ (thickness in nanometer). The film was deposited by magnetron sputtering and patterned into a Hall bar using electron beam lithography (EBL) and an Ar ion milling technique. Figures 1(a) and (b) present the normalized magnetization curve (M/Ms) and the Hall resistance curve (R_{AHE}) as a function of the out-of-plane magnetic field with a DC current of 1 mA, respectively. It is obvious that both of the M-H and R-H loops indicate an antiferromagnetic (AFM) interlayer coupling as well as a strong PMA in the multilayer structure. The current-induced magnetization switching is presented in Fig. 2. As shown in Fig. 2(a), the saturated R_H increases with increasing the applied maximum channel current under an external field of +300 Oe, which indicates that more domains can be reversed under a large current. Fig 2.(b) presents that the magnetization can be switched and the orientation depends on the direction of the external field. The anomalous switching behavior is also shown in Fig 2.(b). The switching orientation changes with a larger in-plane external field, indicating the anomalous switching mechanism in SyAFs. According to our study, the total thickness of magnetic layer Co is up to 3.2 nm, which is much thicker than previous reports, which is meaningful for real application in spintronics devices.

Palladium/cobalt bi-layer films demonstrate a host of important magnetic and spintronic effects, namely strong perpendicular magnetic anisotropy (PMA) induced at the interface [1] and a strong Spin Hall Effect. It has been shown that a strong spin-pumping effect across the interface [2] during driven ferromagnetic resonance (FMR) in the Co layer leads to a strong inverse Spin Hall Effect (iSHE) in the Pd layer [3]. In these conditions, iSHE is seen as a sharp peak in the dependence of a *dc* voltage across the Pd layer on the static magnetic field applied to the sample. Unique for Pd is its strong affinity to hydrogen gas making it useful for gas sensing applications. In particular, sensors exploiting FMR-based probing of the interfacial PMA in Pd/Co bi-layer films have an important advantage: demonstrated capability of hydrogen gas concentration measurements in a very wide concentration range, including near 100% [4]. It has been demonstrated that absorption of hydrogen gas affects the effective field of interface PMA [5, 6, 7], resulting in a downward shift (in field) of the in-plane FMR peak for the Co layer [8]. In the present work we explore the effect of hydrogen gas on the iSHE response of Co/Pd films when their Co layers are driven to FMR. We demonstrate that the iSHE voltage across the Pd layer is altered in the presence of the gas [9]. This demonstrates the potential for FMR-based hydrogen gas sensing using a device-generated *dc* output, as opposed to the microwave voltage generated from the FMR measurements as in previous studies [10], simplifying the design of the magnetic gas sensor. Palladium/Cobalt bilayer films were deposited onto Silicon substrates using DC magnetron sputtering. Each sample consists of a 10 nm Co layer with a capping Pd layer of varying thickness. Leads were attached to opposite edges of each sample using a conductive epoxy. Similar to [3], the samples were mounted in the center of a microwave cavity and subject to an in-plane external magnetic field. The microwave power source was tuned to the cavity resonance and the external field swept to induce FMR in the Co layer. The iSHE-induced voltage across the sample length perpendicular to the in-plane field was measured using a nanovoltmeter. We also measure conventional field-resolved FMR spectra. Each Pd/Co sample is measured first in N_2 gas atmosphere and then exposed to a 3% concentration Hydrogen gas atmosphere (“3% H_2” from here). Upon exposure of the sample to 3% H_2, a distinct shift to lower fields of both iSHE and FMR peaks is evident. The minimum resonance field corresponds to a sample with a 7.5 nm thick Pd cap (Fig. 1(a)). The smallest FMR field corresponds to the largest effective PMA. Interestingly, this sample shows the smallest FMR and iSHE peak shift in the presence of Hydrogen gas (Fig. 1(b)). This may be related to a change in the crystal structure of the Pd layer as a function of thickness, similar to that previously observed for other heavy metals [10]. We find a consistent decrease in the resonance field upon hydrogenation (Fig. 1(b)). The peak shift to lower fields is related to a decrease in the effective field of the interface PMA. The hydrogen gas induced shift of the iSHE peak is the main finding of this work. The fits demonstrate a very good agreement between the FMR and iSHE peak positions for all the samples, consistent with spin pumping effect by the precessing magnetization in the Co layer underlying the iSHE response [3, 12, 13]. We also find that absorption of H_2 induces a decrease in the linewidth (Fig. 2(b)) of both FMR and iSHE peaks. This observation is consistent with our previous studies in which we also saw a decrease in the linewidth of the FMR peak [8, 14]. However we observe a difference in the linewidths measured through the iSHE and FMR channels (Fig. 2(a)). Also, from comparison of Fig. 2(b) and 1(b) one sees that the decrease in the linewidth correlates with the change in the peak position. In our previous work, we consistently observed an increase in the height of the FMR peak upon H_2 gas absorption [4, 8, 14, 15]. The same occurs here however the change in the height of the iSHE peaks is smaller. Fig. 2(c) shows the ratio of resonance peak heights for the FMR and ISHE traces in 3% H_2 and N_2 atmospheres. To understand the difference between the changes to the heights of the iSHE and FMR peaks we attempt to quantify the changes to the iSHE response using a method similar to that employed in [3], where the same cavity FMR approach was used to measure the iSHE response of Pd/Co films. Our analysis suggests that one possible reason for the decrease in the iSHE peak amplitude is a decrease in the Spin Hall Angle in the presence of H_2. However, the absolute value of the decrease in the angle could not be extracted, because the registered change in the iSHE amplitude due to absorption of H_2 is comparable with a numerical error which accumulates during the multi-step calculation of the Spin Hall Angle based on the raw FMR and iSHE data. The finding of this experiment opens up a pathway to design a magnetic-film based hydrogen gas sensor whose output signal will be a *dc* voltage.

BV-12. The effect of inserting a Pt layer in Pt/Co/Ta structure on spin orbit torque.

S. Li[1], G.J. Lim[1] and W. Lew[1]
1. School of Physics and Physical Science, Nanyang Technological University, Singapore, Singapore

Spin-orbit torque (SOT) arising from ferromagnetic heterostructures consisting of an ultra-thin ferromagnet (FM) sandwiched between a heavy metal (HM) and an oxide layer has attracted extensive attention for low power spintronics devices applications.[1-3] The charge current flowing through the HM can influence the magnetization of the adjacent FM layer via the SOT effect that collectively contributed by the effects of spin Hall[4] and Rashba[5]. To quantify the magnitude of the SOT, two effective fields, a damping-like term alone the current direction, and a field-like term transverse to the current direction, are introduced. The Pt/Co/Ta structure has an enhancced SOT generating from both Pt and Ta layers as they have opposite spin Hall angles.[6] In this work, a Pt layer with different thicknesses was inserted between the Co/Pt and its effect on the SOT effective fields was investigated. Our measurements show that the field-like term is negligibly small after inserting the Pt layer because the Rashba effect at the Pt/Co interface counteracts the effect at the Co/Pt interface. However, the damping-like term can be continuously tuned by inserting the Pt layer, including both the sign and magnitude of the SOT effective fields. When the Pt thickness is small, the damping-like term are contributed by both the Pt and Ta layers, however, when the Pt thickness increases, the contribution from the bottom and top Pt layers became significant. The deposited stacks are Pt (3 nm)/Co (0.9 nm) /Pt (t)/Ta (3 nm), where t = 0.9, 2, 2.5, 3, 3.5 and 4 nm. Harmonic Hall voltage measurement technique was used to characterize the SOT effective fields. Figure 1 shows the first and second harmonic Hall voltage signals for t = 0.9 nm sample under longitudinal and transverse magnetic fields, for both up and down magnetized states. The slope of the second harmonic Hall voltage under the transverse magnetic fields is zero, indicating that the field-like SOT is negligibly small, which applied to all measured samples. The damping-like effective fields were plotted as a function of the Pt thickness for up and down magnetized states, as shown in Fig. 2. The result show that the damping-like term can be tuned continuously by the inserted Pt layer. The sign of the damping-like fields is inversed when t < ~2.1 nm and t > ~2.1 nm. The magnitude of the damping-like fields is firstly decreased with the increse of t under 2.1 nm, and becomes greater when the Pt thickness is larger than 2.1nm. The change of the damping-like fields is small at Pt thickness greater than 3 nm.

The spin pumping phenomenon attracts intensive interest for the applications of pure spin current devices with high energy-efficiency. With the excitation of ferromagnetic resonance (FMR) in a bi-layer system, spin torque is transferred from a ferromagnetic (FM) layer to a non-magnetic metal (NM) layer, activating the spin current in NM. Spin current reveals itself as an inverse spin Hall Effect (ISHE) induced DC voltage along the transversal direction of magnetic polarization. It has been demonstrated that beside the coherent excitation, individual spin-wave resonance (SWR) mode can also induce a spin pumping effect. [1] Previous studies mostly focused on the semi-2D excitations of SWR, such as in the magnetic insulator $Y_3Fe_5O_{12}$ (YIG) films on $Gd_3Ga_5O_{12}$ substrate. In this work, we report SWR induced spin pumping effect in YIG single crystal plates for the first time. 10 nm of Pt film is deposited on 1.5 x 1.5mm YIG plates with thickness (t) of 80, 220, 270 and 320 μm. 9.8 GHz of microwave is applied with a cavity of TE_{102} mode. Fig. 1(a) shows the microwave absorption intensity vs. in-plane DC field (H) for YIG plate with t = 320 μm. Both backward-volume magnetostatic modes (bulk mode) and Damon–Eshbach modes (surface mode) are observed at H higher and lower than resonance field of uniform mode, respectively. However, the bulk modes have an unusually low intensity at the second peak compared with the first (B1) and third (B2) peak. It is called V1 and doesn't belong to the series of bulk SWR mode along the H direction. Both surface and bulk modes generate the correspondent inverse spin Hall voltage as displayed in Fig. 1 (b). The Power-dependent voltage for each SWR mode is plotted in Fig. 2. The surface mode, S1, shows a linear behavior with power. On the other hand, in bulk mode region, B1 and B2 intend to saturate at high power. The V1 mode induced voltage is linear with power, which may exceed the B1-induced one at the power higher than 15mW. The solid curves in Fig. 2 are the theoretical fits using spin-backflow model. The sample displays a systematic change in the resonance-field/linewidth of both bulk and surface modes with decreasing the thickness, which will be discussed further in the text.

The anomalous Nernst effect in perpendicularly magnetized $Ir_{22}Mn_{78}/Co_{20}Fe_{60}B_{20}$/MgO thin film is measured using well-defined in-plane temperature gradients. The geometry with out-of-plane magnetic field and in plane temperature gradient is the natural configuration to avoid longitudinal spin Seebeck effect and allow a precise determination of the temperature gradient. The anomalous Nernst coefficient reaches 1.8 μV/K at room temperature, which is almost 50 times larger than that of $Ta/Co_{20}Fe_{60}B_{20}$/MgO thin film with perpendicular magnetic anisotropy. The anomalous Nernst and anomalous Hall results in different sample structures reveal that the large Nernst coefficient of $Ir_{22}Mn_{78}/Co_{20}Fe_{60}B_{20}$/MgO thin film is related to the interface between CoFeB and IrMn. Finally, we point out a possible application of ANE that takes advantage of the perpendicular magnetization to obtain large Nernst voltage, owing to the in-plane geometry of the device.

BV-15. Spin pumping effect via an evanescent state in ferromagnetic insulator.

K. Hoshi[1] and J. Ohe[1]
1. Physics, Toho University, Narashino-shi, Japan

To generate and control the spin current such as the conduction electrons spin current and the spin- wave spin current is the key task of the spintronics field. Spin pumping effect in the normal metal/ferromagnetic metal junction system is typical mechanism for generating the conduction electrons spin current. The spin pumping effect in variety junction systems such as the antiferromagnetic insulators/normal metal and ferromagnets/topological insulators/ferromagets have been also experimentally reported. The spin pumping current in the normal metal is induced by the precession of the magnetization. The spin pumping current in normal metal is converted into the charge voltage via the inverse spin Hall effect due to spin-orbit interaction. The spin pumping effect was theoretically researched by Mizukami et al. by using the spin diffusion equation. On the other hand, Tserkovnyak et al. has applied the scattering theory including the spin mixing conductance to the spin pumping effect. These theories predicted the spin current polarized in the direction of the spin precession axis and are difficult to investigate the microscopic origin of the spin pumping effect. Recent analytical work has clarified that the mechanism of spin pumping effect is different between the ferromagnetic metal case and the ferromagnetic insulator case. For the ferromagnetic metal case, spin pumping effect was presented by using a quantum mechanical picture and field theoretical derivation. On the other hand, for the insulating case, the proximity effect causing the additional spin accumulation in the normal metal is required to generate the spin current. The conventional approach of the scattering matrix theory also show the absence of the spin pumping effect when the electron state does not exist in the magnetic region such as ferromagnetic insulators. When the electron energy is close to the potential energy of the insulator, however, the electron wave function can penetrate into the region of ferromagnetic metal and feels the s-d coupling via the evanescent mode of the electron conductions. In this report, we investigate numerically the spin pumping effect by using the normal metal/ferromagnetic insulator (NM/FI) junction system with the additional gate voltage. In order to calculate the spin current from the FI with the precessional magnetization to the NM, We employ the quantum pumping current formula based on scattering matrix approach. We calculate the scattering matrix by using the Green's function technique by which the evanescent mode of the electron in the FI is treated precisely. The ferromagnetic system under the static potential due to gate voltage can represents both the metallic system and the insulating system by comparing the Fermi energy of the injected conduction electrons in NM. Numerical results show that the pumping spin current is generated even in the insulating regime. By increasing the static potential, the spin pumping current diminishes as a results of the conventional scattering theory. In order to clarify the mechanism of the spin pumping effect, we develop the numerical technique that can solve both the Landau-Lifshitz- Gilbert equation and the Schrödinger equation simultaneously. We calculate the dynamics of the conduction electrons wave packet that is injected to the ferromagnetic insulator. Although the static magnetization does not induce the spin current, we obtained the pumped spin current when the magnetization processes due to the applied magnetic field. The wave packet dynamics reveals that the spin-dependent scattering via the evanescent mode of the electrons in the ferromagnetic insulator plays an important role for generating the spin current. We also investigate the modulation of the Gilbert damping in the FI due to the spin pumping effect. Proposed effect gives us the possibility of new type of the spintronics devices that can control of the spin current by the additional gate voltage.

Peking University, Beijing, China

INVITED PAPERS

9:00

CA-01. Skyrmions in magnetic multilayers at room temperature: electrical creation, detection and manipulation, 3D shaping.

A. Fert[1,2], W. Legrand[1,2], D. Maccariello[1,2], J. Chauleau[3,4], N. Reyren[1,2], S. Collin[1,2], K. Bouzehouane[1,2], K. Garcia[1,2], N. Jaouen[3] and V. Cros[1,2]
1. UMP CNRS-Thales, CNRS, Palaiseau, France; 2. UMP CNRS-Thales, Université Paris-Saclay, Orsay, France; 3. Synchrotron SOLEIL, Gif-sur-Yvette, France; 4. SPEC, CEA, Gif-sur-Yvette, France

Up to the last years, skyrmions were observed only at low temperature but an important effort of research has been recently devoted in several groups to stabilize small (< 100 nm) skyrmions above room temperature (RT) in magnetic multilayers having additive interfacial DMI [1]. The talk will present experimental results at RT on small skyrmions (30-80 nm) in several types of multilayers associating magnetic layers of Co and nonmagnetic layers of heavy metals (Pt, Ir, W, Ta, Ru). First, the talk will be devoted to the electrical creation, detection and manipulation of skyrmions in narrow tracks. We will describe and discuss: i) the creation of skyrmions by current pulses and its mechanism (spin transfer torque vs thermal effects) [2], ii) the detection of skyrmions (one by one) by Anomalous Hall Effect measurements [3], iii) the current-induced motion of skyrmions, the influence of defects on velocity and Skyrmion Hall Angle [2]. Then, we will present results [4] on skyrmions shaped in 3D by a control of the relative values of DMI and dipole interactions for a given number of layers (3D structure experimentally determined by x-ray magnetic scattering, XRMS). We will discuss the impact of a 3D structure on spin torque induced dynamics. A list of pending problems will conclude the talk. CA-02. Atomic-Scale Observation and Manipulation of Individual Nanoscale Skyrmions by Local Spin Currents and Electric Fields.

R. Wiesendanger[1]
1. Dept. of Physics, University of Hamburg, Hamburg, Germany

Nanoscale skyrmions in metallic ultrathin films and multilayers [1,2], stabilized by interfacial Dzyaloshinskii-Moriya (DM) interactions [3], have recently become of significant interest due to their great potential for future magnetic memory and logic devices [4]. Based on the first observation and manipulation of individual skyrmions in Pd-Fe bilayers epitaxially grown on Ir substrates [5-7] by spin-polarized scanning tunneling microscopy (SP-STM) techniques [8], a large number of skyrmion-based device concepts have been proposed which profit from the small size, enhanced stability and easy movement of skyrmions in nanostructured magnetic films and multilayer structures. Atomic-resolution three-dimensional spin maps of nanoscale skyrmion lattices [9-11] as well as individual skyrmions [5-7] by SP-STM were found to be in excellent agreement with early pioneering theoretical predictions of chiral magnetic skyrmions [12,13]. Magnetic-field dependent SP-STM studies of individual magnetic skyrmions allowed for a determination of material-specific parameters such as the exchange stiffness, the magnetic anisotropy, and the DM constant [6]. The properties of magnetic skyrmions can widely be tuned, e.g. by multiple interface engineering, leading to skyrmionic states in metallic multilayer systems being stable up to room temperature [14-16] and in zero magnetic field. In this case, however, magnetic dipolar interactions play an additional important role for the stabilization of magnetic skyrmions. Alternatively, chemical treatments, e.g. by oxidation or hydrogenation of ultrathin magnetic thin films can serve as a simple route towards tailored skyrmionic states. Recent investigations by our group show that hydrogenation can induce skyrmionic phases in ultrathin magnetic films which do not exhibit such phases in the pristine state [17]. Any kind of storage and logic applications of magnetic skyrmions requires the ability to write, manipulate, and to delete individual skyrmions. This can be achieved by various experimental approaches: By locally injecting spin-polarized electrons from an atomically sharp SP-STM tip, writing and deleting of individual skyrmions has been demonstrated, making use of spin-transfer torque exerted by the injected high-energy spin-polarized electrons [5]. Alternatively, individual skyrmions can be created and deleted by local electric fields [18], which can be of great advantage in view of energy-efficient skyrmionic device concepts. The subsequent detection of the written skyrmions can also be achieved by electrical means rather than by using a magnetic sensing element [19,20]. Recently, it has been demonstrated that it is also possible to drive trains of individual room-temperature skyrmions along magnetic nanowire tracks at speeds exceeding 100 m/s using short current pulses [16]. These results highlight the potential of current-driven skyrmions for future racetrack-type memory applications [21]. However, detailed investigations of the role of pinning [22] and edge effects [23] are required in order to achieve a reliable operation of skyrmion-based racetrack memories. An interesting challenge for the future is the observation and manipulation of interface-stabilized nanoscale magnetic skyrmions in oxide-based thin films and heterostructures. In this case, SP-STM cannot be applied to reveal the atomic-scale spin texture of such magnetic skyrmions due to the electrically insulating nature of the materials. However, our group recently demonstrated the successful application of Magnetic Exchange Force Microscopy (MExFM) [24,25] to non-collinear spin textures such as skyrmion lattices [26]. Since this particular atomic-resolution imaging technique is not limited to electrically conducting materials, it can be very useful for the discovery of yet unknown skyrmionic states in novel classes of insulating material systems including multiferroics.

CA-03. Skyrmion Dynamics – from thermal diffusion to ultra-fast motion.

M. Kläui[1,2]
1. Universität Mainz, Mainz, Germany; 2. Materials Science in Mainz, Johannes Gutenberg University, Mainz, Germany

Spintronics promises to be a paradigm shift from using the charge degree of freedom to using the spin degree of freedom. To this end three key requirements are: (i) stable spin structures for long term data retention; (ii) efficient spin manipulation for low power devices and (iii) ideally no susceptibility to stray fields as realized for antiferromagnets. We explore different materials classes to tackle these challenges and explore the science necessary for a disruptive new technology. To obtain ultimate stability, topological spin structures that emerge due to the Dzyaloshinskii-Moriya interaction (DMI), such as chiral domain walls and skyrmions are used. These possess a high stability and are of key importance for magnetic memories and logic devices [1,2]. We have investigated in detail the dynamics of topological spin structures, such as chiral domain walls that we can move synchronously with field pulses [3]. We determine in tailored multilayers the DMI [4], which leads to perfectly chiral spin structures. For ultimately efficient spin manipulation, spin transfer torques are maximized by using highly spin-polarized ferromagnetic materials that we develop and we characterize the spin transport using THz spectroscopy [2]. Furthermore, we use spin-orbit torques, that can transfer 10x more angular momentum than conventional spin transfer torques [4-6]. We then combine materials with strong spin-orbit torques and strong DMI where novel topologically stabilized skyrmion spin structure emerge [5]. Using spin-orbit torques we demonstrate in optimized low pinning materials for the first time that we can move a train of skyrmions in a "racetrack"-type device [1] reliably [5,6]. We find that skyrmions exhibit a skyrmion Hall effect leading to a component of the displacement perpendicular to the current flow [6]. We study the field - induced dynamics of skyrmions [7] and find that the trajectory of the skyrmion's position is accurately described by our quasi particle equation of motion. From a fit we are able to deduce the inertial mass of the skyrmion and find it to be much larger than inertia found in any other magnetic system, which can be attributed to the non-trivial topology [7]. While thus highly reproducible driven skyrmion motion is possible, we have recently developed new ultra-low pinning multilayer stacks, which exhibit thermally activated dynamics of skyrmions. Here the energy landscape is sufficiently flat so that we observe pure diffusive motion of skyrmion quasiparticles. In contrast to predictions where diffusion was expected to be largely suppressed [8], we find that skyrmions exhibit diffusion at a range of temperatures. Furthermore, in contrast to the analytical calculations, we find a strong temperature and size dependence of the diffusion and we can explain these observations based on thermally activated excitations of the skyrmions. By varying the temperature and drive, we finally probe the transition from thermally activated diffusion to the viscous flow regime for the first time and quantify the skyrmion Hall angle across the full dynamics range.

Symmetry breaking together with a strong spin-orbit interaction give rise to many exciting opportunities for the condensed matter physics community. Topologically protected magnetic skyrmions are one of the examples [1-3]. In this talk, I will first present our experimental results in the electric creation and manipulation of magnetic skyrmions at room temperature in a common material system - heterostructures with an interfacial inversion symmetry breaking. This is enabled by the inhomogeneous current induced spin-orbit torques in a Ta/CoFeB/TaO_x trilayer [4-6]. Secondly, I will demonstrate experimentally a real space spin-topology driven dynamics of magnetic skyrmion – the skyrmion Hall effect [7-8]. Namely, an accumulation of skyrmions at the transverse side of the device is experimentally achieved. Thirdly, investigation of sub-50 nanometer skyrmions in a Pt/Co/Ir multilayer [9] in the absence of magnetic field was conducted, through which we further demonstrated a robust skyrmion phase existing for temperature up to 245 °C. Finally, some open questions and future focus points will be addressed.

Skyrmions are localized spin textures that exist in magnetic materials where spatial inversion symmetry is broken. In such systems, the Dzyaloshinskii-Moriya interaction (DMI) favoring perpendicular alignment of neighboring spins competes with the ferromagnetic exchange interaction and magnetic anisotropy to form a variety of non-collinear spin textures including skyrmion, helical, and conical phases, whose stability depends on the external magnetic field (H) and temperature (T). The most well-studied materials are the non-centrosymmetric B20 crystals such as MnSi [1,2] and FeGe [3], where the broken bulk inversion symmetry generates a bulk Dresselhaus DMI. While most of the initial work on B20 materials has focused on bulk crystals, the advent of B20 thin films via sputter deposition and molecular beam epitaxy (MBE) has opened up the possibility for new interface-stabilized spin textures due to the presence of interface Rashba DMI and interface magnetic anisotropies. One of the fascinating predictions for thin films of non-centrosymmetric materials is the presence of new spin textures forming at the surfaces and interfaces including the "chiral bobber" [4] and "stacked spiral" [5] phases. In Fig. 1, we illustrate the interfacial chiral bobber crystal (Fig. 1a) and compare with the well-known bulk skyrmion crystal (Fig. 1b). The skyrmion phase consists of a hexagonal array of skyrmion tubes that extend throughout the crystal and are aligned with the external magnetic field. Like skyrmions, chiral bobbers (Fig. 1a) have moments that wind around a centerline. However, unlike skyrmions, chiral bobbers are localized to the surface of a film in a region with thickness $\sim L_D/2$, where L_D is the helical pitch length (~70 nm for FeGe). Here, we report experimental and theoretical evidence for a stable chiral bobber region through magnetization measurements on a series of epitaxial FeGe thin films grown by MBE [6]. We first establish the presence of skyrmions in our FeGe/Si(111) samples with thickness below $L_D/2$ through Lorentz transmission electron microscopy, and also demonstrate similar topological Hall characteristics as in previous studies on sputter deposited FeGe films. The experimental evidence for chiral bobbers comes through magnetization measurement on FeGe films as a function of film thickness. Specifically, we investigate the magnetic phase diagram through magnetization measurements (M vs. H) and analysis of the susceptibility curves (c vs. H) for different temperatures and film thicknesses (L). Fig. 2a-2c show representative susceptibility curves at 10 K for FeGe thickness of 35 nm, 80 nm and 500 nm. Notably, the susceptibility exhibits a negative slope in the field range between 2.5 kOe and 5.0 kOe (blue shaded regions), and Fig. 2d summarizes the susceptibility curves in this range for FeGe thicknesses from 14 nm to 1000 nm. As shown in Fig. 2e, we find that the experimentally measured susceptibility has a slope ($d\chi/dH$) that is constant for $L < L_D/2$, and scales as $1/L$ for $L > L_D/2$. This implies an interfacial spin texture which penetrates a distance $L_D/2$ into the sample. We then use micromagnetic calculations to identify this spin texture as a skyrmion lattice in the very thin films and a chiral bobber lattice on the surface of a bulk cone phase in the thicker samples. We need to include two new ingredients – interface DMI and magnetic anisotropy – in the simulations to understand the experimental observations. It is known that the bulk Dresselhaus DMI of B20 materials leads only to metastable [4] chiral bobbers in the thin film geometry. We show that interface Rashba DMI, arising from broken surface inversion symmetry in a thin film, together with the bulk DMI leads to stable interfacial chiral bobbers. Further, an analysis of our experimental saturation fields indicates an effective easy-plane magnetic anisotropy in our films. We show that this too is an important input parameter in the simulations that give us insight into the evolution from skyrmions to chiral bobbers with increasing film thickness. The combination of experimental susceptibility data and micromagnetic simulations provide strong evidence for chiral bobbers at the interfaces of FeGe thin films. Beyond individual FeGe layers, new possibilities are enabled by the synthesis of a new class of artificial skyrmion materials, namely B20 superlattices. We report the successful growth of B20 superlattices comprised of single crystal thin films of FeGe, MnGe, and CrGe on Si(111) substrates [7]. Thin films and superlattices are grown by MBE and are characterized through a combination of reflection high energy electron diffraction, X-ray diffraction, and cross-sectional scanning transmission electron microscopy. X-ray energy dispersive spectroscopy distinguishes layers by elemental mapping and indicates good interface quality with relatively low levels of intermixing in the [CrGe/MnGe/FeGe] superlattice. This demonstration of epitaxial, single-crystalline B20 superlattices is a significant advance toward tunable skyrmion systems.

CA-06. Magnetic antiskyrmions above room temperature in tetragonal Heusler materials.

S. Parkin[1]
1. NISE, Max Planck Institute for Microstructure Physics, Halle (Saale), Germany

Over the past few years there have been remarkable discoveries in spin-based phenomena that rely on *spin-orbit coupling* that could spur the development of advanced magnetic memory devices [1-3]. These include the formation of *chiral* spin textures in the form of Néel domain walls and topological spin textures, and skyrmions, that are stabilized by a Dzyaloshinskii-Moriya exchange interaction. The Dzyaloshinskii-Moriya exchange interaction is derived from broken symmetries and spin-orbit interactions at interfaces or within the bulk of materials. Recently we have discovered magnetic *antiskyrmions* in a tetragonal Heusler compound, $Mn_{1.4}Pt_{0.9}Pd_{0.1}Sn$ using Lorentz transmission electron microscopy [4]. Direct imaging by Lorentz transmission electron microscopy shows field- stabilized antiskyrmion lattices and isolated antiskyrmions from 100 K to well beyond room temperature, and zero-field metastable antiskyrmions at low temperatures. We show that the anti-skyrmions become more stable as the thickness of the slab in which the antiskyrmions are imaged is increased, in contrast to previous work on the thickness dependence of skyrmions. We discuss the origin of this important difference. Finally, we discuss the observation of antiskyrmions in thin films of Mn_2RhSn, another inverse tetragonal Heusler which has D_{2d} symmetry, using variable temperature magnetic force microscopy.

CB-01. Magnetic properties and microstructure of newly developed iron-based soft magnetic powders. ***(Invited)***

N. Imaoka[1], S. Yamamoto[1] and K. Ozaki[1]
1. Magnetic Powder Metallurgy Research Center, National Institute of Advanced Industrial Science and Technology (AIST), Nagoya, Japan

The world market for electric vehicles is expected to reach 15 million by 2020. With the expansion of this market, the sales of soft magnetic materials for drive motor applications will increase to several hundred million dollars [1]. Currently, soft magnetic stators for electric motors in automotive applications are typically assembled by stacking several hundred rolled electrical steel sheets with surface insulating layers (each about 300-μm-thick). The high cost of drive motors arises from the complex process of assembling the stators, and the resolution of this problem is one of the several challenges that need to be addressed for the wide usage of electric vehicles. We have attempted to develop novel high-performance soft magnetic powders using a simple and low-cost fabrication process for solidification of powders without rolling and stacking. In this paper, we report high-magnetization Fe-Mn powders, which can be easily solidified by conventional powder metallurgy processes [1–3]. The Fe-Mn powders doped with 0.1 and 33 atomic-percent manganese (hereafter denoted as Mn0.1 and Mn33, respectively) were fabricated by the reduction of manganese-doped ferrite $(Fe,Mn)_3O_4$ nano-powders with a hydrogen gas at 900–1100 °C. The sample powders were ground using an agate mortar and pestle to an average particle size of about ten to several tens of microns. The starting manganese-doped ferrite nano-powders with a particle size of 5–50 nm were prepared by our aqueous process [2–5]. The magnetization curves of these samples were measured using a vibrating sample magnetometer (VSM) at 300 K, and the magnetic field was applied up to 9 T. The value of saturation magnetization was determined by the law of approach to saturation using the magnetization curve in fields between 2 and 9 T. The saturation magnetization of the Mn0.1 sample was about 2.2 × 100 emu/g, which is comparable to those of pure iron powders. Mn0.1 and Mn33 powders exhibited a coercivity of 0.1–1 Oe, as measured by VSM. These values are much lower than those of iron powders of the same size. Fig. 1 shows the characteristic X-ray map of manganese for about 100-nm-thick cross-section of Mn33 coagulation powders by transmission electron microscopy (TEM) combined with energy-dispersive X-ray spectroscopy (EDS). The Mn33 specimens for TEM were milled using a focused ion beam (FIB) system. The content fluctuation of manganese was observed in the plane of the specimen surface, and the size of the content fluctuation was 20–100 nm. A similar content fluctuation was observed in the Mn0.1 specimen, and the size of the content fluctuation was close to that of the Mn33 sample. Furthermore, the crystallite sizes of these powders were estimated between 30 and 100 nm by X-ray diffraction (XRD), which is consistent with the TEM-EDS results. Fig. 2 shows the relationship between the contents of iron or oxygen and manganese in the pixel regions (20 × 20 nm) of the same Mn33 specimen as Fig. 1, which were measured on a pixel-by-pixel basis by EDS. The results from the EDS measurement of 65,536 pixels revealed that Mn33 powders were a composite of Fe-Mn metal phases and MnO phases in areas of about 20 × 20 nm and thickness of about 100 nm. The coexistence of the MnO oxide phase in the Fe-Mn metal phase of the Mn33 sample was confirmed by XRD. However, the size of the Fe-Mn metal phase is rather large, if the coercivity is assumed to be controlled by the random anisotropy model [6]. The Fe-Mn metal phase in our powders includes only a small amount of manganese [1, 2]; therefore, the magnetic crystalline anisotropy energy of the metal phase is almost the same as that of iron, and much higher than that of the Fe-Si phase reported in Ref. 6. Consequently, the ideal crystal size of the Fe-Mn metal phase should be much smaller than that of the Fe-Si phase (about 10 nm) under the control of a magnetic reversal via the random anisotropy model. We predict a novel mechanism of magnetic reversal functions in our Fe-Mn powders.

CB-02. XAFS studies of the newly developed iron-based soft magnetic powders.

S. Yamamoto[1], N. Imaoka[1] and K. Ozaki[1]
1. National Institute of Advanced Industrial Science and Technology (AIST), Nagoya, Japan

As environment-friendly modes of transportation, vehicles which consume less or no fossil fuels such as electric and hybrid vehicles have been gaining much attention. The global market for such environment-friendly vehicles is expected to reach 15,000,000 by 2020, which is almost ten times as large as that in 2015 [1]. The global market for high performance soft magnetic materials necessary for high efficiency motors is expected to grow up to US $ 6.6 billion by 2020 [1]. Such global trends accelarate development of new soft magnetic materials which realize further higher efficiencies as well as lower cost of production. Currently, relatively large soft magnetic components of car motors such as a stator are fabricated by stacking hundreds of insulation coating-fitted thin magnetic steel sheets. Their typical thicknesses are around a few hundred micrometers and thus complicated and costly processes are necessary for fabrication. Further larger saturation magnetic flux density (B_s) and lower iron losses have been strongly demanded to improve efficiency. In order to fulfil these requirements, we have tried to develop new powdery soft magnetic materials featuring high B_s, low iron losses and easiness to be compacted/sintered by conventional powder metallurgy processes [2-5]. Our newly developed iron-based powders, especially those doped with tiny amount of manganese (*ca.* 0.1 atomic%), are found to have excellent soft magnetic properties, *e.g.*, B_ss of more than 2.1 T and coercivities of less than 10 A/m. Possible origins of such good soft magnetic properties are believed to the fine microstructures induced by the doped manganese, although detailed mechanisms are not clear at present. As part of our efforts to clarify the mechanisms underlying such good soft magnetic properties, we carried out X-ray absorption fine structure (XAFS) measurements on our manganese-doped iron powders. In this presentation, we will show the results from the XAFS measurements with particular emphasis on chemical states of the doped manganese. The manganese-doped iron powders were prepared by reduction of manganese-doped ferrite nanoparticles with H_2 gas at 900-1100 ^{o}C. The starting manganese-doped ferrite nanoparticles were prepared by the coprecipitation method under basic conditions. Details of the preparation methods were reported elsewhere [2]. XAFS measurements at the Fe-K and Mn-K edges were carried out at BL14B2 of SPring-8. Fig.1 shows the X-ray absorption near edge structure (XANES) spectrum of the sample doped with 0.1 atomic% manganese (hereafter denoted as Mn0.1) measured at the Mn K-edge. The XANES spectra of the MnO and α-Mn standards measured at the Mn-K edge are also shown for comparison. The spectrum from the Mn0.1 sample is clearly different from that of the MnO standard, but is similar to that of the α-Mn standard, interestingly. These data strongly indicate that a considerable fraction of the doped manganese in the Mn0.1 sample is in metallic state. It is quite surprising if we remember the preparation method, *i.e.*, reduction of the manganese doped ferrite nanoparticles with H_2 gas. Results from structural analyses using the extended X-ray absorption near edge structure (EXAFS) spectra will also be shown in the presentation.

Soft magnetic materials exhibit typical properties as low coercivity, high permeability or low energy losses and comprise various kinds of materials (e.g. electrical steels, soft ferrites, various alloys or powder compacted and composite materials), being used in a wide range of applications. At present the powder compacted materials are still more attracting the research interest and are progressively replacing e.g. electrical steels in many applications [1]. The magnetization reversal is characteristic for each ferromagnetic material. The goal of this work was to propose and verify the relations for irreversible relative permeability at initial magnetization curve for selected soft magnetic powder compacts – the compacted and sintered NiFe powder and the non-sintered warm compacted Fe powder. The relations were derived based on the well-known Steinmetz law [2] for DC energy losses: $W_{DC} = K_{DC} B^x$, where K_{DC} and x are the Steinmetz coefficients and [H, B] denote the magnetic field and induction of the maximum point of minor DC hysteresis loop. The DC losses W_{DC} depend on the amount of structural imperfections in material, surface roughness and stress regions – the possible pinning centres for moving domain walls [1,3,4]. W_{DC} characterize the amount of irreversible magnetization processes within the magnetizing cycle of minor DC hysteresis loop, as they are accompanied by energy dissipation. The quantity irreversible relative permeability μ_{irr} is the difference between the differential one μ_{diff} and the reversible one μ_{rev} [3,4]. Irreversible relative permeability at initial curve μ_{irr}^{IN} reflects the proportion of irreversible processes at particular point of the initial curve. The relations for μ_{irr}^{IN} were expressed on the basis of Steinmetz law. Two types of soft magnetic powder compacted materials have been investigated, prepared in the form of a ring of outer diameter ~ 24 mm, inner diameter ~ 18 mm and height ~ 2.5 mm. The first one was the polycrystalline NiFe (50 wt.% Ni and 50 wt.% Fe) powder obtained by high-energy ball milling of the ribbon (for 6 h, ball to powder ratio 9:1, RPM 200) and annealed at 800°C in air atmosphere for 1 h in order to relieve the stresses induced during milling process. The powder was compacted at uniaxial pressure 800 MPa, followed by a sintering at 400°C for 30 min and at 1180°C for 1 h in electric furnace in air atmosphere. The second sample was the pure polycrystalline Fe ASC 100.29 powder (from producer Höganäs AB Sweden [5]), which was compacted at a temperature 290 °C for 5 min (the compaction pressure was 700 MPa) without follow-up sintering. The samples represent different kinds of powder compacts – differing in the composition, the porosity content (~ 20 % and ~ 10 %, respectively) and the preparation conditions resulting in the qualitatively different contacts between ferromagnetic particles. W_{DC}, μ_{tot} and μ_{diff} values were obtained from the measurements of initial magnetization curves and DC hysteresis loops, by the fluxmeter-based hysteresisgraph, the magnetic induction was measured referred to the ferromagnetic material in sample. μ_{rev} was measured at each point of the initial curve by the developed setup based on the lock-in amplifier, described in [6], according to general definition of μ_{rev} [3,4]. The proposed relations were verified by the comparison of the calculated dependences of μ_{irr}^{IN} vs. H with the experimental ones, where the function F_{Stein} was found for each sample, within the range of validity of Steinmetz law of given material. The form of F_{Stein} revealed its significant dependence on the magnetic interaction between ferromagnetic particles, which is given by the inner demagnetizing fields and characterized by μ_{tot} of material. For the non-sintered warm compacted Fe powder this interaction was slightly worsen compared to the sintered NiFe sample (with μ_{tot} approximately 10-times higher), due to the worse contacted particles. The derived relations enabled to calculate μ_{irr}^{IN} as a function of H or B, fitting the experimental data in the range of validity of Steinmetz law with a good accuracy (relative standard deviation ~ 5 %). In Fig. 1 the comparison of calculated dependence μ_{irr}^{IN} vs. H with the measured one is shown for the non-sintered iron powder. We assume the relations may be helpful to find the irreversible permeability values and the proportions of irreversible magnetization processes within the whole magnetization process in selected powder compacts. CB-04. Effect of ordering on the antiferromagnetic properties of near-equimolar FeCr-based magnetic alloys.

Z. Leong[1], S. Baco[1] and N. Morley[1]
1. University of Sheffield, Sheffield, United Kingdom

The magnetic properties of multi-components alloys (>4 components, near equimolar) have received modest attention; the strain fields in these alloys may play a role in the partial ordering of these alloys. In the equimolar FeCoCrNi system, the Cr site occupancy is observed to be dependent on the fabrication process [1,2]. Similarly Wei *et al.* reported the cooling-rate dependency of the coercive field of a $Fe_{26.7}Co_{28.5}Ni_{28.5S}Si_{4.6}B_{8.7}P_3$ multi-component alloy [3]. The reported results suggest that Cr additions to an alloy system may be tuned by control of both the amount of addition, and the fabrication method. Magnetostrictive FeCo thin films are used for a variety of applications, such as in artificial multiferroic structures, sensors and actuators. However, one disadvantage is their large coercive field (>10kA/m), which means that 100% switching is not achievable. The effect of Cr addition to FeCo has not been fully explored, and previous results in the literature investigate only small amounts of Cr addition to equiatomic FeCo [4–6]. In this work, we investigate the phase structure and magnetic properties of equimolar $Fe_{0.25}Co_{0.25}Cr_{0.25}Ni_{0.25}$ and near-equimolar $Fe_{0.4}Co_{0.4}Cr_{0.2}$ samples (henceforth designated as FeCoCrNi and $FeCoCr_{0.5}$) synthesised as both bulk and thin film samples, to try and understand the co-dependency of alloying and processing on structure and the coercivity field. Both bulk alloy compositions (equimolar FeCoCrNi and $FeCoCr_{0.5}$) were synthesised into 2.5g ingots *via* arc-melting in a copper hearth, while the thin films were evaporated from the synthesised ingots onto a cleaned Si substrate at a deposition rate of 0.07Å/s. All four samples were characterised using x-ray diffraction (XRD) and magneto-optic Kerr effect (MOKE) magnetometer (*cf.* Figure 1). The FeCoCrNi and $FeCoCr_{0.5}$ compositions possess a rule-of-mixtures Mulliken electronegativity of 4.06 and 4.11 respectively; following previous work, this suggests that their as-cast structures will possess the FCC structure, or a mixed FCC+BCC structure [7]. These predictions deviate from the indexing of the XRD patterns of the bulk specimens (3.56A FCC and 2.53A/4.08A HCP for FeCrCrNi and $FeCoCr_{0.5}$ respectively); the HCP and FCC phases are very close to one another as both are close-packed structures, which may explain the inaccuracies in the prediction [8]. A diffused halo/peak was observed for the $FeCoCr_{0.5}$ thin-film composition, suggesting a disordered structure, while peak broadening was similarly observed for the FeCrCrNi thin film composition, suggesting a semi-ordered structure. The breakdown in structure is expected to reduce spin-orbit coupling effects. Accordingly, a decrease in coercivity is observed for the thin films, as compared to the bulk samples (a decrease from 200 to 37 A/m and 150 to 35 A/m for the $FeCoCr_{0.5}$ and FeCoCrNi compositions, respectively). The structural dependency and stability of HCP and FCC Co is reported be dependent on its magnetic state (whether ferromagnetic, paramagnetic, and non-magnetic) [9], which may be correlated to the observations here, highlighting the possible complexity of structural relationship with processing methods [1]. Further understanding of this relationship will lead to and allow the design of stoichiometric compositions with specific magnetic properties.

CB-05. Anisotropy and demagnetizing effects on the magnetic behavior of polycrystalline gadolinium across the spin-reorientation revealed by a magneto-thermal protocol.

V. Provenzano[2], R. Witte[4], H. ElBidweihy[1], A. Arrott[3], C. Radu[5] and H. Hahn[4]

Institute of Nanotechnology, Eggenstein-Leopoldshafen, Germany; 5. Lake Shore Cryotronics Inc., Westerville, OH, United States

Polycrystalline samples of high purity gadolinium (Gd) exhibit memory of fields applied during cooling to low temperatures starting from above the Curie temperature (T_C). Such cooling effects were first seen by Miekeljohn and Bean for cobalt with a surface coating of cobalt oxide and explained by exchange anisotropy arising from the coupling of the ferromagnetic cobalt to the anti-ferromagnetic cobalt oxide [1]. In an ideally soft magnetic material, as there is no anisotropy, the magnetic charge density is all on the surface, from which it creates a shape-dependent demagnetizing field equal and opposite to the applied field. A magnetically soft polycrystalline material with a small anisotropy, like gadolinium, approximates the ideally soft magnetic material when the magnetic charge density near the grain boundaries creates magnetic fields perpendicular to the magnetization equal and opposite to the anisotropy fields perpendicular to the magnetization in each grain [2]. If the magnetization in two adjacent grains do not have the same component perpendicular to the grain boundary, local energy densities of magnetic charge near the grain boundary increase as the square of the difference in the components perpendicular to the interface. The anisotropy energy in each grain is decreased linearly with decrease in angle between the magnetization direction and the preferred anisotropy axis. This rotation is small. Anisotropy-dependent buildup of charges gives rise to magnetic hysteresis, both at constant field with varying temperature and at constant temperature with varying field. Memory effects can be erased at low temperature by application of a field in the opposite direction that is sufficiently larger in magnitude than the cooling field. Like many uniaxial magnetic materials, the first order anisotropy constant K_1 of Gd changes sign at what is known as the spin reorientation temperature, T_{SR}. This temperature dependence of the uniaxial anisotropy, particularly the change in sign in a narrow temperature range, allows insight into the role of anisotropy in polycrystalline materials [3]. The essence of the magneto-thermal protocol adopted here is shown in Figure 1 for an irregularly-shaped sample (roughly a thin rectangular platelet) in the as-received condition from Alfa Aesar (99.9% purity). The measurements are shown for the sample oriented either with its long axis or with its intermediate axis along the field direction. Figure 1(a) curve C1 shows the magnetization (multiplied by -0.1 for graphic comparison) in a negative applied field $\mu_0 H_{FC}$=-50 mT as the sample is cooled from 300 K to 5 K. When the susceptibility is large, the magnetization is given by M = <mv>/V + χ_D H_A, where <mv> is the averaged moment of the trapped magnetization from field cooling, v/V is the volume fraction of trapped magnetization, and $1/\chi_D$, the magnetic stiffness, is the demagnetizing factor. This is the case below 210 K where the first uniaxial anisotropy constant is negative and the magnetization rotates in the easy plane perpendicular to the anisotropy axis. The lower internal susceptibility χ_i between 250 K and 290 K is more easily seen for the field along the Long Axis where χ_D is larger, as $1/\chi = 1/\chi_i + 1/\chi_D$. The trapped magnetization is less for the Intermediate Axis as the internal field is less because of the greater demagnetizing field. The choice of -50 mT for field cooling was based on the smaller demagnetizing factor, for which higher applied fields produces less trapped magnetization, a measure of which is the difference in each of the C1 curves between 210 K and 5 K. The curves W1 are for warming from 5 K to 380 K in a positive applied field of $\mu_0 H_A$=5 mT. This field is small enough not to erase the trapped moment at low temperatures, yet provides the comparison shown in Figure 1(b) in the second cooling C2 and second warming W2 in the same field from 380 K to 5 K and back to 380 K. The measure of the trapped magnetization on warming is the difference between W1 and W2 for the same orientations. This sequence is our standard protocol for revealing the role of grain boundary trapped magnetization. Measuring in the same field as the cooling field is not informative when the demagnetizing factors are large. Yet one can still discern the effect of field cooling for the data along the Long Axis. Note that the magnetization at 210 K is almost fully determined by the demagnetizing field even though there still is trapped moment at that temperature. To isolate the effects of the several temperature regions of different anisotropy, the cooling field $\mu_0 H_{FC}$=-50 mT was applied at a series of lower starting temperatures (270 K, 255 K, 235 K, and 150 K) and the W1, C2, and W2 sequences were measured (Figure 2). It is clear from analyzing this data, that the blocking temperature is close to 270 K. The details of freezing the magnetization at the grain boundaries changes with the temperature range. When in the temperature regions of an easy plane of magnetization, it is more likely the magnetization is frozen in directions other than that of the applied field. If polycrystalline Gd is to be employed in operations below 270 K, it will be important to understand these effects.

CB-06. Design, Fabrication and Performance Evaluation of Magneto-Dielectric Based Electromagnetic Wave Absorbers Optimized Using Biologically Inspired Optimization Strategies.

R. Panwar[1] and D. Singh[2]
1. Electronics & Communication Engineering, IIIT, Jabalpur, India; 2. IIT, Roorkee, India

A lot of efforts have been devoted in the past few decades to realize electromagnetic (EM) wave absorbers for commercial and military applications [1]-[8]. Certain practical applications require a broadband absorber with the constraint of lower coating thickness. But it is a very challenging task to design a lightweight and wideband absorber using the material alone due to certain physical limitations. However, the multilayering based EM technique can be utilized to overcome the limitations of single layer materials [3]-[5]. Therefore, in this work, magneto-dielectric materials based dual and triple layer structures with wide bandwidth and a lower coating thickness have been designed, fabricated and measured for their EM wave absorbing performance. A thickness restriction ($t \leq 2.0$ mm) and wide bandwidth of reflection loss (*RL*)$\leq$ -10 dB are the main design constraints for this study. The optimization of multilayered structures is a very complex problem, due to the involvement of several design parameters, i.e., selection of suitable materials, layer preferences, and their thicknesses etc. However, a good prediction of their effective dielectric and magnetic properties can simplify the task. It is well known that the design of an absorbing material depends upon the selection and proper arrangement of dielectric and magnetic components, which can provide a proper impedance matching. The dielectric and magnetic properties of a material depends on its composition, particle shape & size, etc. [6], [8]. The material selection is a very important aspect in the development of multilayered structures. The materials utilized for this study are ferrite-graphene and Fe_3O_4-Ti based heterogeneous composites developed using bottom up and top-down nanaofabrication approaches. The frequency dependent complex permittivity and permeability values of materials have been measured using a vector network analyzer, N5247A PNA series network analyzer, 10 MHz - 67 GHz. Genetic Algorithm (GA) has been employed for the optimization of dual & triple layer structures. Further, results obtained from GA are validated with the help of Particle Swarm Optimization (PSO) and HFSS based EM simulator. Figure 1 (a) and (b) depicts the frequency dependent reflection loss (RL) characteristics of dual and triple layer EM wave absorbing structures. One can notice a quite good agreement between GA, PSO and HFSS data in terms of peak RL values, -10 dB absorption bandwidth and coating thickness. The dips in RL-frequency spectra's indicates the occurrence of absorption or minimum reflection of the EM wave for the particular thickness and frequency. The occurrence of the dips has been found to be due to a successive odd number multiple of the quarter wavelength thickness of the absorber, which is known as matching thickness and it can be expressed as: $t_m=n\lambda_g/4$ (n = 1,3,5….), where n = 1 corresponds to the first dip at low frequency [7]. In general, matching thickness t_m corresponds to the minimum RL value. The coating thickness greatly affects the EM wave absorption characteristics. Here, the matching thickness for dual and triple layer absorbers has been obtained using GA and PSO. The optimal thickness values for dual and triple layer absorbing structures are 1.4 mm and 1.6 mm, respectively. The next step was the fabrication and performance evaluation of optimum structures with corresponding matching thickness only. A flat rectangular aluminum alloy plate with dimensions of 94.5 mm (length) × 74.2 mm (width) × 2.0 mm (thickness) has been used for the coating purpose. The Al alloy substrate was properly polished with belt followed by different grades of emery papers and cleaned with the help of distilled water and acetone. Subsequently, optimum material (70 wt%) has been uniformly mixed into the epoxy resin (30 wt%) in order to form an EM wave absorbing paint. The prepared paint was coated on a conducting Al alloy sheet to study its absorption property. An indigenously developed single port waveguide measurement setup has been employed for the performance evaluation of fabricated absorbing coatings. Figure 2 (a) and (b) shows an image of measurement setup and corresponding fabricated sample. A triple layer absorber is found to possess a measured RL of -36.61 dB at 11.0 GHz with an effective absorption bandwidth of 3.0 GHz (9.0-12.0 GHz) for 1.6 mm absorber layer coating thickness as shown in Figure 2 (c). There is a slight deviation in RL curve, that may have arose due to fabrication errors. The concept of multi-layering benefits from the change of effective impedance with the distance into the composite, so that the reflections can be minimized. Multilayered structures have varying properties, such that their surface impedance is as close as possible to the incident wave impedance, which results in a change in their intrinsic impedance inside by gradually increasing their conductivity to provide minimum reflections at the boundary of each layer. The EM wave can go deeper into the multilayered structures as compared to single layer absorber and may result in more scattering within the absorber. This phenomenon prolongs the propagation path of EM wave in the structures and more absorption of the wave takes place.

CB-07. The influence of cobalt content on structure and magnetic properties of Fe-Si soft magnetic composites.

C. Zhou[1], C. Wu[1] and M. Yan[1]
1. Zhejiang University, Hangzhou, China

Fe-Co-Si soft magnetic composites (SMCs) containing Fe-Co-Si powers were firstly prepared by ball milling, phosphorus acid passivation and compaction. Phase composition with the Co content varied from 0 to 20 at% has been investigated and A2 + $D0_3$ phases have been obtained for the Fe-Co-Si alloy. The influence of Co content on saturation magnetization (M_s) of Fe-Co-Si powers have been investigated and the highest M_s was 175.9 emu/g obtained at 4 at% Co content. The effect of Co content on permeability and core loss of Fe-Co-Si SMCs have also been revealed. The optimal performances with the highest permeability of 110 and lowest core loss of 280.7 mW/cm^3 (50 mT, 100 KHz) were obtained at 12 at% cobalt content. Core loss was separated into eddy current loss (P_e) and hysteresis loss (P_h), indicated that the variation of core loss was determined by P_h. The mechanism of the variation of permeability and P_h was investigated through magnetocrystalline anisotropy constant (K_1) and saturation magnetostriction constant (λ_s). The λ_s.was proved to be the decisive role and it determined the variation of permeability and P_h, which was influenced by the couple effect between A2 and $D0_3$ phase.

CB-08. The effect of mechanical stress on the static hysteresis loop shape in NO electrical steel.

B. Schauerte[1], S. Steentjes[1], N. Leuning[1] and K. Hameyer[1]
1. Institute of electrical machines (IEM), RWTH Aachen University, Aachen, Germany

Magnetic properties of soft magnetic steel sheets alter significantly mainly due to mechanical stress [1]. This mechanical stress originates either from the different manufacturing processes [2-4] or the operation of electrical machines, e.g., centrifugal force or magnetic forces. Static hysteresis models that are used in the design process to represent the constitutive relation between the magnetic flux density and magnetic field are usually parametrized by means of standardized magnetic measurements on a single-sheet tester or Epstein frame according to the *IEC 60404-2* and *IEC 60404-3* standards. During these measurements either stress-relief annealed samples or samples that are made by a gentle method of cutting, e.g., wire or water jet cutting, are used. Commonly, the samples are not subjected to any external mechanical stress or specific residual stress during the measurements. However, when measuring the hysteresis loops of samples that are processed by a specific non-gentle method of cutting, such as blanking or laser cutting, samples of different width or assembled magnetic components, various hysteresis loop shapes can be obtained. These can deviate significantly from the hysteresis loop shapes of unprocessed (or gently-processed) soft magnetic material. The neglection of stress effects leads to a strong simplification that is often inadequate when considering the influence of the varying magnetic properties on the hysteresis loop shape and its dynamic behavior [5]. The underlying magneto-mechanical coupling is the result of intricate mechanisms at different spatial scales and is typically modelled by using micromagnetic or multiscale approaches. However, these are not suitable for an implementation in numerical tools such as Finite Element simulation packages due to their prohibitive huge computational effort. Simplified thermodynamic approaches were developed which are based on a phenomenological definition of a free energy density [6]. However, these approaches require a huge amount of measured data to represent the magneto-mechanical free energy density. This paper presents a thorough analysis of the effect of internal mechanical stress state on the static hysteresis loop and an efficient approach to include the magneto-elastic coupling in an energy-based hysteresis model, which allows one to replicate the material behavior based on a reduced amount of measured data. This energy-based hysteresis model is based on the decomposition of total field strength into reversible and irreversible components. The values of the model parameters are determined by using experimental data obtained at a uniaxial single-sheet tester which is equipped with a tensile and compression hydraulic loading unit. This enablesthe application of uniaxial mechanical stress collinear to the magnetic flux up to a maximum force of 5 kN. For the model parameter identification, two different schemes are developed: (i) a semi-physical scheme that uses the anhysteretic curve to identify the reversible field component and coercivity to identify the irreversible components and (ii) a mathematical scheme based on the least-square error minimization by means of a Levenberg-Marquardt and a differential evolution algorithm. The model's accuracy and predictive capability is analyzed in terms of energy loss and hysteresis loop shape prediction. The hysteresis model uses the magnetic flux density B as the independent field variable. The magnetic field H is separated into an anhysteretic component H_{An}, and a hysteretic component H_H, that considers the energy loss linked to the jerky domain-wall motion. In contrast to [7], this paper utilizes a set of two Langevin functions [8] to represent the anhysteretic field H_{An}: $H_{An} = B/\mu_0 - M_S\,[w\,(\coth(\lambda_a) - 1/\lambda_a) + (1 - w)\,(\coth(\lambda_b) - 1/\lambda_b)]$ with $\lambda_{a,b} = [H_{An}\,(1 - \alpha_{a,b}) + B\,(\alpha_{a,b} / \mu_0)] / a_{a,b}$ The hysteretic component H_H can be derived by the solution of the implicit function [7]: .$I_D Y_H\,(H_H - H_{H,0}) = (B_H - B_0)(H_{HS}£(\lambda_H) - H_H)$. I_D denotes the sign of the magnetic-flux-density change from the value at the previous step B_0 to the current step B. Y_H is a model parameter. $H_{H,0}$ denotes the previous value of H_H. The sought-after H_H has to be determined by iterative algorithms, such as Newton's method. £ is short for the Langevin function. The input variable for the Langevin function λ_H can be calculated by means of H_{HS} and model parameter a_H. $\lambda_H = [H_H - I_D H_{HS}] / a_H$ H_{HS} and a_H are model parameter. The proposed hysteresis model requires a set of eight parameter. Fig. 1 depicts a comparison of model prediction and measured data at three different stress levels. The full paper will show the model parameters with respect to the different mechanical stress levels and a parameter sensitivity analysis in which the parameters will be set in relation to characteristic values and the shapes of the modeled hysteresis curves. The energy-based hysteresis model allows one to gather an improved understanding of the magneto-mechanical modeling and to efficiently replicate the hysteresis loops for mechanical stress values between the examined operation points. This will be discussed in detail in the full paper.

CB-09. Improvement of Grain-Oriented Electrical Steel Sheet by Hyperfine Processing Magnetic Domain Structure on Vector Magnetic Characteristics.

M. Enokizono[1], D. Wakabayashi[3], T. Sato[2] and Y. Mamiduka[1]
1. Vector Magnetic Characteristic Technical Laboratory, Usa-city, Japan;
2. Faculty of Science and Technology, Oita University, Oita, Japan;
3. Mechanical and Electrical Engineering, Nippon Bunri University, Oita, Japan

Grain oriented electrical steel sheet has strong uniaxial anisotropy by grain orientation. The strong magnetic anisotropy using the tension effect of the coat has been manifested. The scratch sheet treated by the laser stress was developed so that this loss may decrease. However it increases the rotational loss in T-joint corner parts of three-phase transformer core. Furthermore the anomalous eddy current loss is large due to the effect of large grain and large magnetic domain size. We developed the new grain-oriented electrical steel sheet with low rotational power loss by hyperfine processing magnetic domain. According to this minute effect, faces store core loss were made to decrease to over 40%. According to this hyperfine processing effect of magnetic domain, it was possible the rotational power losses were made to decrease to over 40%. And the core loss of arbitrary direction decrease, also. The size of magnetic domain by hyperfine processing is within 0.25mm × 0.25mm. This hyperfine magnetic domain facilitates magnetization rotation. In this paper, we provide the vector magnetic characteristics of this steel sheet. HYPERFINE PROCESSING MAGNETIC DOMAIN STRUCTURE Figure 1 shows the sheet specimen which is high grade grain-oriented electrical steel for vector magnetic measurement. The specimen size is 80mm x 80mm rectangular sheet, 0.27mm thickness. The center area 40mm x 30mm is treated by hyperfine processing magnetic domain. The pitch width of this treatment by the fiber laser is defined PL in this paper. The pitch width was treated from 2mm to 0.125mm, as sown in Fig. 1. We could not improve over 0.25mm. Then best treated steel sheet was named the vector magnetic controlled steel sheet by hyperfine processing magnetic domain structure. Furthermore, Figure.1.shows the effect of pitch width (PL) on magnetic domain structure. The size of magnetic domain structure has been segmented small with decreasing pitch width size (PL). The magnetic domain structure was observed by magnetic viewer. This structure size by treatment of PL=0.25mm x 0.25mm has been segmented small, as the observation is more difficult. This hyperfine processing was carried by fiber laser system and suppresses the effect of the thermal stress for steel plate. This processing treatment is different from conventional scratch processing [1] [2]. Figure.2. shows the effect of pitch width (PL) on rotational magnetic power loss. The loss decreases with decreasing PL, the optimum effect in PL=0.25mm x 0.25mm are obtained and 26.7% loss reduction was obtained for the before treatment. In order to understand the parameter depend on magnetic power loss can be expressed. $W\theta_{BH}$ due to θ_H decrease but W_H due to |H| increases. That the difference in $W\theta_{BH}$ and W_H will be shown as follow $W_P = - \Delta W\theta_{BH} + \Delta W_H$, $\Delta W\theta_{BH} \rangle \Delta W_H$ Figur.3. shows the relation among B, H and θ_{BH} by hyperfine processing magnetic domain structure. θ_{BH} has been reduced, though H is increased by this effect as shown in this figure. It is indicated that this facilitates the rotation of the magnetization. CONCLUSION The hyperfine processing treatment of magnetic domain facilitates the magnetization rotation. This new improvement steel sheet can be easily design without considering the effect of anisotropic phenomena and high orientation. The advantage of this steel sheet is summarized in the following. (1)Anisotropic property by high grain orientation is eased by the hyperfine treatment of magnetic domain. (2)Rotational magnetic power loss decrease by the hyperfine magnetic domain. (3)The effect of transverse direction with hard magnetizing is large and effective. (4)The main factor of magnetic power loss(iron loss, core loss) reduction I the specific difference angle θ_{BH} between vector B and vector H. (5)By localized treatment near T-joint area of three-phase transformer core, total loss will decrease and upgrade efficiency. The conventional one-dimensional scalar magnetic characteristic measurement is insufficient for the materials development. Vector magnetic characteristic measurement is very important about research and development for reduction of loss and upgrading efficiency of electric power machines.

CB-10. Improvement of Grain-oriented Electrical Steel Sheet by Hyperfine Technique on Two-dimensional Magnetostriction.

D. Wakabayashi[1] and M. Enokizono[1]
1. Nippon Bunri University, Oita, Japan

It is known that high iron loss and large magnetostriction occur due to rotating magnetic flux at T-joint part of transformer core. Grain-oriented electrical steel sheet usually is used as the transformer core. In order to decrease the iron loss and the magnetostriction under rotating magnetic flux condition, we developed a newly vector magnetic characteristic control electrical steel sheet[1]. It was developed by laser processing to an existing steel sheet. In this paper, the measurement results of the new steel sheet are reported. Fig.1 (a) shows the laser processing equipment and the vector magnetic characteristic control electrical steel sheet. Three-axial stain gauge was passed on the steel sheet to measure two-dimensional magnetostriction. It is processed on the back of the steel sheet. The laser traces are 0.25 mm wide square. Fig.1 (b) shows magnetic domain images before and after laser treatment. The magnetic domain is oriented in rolling direction before the treatment. On the other hand, the magnetic domain is hyperfine after treatment. We call the hyperfine technique, vector magnetic characteristic control technique. Fig. 2 shows the measurement results before (conventional grain-oriented electrical steel sheet) and after (vector magnetic characteristic control electrical steel sheet) laser treatment. Fig. 2 (a) shows vector magnetic characteristic and two-dimensional magnetostriction. The direction of 0 deg.-180deg. is the rolling direction. The red arrow, blue arrow, pink line and black line in the patterns show the magnetic flux density vector, the magnetic field strength vector, expansion and contraction of two-dimensional magnetostriction respectively. These figures show relationship between direction of B-vector, H-vector and maximum magnetostriction[2-4]. Fig. 2 (b) shows iron loss and magnetostriction dependence on maximum magnetic flux density. Both the iron loss and magnetostriction are decreasing due to laser treatment. These results show the laser treatment is effective to lower the iron loss and magnetostriction of the transformer core. The full paper presents the detailed measurement results of two-dimensional mgnetostriction under vector magnetic characteristics on the new control steel sheet.

CB-11. Evolution of Residual Magnetic Field of U75V Steel Induced by Uniaxial Tensile Load with Increasing Amplitudes.

M. Fu[1], S. Bao[1] and Z. Zhao[1]
1. College of Civil Engineering and Architecture, Zhejiang University, Hangzhou, China

With a strong demand for methods to evaluate safety of engineering structures, there has been an increased interest in the investigation of the residual magnetic field (RMF) of ferromagnetic materials induced by external loads. Nevertheless previous work were mainly focused on the investigation of the unidimensional RMF variations of demagnetized materials, experimental research on the multidimensional RMF distribution characteristics induced by external loads in undemagnetized materials is scarce. To this end, in this research, the evolution of the RMF signals of initially undemagnetized U75V steel specimen under tensile load with increasing amplitudes was investigated. It was found that the fluctuation of the unidimensional RMF reduces with increase in load in the elastic stage, and remains relatively stable during the plastic stage. An effective way for characterizing deformation stages of the undemagnetized specimen was proposed. The two-dimensional vector distribution of the RMF indicates that the specimen tends to be magnetized as a rectangular magnet with an N pole and S pole at two ends with the increase of load. The possible reasons underlying the experimental results were discussed as well.

Magnetic structures exhibit a rich variety of nanometric scale patterns, textures and topological states, governed by various spin-coupling and spin-orbit-coupling mechanisms [1,2]. Mapping magnetization features in space and their dynamics is essential to understand magnetic behavior at the smallest scale. To date, imaging of the spin-state with high spatial and ultrafast temporal resolution is exclusively accessible in synchrotrons and free-electron lasers (FELs), providing for extreme-UV and soft-X-ray beams with circular polarization [3-5]. These large scale facilities enable magneto-optical microscopy since their high flux compensates for the small probability of the magneto-optical scattering. Sources of nanometric-wavelength radiation based on high-order harmonic generation (HHG) from visible and infra-red lasers are very appealing for dynamical imaging applications since they provide for exquisite spatial coherence [6], few-femtosecond pulse duration, controllable polarization [7-9], with a footprint of a standard optical table. In the last decade, the imaging capabilities of HHG were repeatedly demonstrated [6,11,12] for high-contrast micro-machined samples, however, imaging of material systems capable of pico- and femtosecond dynamics remained elusive. This work demonstrates the first magnetic imaging with high-harmonic radiation [10]. The XMCD (X-ray magnetic circular dichroism) phase and amplitude contrast of cobalt are independently mapped for a Co/Pd multilayer structure, revealing a worm-like ordering of the magnetic domains. The magnetic spatial features are retrieved from the diffraction pattern of a circularly-polarized high-harmonic beam passing through the magnetic multilayer and a partly transmissive mask, using coherent diffractive imaging (CDI) methods [12]. The ratio between the complex exit-waves recorded with left- and right-handed circular polarizations provided for a quantitative mapping of the magnetization components parallel (or anti-parallel) to the beam, with a resolution below 50 nm. To enhance the weak magneto-optical scattering signal, we use heterodyning with a strong auxiliary field, thereby overcoming the weak scattering probability. The experimental system is illustrated in Fig. 1a. Amplified pulses from a Ti:Sapphire laser system (repetition rate, 1 kHz; central wavelength, 800 nm; pulse energy, 2 mJ; pulse duration, 45 fs) are converted to a bi-circular field (circularly polarized field propagating with a counter-rotating second harmonic) by a MAZEL-TOV apparatus [9] for the generation of circularly polarized high harmonics [7,8] in a He-filled gas cell. The harmonics are focused and spatially dispersed by a toroidal grating, where the 38th order (21 nm, 59 eV) illuminates the sample. The sample (see Fig. 1b) is a free-standing 200-nm-thick Si membrane coated with a Co/Pd multilayer on the front and an opaque gold layer on the back-side. Using ion-beam milling, the gold is removed from the central aperture (4 um diameter) and 4 auxiliary holes are drilled through. The high quality diffraction and the resulting flat contrast reconstruction (see Fig. 2) allows to quantitatively evaluate the magneto-optical refraction for the cobalt in our multilayer, $\Delta\delta_{Co}$=0.022±0.002. To conclude, this approach will facilitate quantitative, spatially-resolved studies of ultrafast magnetization dynamics, that offer new opportunities in nanoscale magnetism. We believe that the increasing interest in ferrimagnets materials and structures for data-related applications may benefit a great deal from such a compact magneto-optical microscope, accessing the nanoscale, element-specific magnetization, even in the absence of a stray magnetic field.

CC-02. Exploring magnetism at the nanoscale with a single spin microscope.

V. Jacques[1]
1. Laboratoire Charles Coulomb, UMR5221, CNRS and Université de Montpellier, Montpellier, France

In the past years, it was realized that the experimental methods allowing for the detection of single spins in the solid-state, which were initially developed for quantum information science, open new avenues for high sensitivity magnetometry at the nanoscale. In that spirit, it was proposed to use the electronic spin of a single nitrogen-vacancy (NV) defect in diamond as an atomic-sized magnetic field sensor [1,2]. This approach promises significant advances in magnetic imaging since it provides non-invasive, quantitative and vectorial magnetic field measurements, with an unprecedented combination of spatial resolution and magnetic sensitivity under ambient conditions. In this talk, I will show how scanning-NV magnetometry can be used as a powerful tool for exploring exotic spin textures in thin magnetic materials focusing on (i) domain walls and magnetic skyrmions in ultrathin ferromagnets [3,4] and (ii) cycloidal antiferromagnetic order in multiferroic materials [5].

Central Facility for Electron Microscopy, RWTH Aachen University, Aachen, Germany

The atomic-level knowledge of local spin configuration of the magnetic materials is of great importance to predict and control their physical properties, in order to meet the challenges of ever-increasing demands on performance of functional materials. However, it is highly challenging to experimentally characterize magnetic properties of such materials with atomic scale spatial resolution. The leading techniques in spatially resolved magnetic imaging are magnetic exchange force microscopy and spin polarized scanning tunneling microscopy. However, as they are surface sensitive, very little information can be obtained regarding bulk or buried materials. The X-ray magnetic circular dichroism (XMCD) combined with photoelectron emission microscopy (PEEM) technique is a very attractive alternative because it has the spatial resolution as high as the polarized x-ray beam size besides element specific feature, as it is less surface sensitive and can be used to look at the interior of the thin films. However, the length scale of magnetic contrast using highly brilliant left and right circularly polarized X-ray beams is around 15nm [1]. The best option to push the spatial resolution of the spectromicroscopies lies in the electron beam equivalent technique electron energy-loss magnetic chiral dichroism (EMCD) [2], which is also called electron magnetic circular dichroism. Physically, XMCD and EMCD shares the same underlying physics in which the angular momentum transferred during X-ray absorption or inelastic electron scattering can selectively excite magnetic sublevels in atoms. The structured electron beams generated through interference of suitably phased plane waves can produce beams with orbital angular momentum. Electron beams can be easily focused compared with X-rays, allowing for atomic scale magnetism to be probed. Previously, we have found a strong EMCD signal in transition metal oxides allowing them to use standing wave methods to identify the different spin states of Fe atoms with site specificity [3]. In principle EMCD can offer higher spatial resolution and greater depth sensitivity due to the short de Broglie wavelength and penetration of high-energy electrons compared to XMCD. Recently by using EMCD and achromatic electron microscopy, we are able to access the magnetic circurlar dichroism with unit-cell resolution and even with atomic resolution [4,5]. Combining with advanced capobility of structural and chemical imaging by using aberration-corrected transmission electron microscopy, all the information including magnetic polarization, atomic configurations, chemical states can be simultaneously accessed from the very same sample region. In the examples of complex oxides including Sr_2FeMoO_6, $NiFe_2O_4$ and $La_{0.7}Sr_{0.3}MnO_3$[3-6], we would like to show how to achieve local atomic-scale magnetic, chemical and structural information and understand the structure-property relationship of these magnetic materials at the atomic level.

CC-04. Smart Magnetic Probes with Controllable States for Quantitative MFM.

O. Kazakova[1], V. Panchal[1], H. Corte-León[1], R. Puttock[1], L. Rodríguez[2] and V. Neu[3]
1. National Physical Laboratory, Teddington, United Kingdom;
2. Universidad del Valle, Cali, Colombia; 3. IFW Dresden, Dresden, Germany

A novel method for quantitative magnetic force microscopy (MFM) using smart functional magnetic probes with controllable states is presented [1-3]. A comprehensive method for visualisation and quantification of the magnetic stray field is applied to the particular cases of smart custom-made multi-layered (ML) and domain wall (DW) based probes with high/low magnetic moment states. ML probes were fabricated by deposition of Co/Si/Co layers on one side of a commercial Si probe (Fig. 1 a-b). V-shaped DW-probes were modified out of commercial magnetic probes using focused ion beam lithography (Fig. 1d). Both types of probes can controllably produce 4 stable magnetic states as confirmed by *in situ* MFM studies and e-holography visualisation of the probe states (Fig. 1 d left). *In situ* MFM studies of reference samples are used to define the probe switching fields and magnetization spatial resolution [1]. Quantitative values of the probe magnetic moments are obtained by determining their real space tip transfer function (Fig. 1c). The outcomes of the methods are introduced as inputs into a numerical model. The modelling results fully match the experimental measurements, outlining an all-inclusive method for the calibration of complex magnetic probes with a controllable low/high magnetic moment [1, 3]. Furthermore, a smart probe in the low moment state provide complementary information about the in-plane component of the sample's magnetization, which is not achievable by standard methods, thus allowing for 3D reconstruction of the sample's magnetisation. Through additional development of multivariate statistical methods this approach also provides a route to secure, traceable and authenticated digital solutions.

CC-05. Single Atom Magnets at Surfaces – State-of-the-art and Future Perspectives.

H. Brune[1]
1. Phyics, Swiss Federal Institute of Technology Lausanne (EPFL), Lausanne, Switzerland

Single ion magnets, or more generally single molecular magnets (SMMs), where the magnetic unit comprises more then one atom, are reality since many years. They are discussed as candidates for magnetic information storage, molecular spintronics, and quantum bits [1, 2]. Surface Science has opened up an alternative approach to this field which are single atoms adsorbed onto surfaces and investigated under ultra-high vacuum conditions. Ho atoms on two monolayer thick MgO(100) films grown on Ag(100) where found to exhibit magnetic remanence up to 30 K and relaxation times of at least one hour at 2 K [3]. This result was obtained from ensemble measurements using X-ray magnetic circular dichroism (XMCD). Spin-polarized scanning tunnelling microscopy (STM) measurements demonstrated reading and writing of individual Ho atoms and confirmed their long magnetic lifetimes [4]. Very recent STM experiments show stable magnetization over two hours in external fields of 8 T that are applied opposite to the magnetization of the atoms and at temperatures of 8 K [5]. We have identified two more systems that exhibit permanent magnetism in single adatoms, namely a superlattice of Dy atoms on the moiré pattern formed by graphene on Ir(111) [6] and for Tb/MgO/Ag(100) [7]. Recently, electron paramagnetic resonance (ESR) has been realized on individual Fe atoms with the STM [8]. We elaborate on the Physics giving rise to extremely stable magnetic quantum states of single adatoms and discuss the perspectives opened up by the combination of long magnetic relaxation times in single adatoms with the availability of ESR-STM measurements of magnetic coherence times.

CC-06. Investigation of anisotropic quadratic magneto-optic Kerr ellipticity of Fe(100) grown on Ir(100).

A.V. Pradeep[1,2], K.G. Ajesh[1], S. Ghosh[1,3] and P. Kumar[1]
1. Department of Physics, Indian Institute of Science, Bangalore, India; 2. Dept. of Collegiate Education Kerala, RWPC, Kannur, India; 3. Department of Physics, Cornell University, Ithaca, NY, United States

Magneto-optic Kerr effect (MOKE) is widely used as a tool to investigate anisotropic constants, coercivity, exchange bias field, domain structure and magnetization reversal of magnetic thin films and single crystals. In most of its application, the magneto-optic coupling (M-O) is assumed to be linearly dependent on magnetization. But, this assumption is not always valid. Recently, it is found that the dependence of M-O coupling is not only linear but also quadratic on magnetization. The second order dependence of M-O coupling on magnetization was observed recently from ferromagnetic metals[1], [2], Heusler alloys[3], [4] and half-metallic ferrimagnets[5]. Therefore, the analysis of MOKE measurements based on the assumption that magneto-optic coupling is linear on magnetization, are being modified up to quadratic terms. In addition quadratic magneto-optic Kerr effect (QMOKE) is useful in the investigation of higher order spin-orbit interaction and for measuring spin-orbit induced torque in ferromagnetic/heavy-metal interface[6]. Heavy-metal/ferromagnetic multilayer are the promising candidates in spintronics due to their higher efficiency in manipulating magnetism via electrical means[7]. The knowledge of QMOKE from such systems will be useful in designing spintronics devise. We have investigated the QMOKE signal from Fe(100) grown on Ir(100). We have already reported the real part of the quadratic Kerr angle (Quadratic Kerr rotation) from Fe(100)/Ir(100) system[8]. Here we discuss the imaginary part of quadratic Kerr angle (Quadratic Kerr ellipticity) and its anisotropy with sample rotation. Iron film of thickness 13 nm is grown on a clean (100) surface of a single crystal Iridium, using an e-beam evaporator inside a UHV chamber. The growth condition and deposition system were discussed elsewhere[9]. The substrate and film qualities are monitored using Auger electron spectroscopy (AES). The crystal structure is analyzed using LEED and XRD. Film growth is monitored using medium energy electron diffraction (MEED) and is found to be layer by layer up to 20 monolayer. Fe grows pseudomorphically on Ir(100) with Fe(100) plane parallel to Ir(100) surface and the in-plane [100] direction of Fe(100) parallel to the in-plane [110] direction of Ir(100). QMOKE signal are extracted using a full rotating field method at saturation. For this, we have used a simple QMOKE measurement system discussed elsewhere[5]. In order to extract the imaginary part of the complex Kerr angle, which is the Kerr ellipticity, a quarter wave-plate is installed between the sample and the analyzer of the QMOKE measurement system. Then, at a particular angle of sample rotation (r=90°), the Kerr ellipticity (e) is measured as the function of angle of magnetic field. This is shown in Fig.1(a). The linear Kerr ellipticity (e^L) and quadratic Kerr ellipticity (e^Q) are obtained by symmetrizing and anti-symmetrizing the measured Kerr ellipticity respectively. The linear Kerr ellipticity is shown in Fig.1(b) and quadratic Kerr ellipticity is shown in Fig.1(c). Since the measurements are done at saturation, the magnetization vector follows the magnetic field. Fig.1(d) shows the angle of magnetization (x_M) vs. angle of magnetic field (x_H). This curve is obtained using the relation $e^L(x_H)=L^*\cos(x_M)$ where L^* is the maximum value of linear Kerr ellipticity. Fitting the quadratic Kerr ellipticity with $e^Q=Q^*_1\mathrm{Cos}(x_H)\mathrm{Sin}(x_H)+Q^*_2\mathrm{Cos}(2x_H)$, the Q_1^* and Q_2^* are obtained. Then we systematically rotated the sample and above procedure is repeated to quantitatively measure the imaginary part of linear (L^*) and quadratic (Q_1^* and Q_2^*) components of MOKE for every angle of sample rotation. We followed the sign convention of ref [1]. Kerr ellipticity is measured using both s and p-polarized light. Kerr ellipticity averaged between the s and p-polarized light is plotted against the angle of sample rotation, which is shown as open symbols in Fig.2. Here open black squares represent the imaginary part of linear component of MOKE, which is isotropic with sample rotation and the black solid line represents the linear fit. Red open circles and the blue open triangles represent the imaginary part of quadratic component of MOKE Q_1^* and Q_2^* respectively. The quadratic component of MOKE are anisotropic with respect to the sample rotation. The red and blue solid lines represent the fit to the data using equations $Q_1^*=b^*+c^*\cos(4r)$ and $Q_2^*=(-c/2)\sin(4r)$ respectively. From the fit, the parameter L^*, b^* and c^* which relate the linear (K) and quadratic (G and ΔG) magneto-optic coupling coefficients are obtained. The value of L^*, b^* and c^* are +6.37±0.04 mdeg, −5.95±0.09 mdeg and −4.2±0.2 mdeg respectively.

With the fast development of information storage, exploiting new concepts for dense, fast, and non-volatile random access memory with low energy consumption is a significant and challenging task. To realize this goal, electric-field control of magnetism is crucial. In this regard, multiferroic materials are important and have attracted much attention due to their interesting new physics and potentials for exploring novel multifunctional devices [1,2]. In the multiferroic materials, electric polarization can be tuned by applying an external magnetic field or vice versa. This magnetoelectric (ME) effect originates from the coupling of the magnetic and ferroelectric orders. However, single-phase multiferroic materials are rare and the multiferroic heterostructures, composed of ferromagnetic (FM) and ferroelectric (FE) materials, provide an alternative way for exploring the ME coupling effect. One of the key issues in the study of the FM/FE heterostructures is the control of magnetism via electric fields, which is essential for the new generation information storage technology. We have carried out electric-field control of magnetism in different FM/FE heterostructures in our previous work [3,4]. Although a lot of work have been carried out on electric-field control of magnetism in multiferroic heterostructures via interfacial strain coupling, most of the previous reports on electric-field control of magnetism in FM/PMN-PT through strain-mediated interaction are volatile with a *butterfly-like* behavior. Recently, for the first time, we reported a large and nonvolatile *loop-like* bipolar-electric-field-controlled magnetization at room temperature in $Co_{40}Fe_{40}B_{20}$(/$Pb(Mg_{1/3}Nb_{2/3})_{0.7}Ti_{0.3}O_3$(001) (CoFeB/PMN-PT(001)) and it was proposed that the unusual nonvolatile behavior is related to the 109° FE domain switching in PMN-PT[3]. So far, CoFeB/PMN-PT(001) has been one of the widely studied multiferroic heterostructures. However, one important issue remains to be solved — the magnetic responses of CoFeB corresponding to the different FE domain switching of PMN-PT(001), namely 109°, 71° and 180° domain switching, under bipolar electric fields along the [001] direction. The reason is that in the previous reports, macroscopic magnetic measurements on CoFeB films got the total magnetization from the magnetic responses of CoFeB corresponding to the different FE domain switching of PMN-PT(001). Even using techniques with spatial resolution, it could not get the distinct magnetic behavior of CoFeB related to the different FE domain switching of PMN-PT(001) as shown in our previous work [5] because the intralayer magnetic interactions hinder the complete response of magnetic domain to the strain induced by FE domain switching. This issue is very important for understanding the mechanism of electric-field control of magnetism in FM-FE multiferroic heterostructures and it's also very important for applications in terms of domain engineering for designing devices based on distinct magnetic response of CoFeB related to different FE domain switching. We solve this problem by patterning the CoFeB film of CoFeB/PMN-PT(001) into separated and small non-interacting discs whose size is comparable to the FE domains [6]. Such mesoscopic structures are essential for observing the distinct behaviors of electric-field control of magnetism corresponding to the different types of FE domain switching because the behavior of electric-field control of magnetism for these discs depends on the type of FE domain switching underneath them. By using spatially-resolved techniques including magneto-optic Kerr effect (MOKE) and scanning electron microscopy with polarization analysis (SEMPA) with in situ electric fields, we uncover the distinct behaviors of electric-field control of magnetism corresponding to the different types of FE domain switching in CoFeB mesoscopic discs on PMN-PT(001). For the first time, the 90° rotation of the magnetic easy axis induced by 109° FE domain switching was observed. Both MOKE and SEMPA demonstrate three types of magnetic responses to electric fields, with type I and type II attributed to 109°, 71°/180° FE domain switching, respectively, and type III attributed to a combined behavior of multi-FE-domain switching. In addition, for the first time, we systematically studied the variations of effective magnetic anisotropy field with electric field and correlated them with the proposed different FE domain switching paths. This work is significant for understanding the distinct magnetic responses to different FE domain switching, and shedding light on the path of FE domain switching. The spatially-resolved study of electric-field control of magnetism on the mesoscale paves the way for further nanoscale research, which is important for the realization of low-power consumption and high-speed MRAM utilizing these materials.

RFID has become very widespread in both everyday life and specific scientific applications for the exchange data or the identification and/or tracking of transponders (tags). The performance of a short-range (0 - 1 m) RFID system generally depends on both the properties of the tag(s), and the qualities of the reader antenna and host electronics. The most prolific passive tag-based system, uses tags with no internal power source, which use the EM field emitted by the reader to power their internal circuits [1]. Here we describe and demonstrate the capabilities of an inductive magnetic field mapping platform designed to aid the characterisation and optimisation of passive near-field RFID tags for financial payment and national identity smartcards (ID-1), operating at 13.56 MHz (HF) as defined by the ISO/IEC 14443 standard [2]. Smaller modules are currently being integrated in smaller devices, such as wrist-bands, watches and items of jewlery. Limited flux-integration areas of the antena lead to smaller coupled power and a shorter communication range. One possible counter-measure is the use of flux-concentrating magnetic material. In the HF region, there are two main competing soft magnetic families - low-permeability insulating ferrites and high-permeability metallic micro patricle systems such as sendust. Sendust is a magnetically soft ($H_c \sim 5$ A m^{-1}) iron-rich alloy of Fe, Al and Si of general composition 6-11 wt. % Si, 4-8 wt% Al, discovered by researchers in Sendai, Japan, in 1936 [3] as a higher permeability (max. ~ 1.4 10^5) cheaper alternative to permalloy in inductor and magnetic flux concentrator applications. Other essential properties of sendust are its high resistivity (~ 10^2 μΩ cm) and low loss within the low RF ranges, 0.1-1000 kHz. Unsurprisingly, as the frequency of operation increases, the real part of the magnetic permeability decreases and the losses (hysteretic, eddy current and anomalous) increase. The integration of sendust components in RFID tags is therefore subject to a number of constraints and poses a non-trivial multiple-parameter optimisation problem, which requires the detailed and quantitative understanding of the near field RF distributions created. The quantitative RF field imaging system, presented on fig. 1a is comprized of two main sub-systems: a stepper motor-driven 4-axial table, which holds the measured RFID tag-assembly, and a source coil (2 turns of 0.5 mm diameter wire, with an overal diamater of 21 cm), powered by an RF broadband amplifier (constant 40 dB gain, 50 Ω coupled). The second main sub-system is comprized by a 4-micro-coil assembly, allowing for the measurement of H_x, H_y, H_z and dH_z/dz and a 4-channel Vector Network Analyser (VNA), which produces the excitation waveforms and acquires the in- and out-of-phase signals. The individually insulated sensing coils on their poly-carbonate carriers are glued together in one monoblock assembly (see fig. 1b), which is in turn mounted on a transparent poly-carbonate carrier, allowing for easy optical alignment to the Device Under Test (DUT). The VNA used is of the R&S ZVB series with a front-end band-width of 20 GHz and allows for the rapid and simultaneous acquisition of 4 complex transmission spectra (S41 to S44). The measurment consist of acquiring 4 complex transmission spectra (of at least 101 frequency points each) for each spatial point of a rectangular (x, y) grid - i.e. a constant z-cut. The postprocessing of the data involves corrections for direct inductive pick-up between the source coil and the sense coils, corrections for non-orthogonality of the vector components and calibration of the source and measured field magnitudes. An example of a vector field map of the HF magnetic field is shown on fig. 1c. The region of the copper RFID module coils is clearly seen around the perimeter, as are the CMOS chip (at the bottom of the visible field) and the 200 μm thick, sendust film of lateral dimenions (3 x 40 mm). The vector reconstruction corresponds to the peak-resonance frequency region of 13.6-13.7 MHz. As expected, the imaginery components, at resonance, are small and only contain useful information about a small region of space between the sendust strip and the CMOS chip. As frequency spectra are obtained at every spatial point of the scanned field, these can be processed and fitted to simple analytical models or compared to finite element calculations as required. Fig. 2 represents thesimultaneous fitting of the real and imaginery parts of the frequency spectra, for a point just above the copper coils of the tag, half-way up the length of the coil, to a model comprised of two damped harmonic oscillators. The type of complete spatial, full-vector, complex magnetic susceptibility imaging presented here should open pathways to the integration of magnetic materials in near-field short-range communication sysytems, including, but not limited to RFID.

Characterization of magnetic nanoparticles (MNPs) is important for their standardization and optimization for specific applications[1]–[3]. One of the characterization methods is AC susceptibility measurement where this method can provide fast information of MNPs on dynamic magnetization, size distribution and magnetic anisotropy[1], [2], [4], [5]. In this study, we report a development of a sensitive AC magnetometer using induction coils for characterization of MNPs in nonlinear magnetization region. The developed AC magnetometer system consists of two main parts: magnetic field excitation unit and magnetic response detection unit. Using a cylindrical surface current model [6], the excitation coil of the magnetic field excitation unit was designed to produce a high homogeneity and strong excitation magnetic field for a 1-ml cylindrical sample. The excitation coil was wound to be 300 turns with an inner diameter of 30 mm using a Litz wire. To prevent voltage breakdown and sparks, and mitigate the temperature rise of the excitation coil during excitation of high magnitude and frequency of current, a specific fabrication design was adopted. To generate high excitation magnetic field at high frequency, a resonant technique was applied where multiple values of polypropylene film capacitors were connected in series to the excitation coil. The resonant frequency was determined from the selected value of capacitance. For the magnetic response detection unit, an induction detection coil was fabricated using a 0.25-mm Cu wire. The detection coil was configured to be a first-order axial differential coil, whose inner diameter was 15 mm and one coil had 1000 turns. The detection coil was placed into the excitation coil and the cancellation rate of the excitation magnetic field was improved by manually tuning the position of the detection coil at the axis of the excitation coil. The detection coil was connected to a lock-in amplifier (LI5640, NF Corporation) for a phase-sensitive detection. We first measured the complex impedance of the excitation coil. The resistance of the excitation coil showed a constant value of 1.3 Ω until 1 kHz and increased in a higher frequency region. The measured reactance of the excitation coil increased linearly with respect to frequency and the inductance was measured to be 1.52 mH. The increase of impedance at high frequency was found to be due to the inductance of the excitation coil where the increase of the impedance can be compensated using a LCR resonant circuit. To evaluate the effectiveness of the resonant technique, the current magnitude of the excitation coil connected with a current supply and resonant capacitors was measured when the current supply was operated in a constant voltage mode at different resonant frequencies. Compared to the case when the resonant technique was not applied, the current magnitude was maintained to a constant value up to 18 kHz. The homogeneity of the excitation field for a region of 15 mm × 10 mm was measured to be 95%, which was in good agreement with the simulation result. The excitation coil showed a high efficiency of 5.2 mT/ampere at the high homogeneity region, enabling characterization of MNPs in the non-linear magnetization region.[7] The DC resistance and inductance of the detection coil were measured to be 41.46 Ω and 16.76 mH. The complex impedance of the detection coil increased when the frequency was greater than 1 kHz and a self-resonant characteristic was observed at 70 kHz. Using a small 30-turn coil, the gradient characteristic and the sensitivity of the detection coil were measured, where detection sensitivity of a sample can be improved when the sample is placed at an optimized position relative to the detection coil. The developed system showed a sensitivity of 5×10^{-10} $Am^2/\sqrt{Hz}$ at 100 Hz. The feasibility of the developed system was demonstrated by measuring the dynamic magnetization of a commercial multi-core iron oxide nanoparticles, namely nanomag-D-spio D100 (Micromod Partikeltechnologie GmbH, Rostock-Warnemuende, Germany), having a mean hydrodynamic size of 100 nm. Different solutions of iron concentration were prepared from 0.24 mg/ml to 300 ng/ml by diluting the stock solution with purified water. The developed system successfully measured the harmonics response of the iron oxide nanoparticles at different iron concentrations where a linear relation of third, fifth and seventh harmonics were observed with respect to iron concentration. The non-linear magnetization characteristic of the iron oxide nanoparticles was observed when the amplitude of the excitation field was greater than 3 mT. We also demonstrated the ability of the developed to measure the complex susceptibility of the iron oxide nanoparticle solutions. The real component of magnetization m' showed a constant response until 18 kHz while the imaginary component of magnetization m'' slightly increased with increasing frequency, inferring that the Neel relaxation was dominant in the iron oxide nanoparticles. Therefore, a sensitive characterization of magnetic fluid can be expected by using the developed system. This work was supported by Ministry of Higher Education of Malaysia under grant number of RDU 160115 and Research Management Center of Universiti Malaysia Pahang under grant number of RDU 170377.

Current induced domain wall motion (CIDWM) is attractive for several applications arising from spintronics. Since its discovery, the spin-transfer torque (STT) allows one to envision several memory candidates, or magnetic based computation technologies, combining, for example, tunability, high density, rapid operation, altogether with inherent magnetic non-volatility and energy efficient read/write/store operations. CIDWM can be achieved through the spin-transfer torque (STT) given by spin polarized carriers to the local magnetic states [1,2]. Lower threshold current density j_{th} for CIDWM and higher domain wall (DW) velocity v_{DW} are expected if spontaneous magnetization M_S gets smaller as the amount of torque for magnetization reversal should scale with M_S. In addition, j_{th} is expected to be smaller in perpendicularly magnetized layers than in-plane magnetized layers [3,4]. Therefore, magnetic materials possessing perpendicular magnetic anisotropy (PMA) and small M_S are very interesting candidates for spintronic devices based on CIDWM. We are interested in ferrimagnetic Mn_4N thin films. First, Mn_4N has a large perpendicular magnetic anisotropy (μ_0H_K about 3 T) and a small μ_0M_S (0.14 T) [5,6]. So Mn_4N is in principle a promising candidate for CIDWM in materials with strong PMA and small M_S. Second, it is a ferrimagnetic material composed of only abundant, light and cheap elements. In this paper, we characterize and compare domain wall (DW) properties of Mn_4N thin films grown on MgO or $SrTiO_3$ (STO) substrates. Single crystalline Mn_4N films have been deposited at 450 °C using molecular beam epitaxy [6], with a 3-nm-thick SiO_2 cap. The magnetic properties have been evaluated by Magneto-transport, and the magnetic configuration has been observed by magnetic force microscopy (MFM) or Kerr microscopy. We observe large Extra-Ordinary Hall effect (~2%) despite Mn_4N is being made of only light elements. Moreover we show that we can achieve magnetization reversal with millimeter sized magnetic domains in Mn_4N thin layers. Finally, we report very efficient CIDWM properties in Mn_4N nanostrips. Figure 1 presents the hysteresis loops (minor for B) measured by Extra-Ordinary Hall resistivity ρ_{EHE} for the fabricated Mn_4N films. Focusing on the two films grown on MgO, the 30 nm one (A) has better magnetic properties than the 10 nm one (B), with a lower coercive field and a higher remanence. The sample (C), grown on STO, possess a full remanence (M_r/M_S=1.0), a quite sharp magnetization switching and even a smaller coercive field, compared to (A). The higher quality of the films deposited on STO can be seen when imaging its magnetic domains. Figures 2 show domain structures of Mn_4N films captured by MFM or Kerr microscopy after partial magnetization reversal process from the saturated state. The sample deposited on MgO shows small magnetic domains, despite the small M_S and large K_u of Mn_4N which should lead to large equilibrium domain size. We attribute this to the presence of a large distribution of pinning defects, also responsible for the higher coercivity of thinner sample (B). The sample grown on STO has far larger magnetic domains, propagating with incredibly big domain sizes (larger than 1 mm). In addition, the smoothness of the DWs in this layer indicates that there are few intrinsic DW pinning sites, which agrees with the sharp magnetization switching in the hysteresis loop. We attribute the differences observed between the Mn_4N/MgO and Mn_4N/STO systems to the large misfit between Mn_4N and MgO (-7.6%) compared with STO (-0.4%), which leads to defects that can trap DWs. As the relaxation of the strain occurs at the vicinity of the interface, the importance of these defects is clearer in the thinnest film deposited on MgO. We successfully observed the effect of STT on the coercive field and will report very efficient CIDWM in Mn_4N wire. Though the detail will be presented at the conference, STT efficiency ε, calculated by the equivalency between the magnetic field and the electrical current density for magnetization reversal is found to be around 7×10^{-12} Tm^2/A. The threshold current density for CIDWM is observed at 2×10^{11} A/m^2, and the DW velocity v_{DW} reaches over 200 m/s in first attempts, without any assistance of external field or spin-orbit torque from the cap layer. In summary, this paper reports the first investigation of CIDWM in Mn_4N. DW properties in Mn_4N film were drastically improved by changing substrate from MgO to STO. We report magnetization reversal with extremely large domain size, due to few domain nucleation centers and smooth DW propagation. In addition, the Mn_4N/STO system shows great potential for application to CIDWM devices with low threshold current and ultrahigh DW speed. This work was financially supported in part by JSPS (No. 26249037) and JSPS Fellows (No. 16J02879).

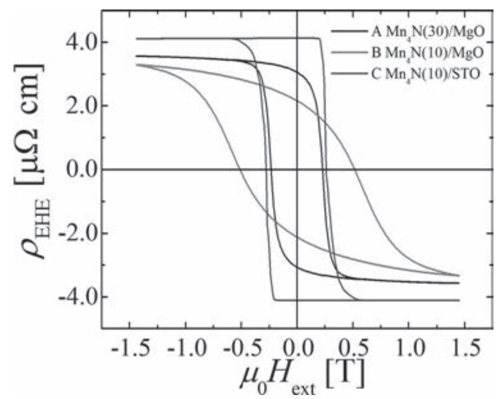

Fig. 1. Hysteresis loops of the samples A-C obtained by Extra-Ordinary Hall effect. The samples on MgO have smooth curves, and thinner sample B cannot be saturated by only 1.5 T. In contrast, sample C on STO has well squared loop with full remanence. The sharp switching around 0.2 T indicates that DW motion in sample C is easier than in the one deposited on MgO.

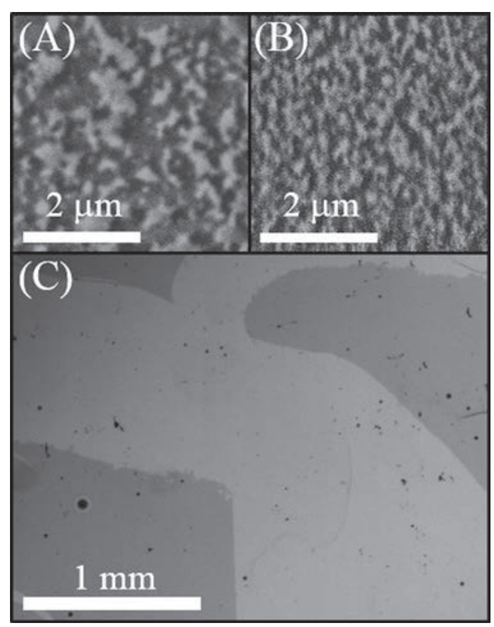

Fig. 2. RMFM (A, B) and Kerr microscopy images (C) of the domain structure after demagnetization. The films on MgO have small and not continuous domains, while that on STO has extremely large domains wider than 1 mm, which indicates few nucleation centers and DW pinning sites.

Recently, antiferromagnetic materials have attracted increasing attention because of their large magnetotransport and thermomagnetic effects, in which the electronic band structure associated with the noncollinear spin configuration is responsible for generating Berry curvature through spin-orbit coupling[1-3]. The anomalous Nernst effect (ANE) is a thermoelectric phenomenon typically observed in ferromagnets under the application of a temperature gradient, in which a transverse voltage is induced perpendicular to both the temperature gradients and the magnetization. Recent experimental studies have shown large ANE in a noncollinear antiferromagnetic metal Mn_3Sn with a vanishingly small magnetization of 0.002 μ_B per Mn atom[4,5], whose band structure has the Weyl points near [6,7]. In previous studies, the fabrication of thermoelectric devices with the enhanced Seebeck effect has proven to be complicated, owing to the requirement for alternately aligned p- and n-type semiconductor pillars[8]. On the other hand, the ANE allows the design of much simpler thermopiles composed of laterally series-connected wires. Toward realizing a thermopile made of the chiral anti-ferromagnet Mn_3Sn, focused ion beam (FIB) lithography was employed to microfabricate a thermoelectric element consisting of a $Ta/Al_2O_3/Mn_3Sn$ layered structure[9]. Figures 1(a) and (b) show a schematic illustration of the microfabricated Mn_3Sn device structure for measuring ANE and the magnetic structure of the Mn_3Sn when the magnetic field is applied along the [01-10] axis, where the thermal gradient is applied along the [0001] axis. In this device, the Ta layer acts as a heater producing Joule heat diffusing across the Al_2O_3 insulating layer into the thin Mn_3Sn layer. All measurements were performed at room temperature in vacuum. Figure 2 shows the ANE results for the configuration shown in Fig. 1(a) obtained for a dc current of ±1.5 mA applied to the Ta heater. The measured AN signal exhibits a clear hysteresis in an applied temperature gradient and magnetic field. The V_{ANE} is indeed independent of the direction of the applied electrical current in the Ta heater. This indicates that the hysteresis loop in Fig. 2(a) is arising from the ANE in Mn_3Sn. The observation of the spontaneous, zero field value is essential for construction of the thermopile element. Figure 2(b) shows the electrical current dependence of V_{ANE}. The voltage increases with the electrical current in the Ta heater. The sign and magnitude do not depend on the direction of the electrical current. The magnitude is also proportional to the square of the electrical current applied to the Ta heater. In addition, the angular dependence of ANE in the configuration shown in Figure 1(a) shows a small anomaly around 60° when the magnetic field is rotated from the [2-1-10] axis (0°) to the [01-10] axis (90°). On the other hand, in another ANE-measurement device of Mn_3Sn, the shape of the hysteresis of ANE has a step structure depending on the electrical current in the Ta heater just beside the microfabricated Mn_3Sn. According to the theoretical study, six magnetic domains that are different at each 60° are proposed in Mn_3Sn[10]. However, an additional study is required to clarify the origin of this structure. In summary, we evaluated the ANE in a microfabricated device comprised of the chiral antiferromagnet Mn_3Sn as a first step to realize a thermopile device. The spontaneous, zero field voltage signal in the device is of the order of a few μV, which is almost the same order of magnitude as observed in the bulk single-crystal Mn_3Sn under a temperature gradient. The anomalous Nernst coefficient S_{ANE} of the microfabricated element was determined using a temperature gradient simulated by finite-element modeling. The experiment and simulation revealed that the ANE coefficient is 0.27 μV/K which is in good agreement with the bulk value. This result indicates that the FIB microfabrication does not significantly alter the thermoelectric properties of bulk Mn_3Sn. As the chiral antiferromagnet produces almost no stray field, our study opens the avenue for the fabrication of an efficient thermopile by densely packing the microfabricated antiferromagnetic elements. In this work, the Mn_3Sn microdevice was fabricated from a bulk crystal, rather than through the deposition of thin films. This approach enables us to investigate thermoelectric phenomena on the nanoscale in wider range of materials than conventional materials used in thin film based devices.

The behavior of a magnetic domain wall (DW) is similar to that of many other types of interfaces in physics, such as vortices in superconductors, soap films or surfaces of liquids. The main parameter required to explain the observed behavior is the surface energy γ. This energy plays a very important role in the dynamics and statics of the DW, such as the topological transition of magnetic textures from domain stripes to skyrmionic bubbles[1]. Moreover, the stabilization and the size of these skyrmionic bubbles is directly determined by the competition between the DW surface tension and the dipolar interaction[2]. Another example, in the artificial pinning of DWs at constrictions, the depinning process is directly related to the increase of the surface energy γ due to the modification of the DW length to move out of the constriction. However, it is difficult to directly observe the effect of the DW surface energy and determine its value. In this presentation, we report the direct observation and measurement of magnetic DW surface tension in CoFeB thin films with perpendicular anisotropy. In small magnetic squares, we observed that semicircular domain bubbles could spontaneously collapse in zero magnetic fields, as shown in Fig. 1(a). This can be explained by the Laplace-Young pressure on the DW induced by its curvature and the associated surface energy, read $P=\gamma/R$, where R is the radius of curvature. Then, an external magnetic field was applied to stabilize these semi-circular domain bubbles. We found that when the external field is larger than a critical value, the bubble expands; when the external is smaller than this value, the bubble collapses. A clear boundary (representing the stabilizing field) between the expanding field and contracting field was found. The stabilizing fields change linearly with the inverse of the radius of bubbles, as shown in Fig. 1(b). This relationship enables us to determine the surface energy of the DW quantitatively. Our experiments further showed that the surface energy could lead to a geometrically induced pinning when the DW propagates in a Hall cross or from a narrow wire into a nucleation pad, as shown in Fig. 2(a). We further demonstrate that the measurement of the depinning field as a function of the wire width, as shown in Fig. 2(b), is another way to estimate the surface energy of the DW. In addition, some other interesting phenomena, such as the interplay of two adjacent bubbles under the competition between the dipole interaction and the unbalanced Laplace pressure were observed. The dynamic process will be presented. Moreover, a new type of magnetic sensors, which can detect the magnetic field based on the surface tension (or elasticity) of the DW is proposed based on the above experiments. In summary, our experiments reveal that the surface tension can be an important fundamental parameter dominating the behavior of DWs, and thus be directly observable. Two new methods to directly measure the surface energy of the DW are proposed and verified. This accurate measurement of the DW surface energy is very helpful to estimate intrinsic parameters such as Dzyaloshinskii-Moriya Interactions (DMI) or exchange stiffness in magnetic materials and to better understand the role played by the different energy terms involved in the physics of DWs. Note that the DMI results in an additional term in the expression of the surface energy γ that is proportional to the DMI coefficient[3]. Moreover, understanding of the dynamic behavior of DWs governed by its surface tension is important to develop novel devices such as racetrack memory and the DW based magnetic sensors[4,5].

The ability to move magnetic domain walls by electrical current enlightens novel ways for developing non-volatile memory and logic devices [1], [2]. The realization of current driven domain wall motion (DWM) in heavy metal (HM)/ ferromagnet (FM)/ oxide heterogeneous structures can be attributed to the combined effect of spin Hall effect from HM and Dzyaloshinskii-Moriya interaction (DMI) at HM/FM interface [3], [4]. Different combinations of spin Hall angle (positive or negative) and effective DMI field (left or right) determine the direction of DWM with respect to the current direction [5]–[7]. Alternating the direction of DWM often requires the selection of different HM or FM materials. Here, we show that it's able to control the direction as well as velocity of the current induced DWM by varying the relative thicknesses of two heavy metal underlayers. In our experiments, all films were deposited by magneton sputtering (DC for metals, RF for oxide) with base pressure ≤ 2×10^{-8} Torr. The film stacks were substrate/ Ta(0.5)/ Pt(3)/ W(0.6, 0.8, 1, 1.5)/ FeCoB (1.2)/ MgO(2)/Ta(1) with units in nanometers. Note that the bottom and top thin Ta layers are for film adhesion and capping purposes, and the effect of spin Hall torques from these layers on the FeCoB layer are negligible. The films were then annealed at 305 ^{0}C under 0.4 T magnetic field perpendicular to the film surface. Magnetization curves were measured by Alternating Gradient Field Magnetometer and all films exhibited perpendicular magnetic anisotropy. Magnetic bubble domain testing [8] was conducted to measure the domain wall chirality at the W/ FeCoB interface. Figure 1 shows the velocity of down-up and up-down domain walls as a function of in-plane magnetic field under $\mu_0H_z = 0.5$ mT. The results show that the domain wall has right-handed chirality at the W/ FeCoB interface, which agrees with previous observations by other group [5]. The minima in Figure 1 indicate the effective DMI field is around 43 mT. Next, films were lithographically patterned into 4 μm-wide 26 μm-long wires with bowtie-like contact pads on each side. The domain wall motion under nanosecond current pulses was tracked by Kerr microscope, where the velocity of domain wall motion was determined with the sequences of Kerr images. The velocity of current driven domain wall is plotted in Figure 2 as a function of W layer thickness, where positive velocity indicates domain wall motion along the current direction. We observe that the domain wall moves in the same direction as the current when W layer thickness is above 0.8 nm. Meanwhile, the domain wall velocity is linearly dependent on W layer thickness. Once the thickness is reduced below 0.8 nm, however, the motion direction switch to that against the current direction. Such phenomenon arises from the injection of two spin currents into the FeCoB layer with opposite signs of spin polarization (Figure 2 inserted), which further causes the competition of two opposite spin orbit torques. The two spin currents are generated by the spin Hall effect of the two heavy metal underlayers, where they reach balance at 0.8 nm thick W layer, as indicated by the zero domain wall velocity. In summary, we have demonstrated that by changing the relative thicknesses of two heavy metal underlayers we are able to control the direction and velocity of current driven domain wall motion. It results from the competition of two pure spin currents with opposite signs of spin polarization generated by the spin Hall effect of the heavy metal underlayers. Such way of manipulating current driven DWM would spark novel designs in spintronic devices and applications.

Current-induced magentic domain wall motion in ferromagnetic materials has been attracted much attention both from scientific and technological points of view [1,2]. When a magnetic DW is driven by electric current via adiabatic spin torque, the theory predicts a finite threshold current even for a perfect wire without any extrinsic pinning [3]. We have shown that this intrinsic pinning determines the threshold current, and thus that the adiabatic spin torque dominates the DW motion resulting in DW motion along electron flow direction, in a perpendicularly magnetized Co/Ni system sandwiched by a symmetric capping and seed layers [4-10]. On the other hand, current-induced DW motion against electron flow direction has been observed in ultrathin magnetic films in which the structural inversion symmetry (SIA) was broken [11, 12].This DW motion against electron flow direction has been explained by the combination of a chiral DW and spin Hall torque [13, 14]. Antiferromagnets are expected to show much faster spin dynamics than ferromagnets because they have higher resonance frequencies than ferromagnets. However, experimental investigations of antiferromagnetic spin dynamics have remained unexplored mainly because of the immunity of antiferromagnets to magnetic fields. Furthermore, this immunity makes field-driven antiferromagnetic DW motion impossible despite rich physics of field-driven DW dynamics as proven in ferromagnetic DW studies. We show that fast field-driven antiferromagnetic spin dynamics is realized in ferrimagnets at the angular momentum compensation point T_A [15]. Using rare-earth–3d-transition metal ferrimagnetic compounds where net angular moment is nonzero at T_A, the field-driven DW mobility remarkably enhances up to 20 km/sT. This remarkable enhancement is a consequence of antiferromagnetic spin dynamics at T_A. Such a high DW velocity leads to coherent terahertz spin-wave emission [16]. Our finding allows us to investigate the physics of antiferromagnetic spin dynamics and highlights the possibility of ferrimagnets for DW devices. The motion of domain walls(DWs) in one-dimensional conduits is expected to sensitively depend on the geometry of the cross-section of the conduit. In flat strips, DWs may be of either transverse or vortex type. These DWs share the same topology, which permits the easy transformation of one into another during motion. This is the Walker breakdown, which results in strongly reduced wall velocities above a few mT[1], and also limits the velocity under current. In cylindrical nanowires, transverse-vortex walls also exist (TVW), however a wall with a different topology has been predicted: the Bloch point domain wall (BPW): a quasi-orthoradial curling of magnetization around the core of the DW, where magnetization vanishes for symmetry reasons. The BPW is named after this micromagnetic singularity[2]. Above a threshold diameter of about 7*Δ_d (where Δ_d is the dipolar exchange length), the BPW should be of lowest energy. When motioned under magnetic field, related to their special topology BPWs are expected [3] to remain locked and reach a steady-state motion with a high mobility (proportional to $1/\alpha$, α being the damping parameter). Besides, the chirality of the BPW, i.e. the sense of its orthoradial curling, should be right with the direction of motion [3]. We report results on wires made of soft magnetic alloys (Ni, Fe_xNi_{1-x} and Co_xNi_{1-x}) electroplated in insulating templates with cylindrical holes. The latter are dissolved so that individual wires can be collected and inspected at a wafer surface. We were first to provide the experimental evidence for BPWs[4], using shadow XMCD-PEEM. Here we report several key advancements of the topic. First, we improved the material quality, exploring composition and annealing conditions. This allowed to decrease extrinsic pinning to propagation fields around 10mT or below. Second, we performed experiments of DW motion under magnetic field, from quasistatic to down to nanosecond pulses. Imaging the DW before and after the pulse allows us to track changes in its configuration with shadow XMCD-PEEM, accessing the type, and chirality in case of BPW. We confirm the tendency for the selection of the chirality depending on the direction of motion. Also, beyond a threshold in the range 10-20mT, we evidenced transformation of DW topology, from TVW to BPW and vice-versa. While the transformation from TVW to BPW could be reproduced with micromagnetic simulations and seems intrinsic, the reverse transformation from BPW to TVW may also be related to material defects. This possibility of change of topology had never been reported nor predicted before. It has importance consequences as the mobility of the two topologies of walls is expected to differ by α^2. Third, we developed a nanofabrication process to contact electrically individual wires in a two- or four-probes geometry. The process was optimized to minimize the contact resistance, so that current pulses of magnitude $2.5x10^{12}$ A/m^2 can be sent with up to 100ns duration. Uniformly-magnetized wires display an anisotropic magnetoresistance of several percent, similar to bulk values. DWs could be moved with a threshold current around $1.0x10^{12}$ A/m^2. The lower estimate for the DW speed is 350m/s, which suggests a high mobility of BPWs also under spin-polarized current

Magnetic domain wall dynamics in the layered antiferromagnet such as Mn_2Au and CuMnAs, driven by staggered field-like current-induced spin-orbit torques [1], is investigated by analytical theory and atomistic spin dynamics simulations. Our findings unveil the inertial character of the moving domain wall when the driving mechanism is of field-like torque type. For experimentally feasible excitation strengths, once the excitation is off, we observe inertial domain wall displacements that can be greater than 100 nm. Additionally, spin waves emission only occur under rapid acceleration/deceleration. Once the domain wall reach state motion even though travelling at speeds of 98% of the maximum magnon group velocity no signature of spin-waves emission is observed [2]. This means that the main reason for a given maximum steady-state velocity at a given excitation amplitude is here not due to dissipation via spin-waves [3]. Instead, at these high speeds, the natural response of the system to release the exchange energy stored within the contracted domain wall is to nucleate a domain wall pair with trivial winding number preserving the overall topological charge. The impact of the new domain wall pair is of great consequence onto the initially moving domain wall. We observe that, the system is able to sustain a moving domain wall at speeds higher than the maximum magnon group velocity revealing a super-magnonic regime of motion. These new observed features challenge the applicability of relativistic principle in such a system at very strong excitation. Additionally, we provide a plausible scenario extending the current theory based on dispersive media to explain this regime of motion based on the repulsive ferromagnetic exchange interaction among the neighbouring domain walls.

In racetrack memory [1] digital data is stored in a series of magnetic domain walls (DWs) in ferromagnetic nanowires. The racetrack memory operates on the base that the DWs can be moved along the nanowires by passing a current through the wire. When a current is applied to a ferromagnetic nanowire, it becomes spin-polarised. The interaction between angular momentum of spin-polarised electrons and the DW, induces a torque on the magnetic moments in the DW and move the DW. Therefore, the racetrack memory is a solid state device without moving parts and can operate faster than hard disk drives (HDDs). In our previous work, we have fabricated a simple pinning scheme for the DWs in straight wires using exchange bias. We have patterned IrMn antiferromagnetic (AF) wires with different widths perpendicularly above and below the CoFe ferromagnetic (F) wires. The AF wires induce exchange bias at AF/F crossing points which act as pinning sites. In the racetrack memory having uniform domain wall pin is essential to control the motion of DWs along the nanowires [3]. Prior to the fabrication of our devices, a vibrating sample magnetometer (VSM, ADE, Model10) was used to characterise an unpatterned continuous film to estimate the pinning strength. The magnetisation curves for the unpatterned films exhibits a loop shift of Hex=46 Oe which is induced by the exchange bias at the CoFe (10nm) / IrMn (5nm) interface [2]. Focused Magneto-Optical Kerr Effect (MOKE) was used to measure local magnetic properties of the FM wires in different devices with four AF wire widths of 1, 1.5, 2, 2.5 µm. The unset racetrack devices show a very small degree of pinning as expected. For the bottom-biased devices, pinning fields increase only slightly with increasing AF wire width. For the top-biased devices, the pinning is larger than that for the bottom-biased structure. These previous results prove that such a structure is ideal for producing DW pins with controlled strength. Following this study we designed a L-shaped magnetic wire with a round corner with a diameter of 650µm, in which one end of the wire is connected to a diamond shaped pad (1.5 µm square) to inject DW and the other end is a sharp arrow to prevent the nucleation of DW. The SEM image of device is shown in Figure 1. We observed that exchange bias gives rise to the domain wall pin therefore we used IrMn bars to pin the DW in our new devices. In this study we fabricated a variety of devices with different AF widths between 100 nm and 500 nm deposited on the 500 nm width F layer. We will report details of current-induced domain wall displacement measured in these devices.

The possibility of manipulating magnetic domain walls (DWs) using electrical current is very attractive for magnetic devices that store and process non-volatile information [1]. To estimate the efficiency of current acting on a magnetic texture (by Spin Transfer Torque for instance), the relevant quantity is a drift speed $u=(g\mu_B P)/(2eMs)$ J where J is the current density, P its spin polarisation in the magnetic media, Ms the net magnetisation, g the Landé factor, μ_B the Bohr magneton, e the electron charge [2]. The analytical q-ϕ model of DW motion along 1D wire shows that DW motion induced just by field or just by STT exhibits 2 different DW propagation regimes [3]. For low field or low current (low u), the DW moves steadily with just a tilt of its central magnetisation. This regime is called translational regime. For stronger field or current (strong u), the DW moves with a continuous precession of its central magnetisation. This regime is called precessional regime. In both regimes, speeds are proportional to H or u. The 2 regimes are separated by a critical field (or critical current) called Walker field (or current). Since the velocity is linear with H or u, it is possible to convert a current density acting on the DW into an equivalent field Heq defined as the field necessary to induce the same macroscopic velocity as the current density. In this equivalent field approach, Heq is proportional to u, with a proportionality constant for each regime. In classical ferromagnetic materials that have been mostly studied, P and Ms have the same physical origin and thermal dependence. Therefore, for those materials, the ratio P/Ms entering u which governs efficiency of STT is fixed. To play with P/Ms, we focused on more exotic materials namely Rare Earth/ Transition Metal (RETM) ferrimagnetics alloys [4] in which it is possible to tune independently Ms or P by composition or temperature. Indeed, in RETM, two populations of magnetic moments are antiferromagnetically coupled: 3d TM moments are antiparallel to 5d and localised 4f RE moments. The alloys net magnetisation is the difference of moments of the 2 populations whereas spin polarisation P arises only from that of RE and TM conduction electrons. We measured amorphous ferrimagnetic TbFe alloys thin films grown by coevaporation. They exhibit perpendicular magnetic anisotropy and P and Ms have clearly different thermal dependence (Fig 1a). The propagation of DWs in TbFe microtracks was analysed using Kerr microscopy. In a first step, we measured the velocity under continuous field (without current pulses) at different temperatures. We observed a nonlinear behaviour of velocity versus field and a strong dependence with temperature (Fig 1b). This type of DW dynamic is called creep regime. In this regime, the DWM is characterised by discrete hopping of the DW between weak pinning centres acting collectively and the DW velocity is described by an Arrhenius law. The energy barrier to overcome by thermal activation depends on the applied field H weighted by a universal exponent (μ=-1/4) that describes the motion of 1D elastic system in 2D random disorder media [5]. Fig 2a illustrates our original results demonstrating Current Induced DW Motion in TbFe wires under combined field and current and Fig 1c shows DW velocities for a few current densities. Two main observations can be done. The STT-like action pushes DWs along the electrons flow and can add or substract to the field action: a signature of STT is the increase of the split between fast (up-triangle) and slow (down-triangle) DWs. Joule heating modifies the creep dynamic and makes DWMs easier in both directions: the mean speed increases. A very careful analysis of the creep velocity was performed taking into account field, current and temperature versus time. We could evaluate Joule heating and the current contribution in terms of equivalent field Heq. In Fig 2b, Heq is reported versus current density (J) and clearly presents 2 regimes. Heq is not proportional to J P/Ms over the entire range (dashed line - material parameters from Fig 1a), as expected in conventional STT [3]. Based on an extended q-ϕ 1D model, we describe two regimes separated by a Walker-like threshold above which the CIDWM is more efficient, maybe thanks to changes of DW structure such as the creation of Néel lines [6]. This allows a determination of both the adiabatic STT parameter and of the damping constant. Investigations of the shape of the DW at sub-micron scale level are under progress. This could further elucidate the mechanisms responsible for motion and depinning under current and validate our theory thermally activated DW depinning after current pulses with the evidence of Bloch/Néel lines.

CD-10. Asymmetric domain wall motion in Pt/Co/Pt induced by electric current.

M. Nsibi[1], J. Nath[1], I. Joumard[1], S. Auffret[1], I. Miron[1] and G. Gaudin[1]
1. SPINTEC, CEA-INAC/CNRS/Université Grenoble Alpes, Grenoble, France

Novel device concepts, for data storage [1] and logic operations, based on current driven magnetic domain wall (DW) propagation have regained attention after evidencing spin-orbit torques (SOT) in ferromagnetic thin layers. The significant contributions of SOT to magnetization switching [2, 3] and to DW dynamics [4] have been demonstrated in [Heavy Metal (HM)/ Ferromagnetic (FM)/ Oxide] stacks. These stacks exhibit a Structural Inversion Asymmetry (SIA). Owing to the combination of spin-orbit coupling and exchange interactions, an electric current flowing in the plane of these stacks gives rise to torques acting on the magnetization of the FM layer. In addition, Dzyaloshinskii-Moriya Interaction (DMI) is present in SIA stacks, and plays a role in forming a Néel-type DW in the FM [5]. In stacks with large SIA, the combined action of SOT and DMI was proposed to account for the fast and efficient propagation of DWs [6, 7], making these stacks promising for spintronic applications. In the present work, we study a $Pt_{3\ nm}/Co_{0.6\ nm}/Pt_{1.5\ nm}$ stack with the magnetic anisotropy perpendicular to the plane. Because a layer of Pt is at both sides of the Co layer, this stack is expected to have a low SIA. Unlike large SIA stacks where DMI and SOT are considered the dominant mechanisms of current-driven DW dynamics, Pt/Co/Pt is a good candidate to investigate DMI and SOT contributions to DW dynamics with other possible relevant mechanisms. Furthermore, such stacks have been demonstrated to exhibit the chiral damping mechanism [8]. SOT act on the magnetization of the DW core [5-7]. We intend to study this by following a non-collinear DW propagation. A non-collinear DW propagation occurs when the direction of the current and the direction of the DW propagation are not parallel. Using wide-field Kerr microscopy, we follow the motion of DWs by applying current pulses to an-initially prepared magnetic circular domain. A circular domain allows us to probe the motion of DWs at all angles simultaneously. The displacements are found to be asymmetric with respect to the collinear configuration where the direction of the current and the direction of the DW propagation are parallel (see figure.1). At a certain angle, the DW is at its largest displacement. Whereas, it is shorter at its corresponding conjugate angle. This asymmetry is qualitatively equivalent to the one reported in Pt/Co/AlOx structure [9]. Now we consider the case where the current is applied in the presence of an external in-plane magnetic field. The magnetic in-plane field acts on the internal configuration of a DW and at a sufficient strength saturates the DW core magnetization along the direction of the field. This alters the action of SOT on the magnetization. We aim then to follow the DW motion asymmetry as we vary the strength and the direction of the applied magnetic field. The obtained results from this study are only partially accounted for by the combined action of DMI and SOT. Hence, the purely model based on DMI and SOT is found to be insufficient to explain all our observations in Pt/Co/Pt. Our findings uncover new aspects of the dynamics of DWs in 2D in SIA stacks. There is a need for an extended model including more and new mechanisms besides DMI and SOT to understand the magnetization interactions. The asymmetry of DW dynamics presented here offer also new ways to manipulate ferromagnetic pillars useful for spintronic devices.

CD-11. Influence of the Tb layer on current driven domain wall motion in Pt / Co / Tb magnetic wire.

H. Awano[1], W.C. Ying[1], R. Yoshimura[1], S. Sumi[1] and P.V. Thach[1]
1. Graduate School, Toyota Technological Institute, Nagoya, Japan

We have reported that the critical current density can be reduced in current driven domain wall motion of magnetic wire composed of (rare earth-transition metal alloy or multilayer/Pt) hetero structure[1, 2]. This may be due to the small magnetization and the high efficiency of the spin orbit torque effect[3,4]. On the other hand, the rare earth metals are heavy metals and cause large spin orbital interaction, so we need to investigate this effect as well. Therefore, Pt / Co / Tb three-layered magnetic were is prepared and the influence of the Tb in current driven domain wall motion was investigated. The specimen wires were establish by conventional fabrication process with different Tb layer thinness (t nm) from 0 to 5 nm. Layers of Ta(3 nm)/Pt(3 nm)/Co (0.9)/Tb (t nm)/Ta(3 nm)/Pt(1.5 nm) were deposited on the thermally oxidized silicon substrates, Pt layer and Ta layer were deposited by DC magnetron sputtering and Co layer and Tb layer were deposited by RF magnetron sputtering. Fig.1 shows Tb layer thickness dependence of satulate magnetization (Ms) per Co in Pt/Co/Tb magnetic wire. In general. when the Tb layer and the Co layer are in contact with each other, a TbCo alloy is formed at the interface and a ferrimagnetic material. That is, since the magnetic moments of Tb and Co sub-networks are opposite to each other, the net magnetic moment shows a small value. When the Tb layer thickness is 0 nm, Ms shows that of Co alone, but as the Tb layer thickness becomes 1 nm, Ms decreases slightly because the TbCo alloy can be formed at the interface. However, when the Tb layer thickness is 2 nm or more, Ms shows a constant value, so it can be considered that the alloy layer thickness at the interface is 2 nm or less. In order to investigate current-induced DW motion by applying voltage pulses of 100-ns duration between two electrodes. The results are shown in Fig.2 for a wire width of 3μm. The slope of domain wall velocity (V) versus current density (J) curves increases when Tb thickness increases. The highest slope was obtained for Tb 5 nm thickness specimen wire. In addition, the critical current density (J_C) *decrease when the Tb thickness increasing. I observed the increasing Tb layer thickness will enhance the spin-orbit torque.*

CE-01. Dispersion Engineering of Nonreciprocal Composite Right/Left Handed Metamaterials Using Ferrite Materials in Microwave Region.
T. Ueda[1] and T. Itoh[2]
1. Electrical Engineering and Electronics, Kyoto Institute of Technology, Kyoto, Japan; 2. Electrical Engineering Department, University of California, Los Angeles, CA, United States

Metamaterials are artificial electromagnetic structures which are composed of smaller elements compared to the wavelength, referred to as unit cell, where macroscopic constitutive relation such as effective permittivity and permeability have been designed and controlled in order to manipulate electromagnetic wave propagation for various applications. Specifically, nonreciprocal metamaterials have been investigated to discover new electromagnetic phenomena and to invent state-of-the-art functional circuits and antennas. Nonreciprocity manifests itself as a result of a combination of two factors; the one is broken time reversal symmetry and another is broken space inversion symmetry. The former factor is realized by using gyrotropic materials such as ferrite in microwave region or magneto-optic media in optical region. For example, a microstrip line constructed on a normally magnetized ferrite substrate supports an edge guided mode [1] showing the field displacement effect in which the fields are asymmetrically concentrated at one of strip edges. The field concentration side can be switched by changing the directions of wave propagation or the externally applied dc magnetic field. In such cases, when stubs are asymmetrically inserted at the strip edges to provide geometrical asymmetry to the wave-guiding structure for broken space inverse symmetry, the propagating wave regards the line as different structures for two anti-parallel propagation directions, which results in nonreciprocal transmission. In the earlier work on nonreciprocal metamaterials, nonreciprocity appearing in the magnitude of transmission coefficients was studied for applications to isolators and circulators [2]. More recently, nonreciprocity appearing in the phase of transmission coefficients was focused on, from the metamaterial point of view [3],[4]. By using the phase-shifting nonreciprocal metamaterials, we can have fascinating situations where forward wave mode is dominant with positive refractive index in one propagation direction and backward wave mode is dominant with negative refractive index in the opposite direction at the same frequency. In the special cases, we can have field profiles with unidirectional wavenumber vectors along the wave-guiding structures regardless of the transmitted power directions. Such nonreciprocal metamaterials were implemented to transmission-line resonators providing unique characteristics in that the resonance frequency is independent of the resonators' size and that the field profiles have uniform magnitude and linearly-varying phase distribution, referred to as pseudo-traveling wave resonators [5]. The phase gradient of the fields along the resonators can be arbitrarily varied by changing the nonreciprocity of the lines under the resonant condition. This tunable phase gradient along the resonant structures was implemented to highly-efficient beam scanning leaky wave antennas [6], and to polarization switchable circularly polarized antennas [7],[8]. Nonreciprocal metamaterials can provide potential solutions to improvement of performance in microwave circuits and antennas. For beam steering antennas based on nonreciprocal metamaterials, the beam angle is determined by magnitude of the nonreciprocity in the metamaterial lines. For circularly polarized antennas based on the nonreciprocal metamaterial rings, the phase shift for one circulation corresponds to 360 degrees. Therefore, the enhancement of nonreciprocal phase gradient along the metamaterial line leads to wider beam swing in the leaky wave antennas and miniaturization of the circularly polarized antennas. Recently, it was demonstrated that an appropriate combination of curvatures of lines and asymmetric insertion of stubs enhances the geometrical asymmetry of the line, resulting in the enhancement of the nonreciprocity [9]. Not only magnitude but also dispersion of phase-shifting nonreciprocity in metamaterials have been designed and controlled for improvement of microwave circuits and antennas. For example, beam scanning leaky wave antennas generally suffer from beam squint problem where the beam direction varies with the operational frequency. For the nonreciprocal metamaterial based beam scanning antennas, the beam squint originates from the frequency dependence of phase-shifting nonreciprocity. To eliminate the beam squint, metamaterials with dispersion-less nonreciprocity was proposed and demonstrated to show the phase-shifting nonreciprocity proportional to the operational frequency [10].

Virtually all electronic and microwave components have been constantly shrinking, including the ones used in Transmit/Receive Modules. The microwave circulator is an essential part of every T/R module and has largely remained unchanged since the inception. The concept of T/R module crystalized in the 1970s and became practical in the 1980s with the emergence of GaAs monolithic integrated circuits. Circulators are not solid state components and have ferrites at their cores. The first attempts to integrate the ferrites and semiconductor platforms have been made in the 1990s, but mostly failed - GaAs substrates could not withstand high temperatures required for spinel ferrite processing. Further work focused on wide band gap semiconductors that offered better temperature stability, such as SiC or GaN. These semiconductors were used as substrates to grow crystallographycally textured hexagonal barium ferrite films (BaM) by means of pulsed laser deposition due to their lattice parameters. Several buffer layers have been explored, including MgO and Pt. A number of promising results on SiC substrates have been published in the 2000s [1-2]. Eventually, it turned out that even SiC coated with magnesium oxide (MgO) is not stable under barium hexaferrite films at elevated temperatures [3]. Z. Chen et al. concluded that this phenomenon is due to the chemical affinity of Si and Fe. In fact, the eutectic transition in the Fe–Si phase diagram occurs at about 875^{o}C, and barium hexaferrite films are usually grown at temperatures exceeding 900^{O}C. To address this problem, we investigated the behavior of buffer layers commonly used between SiC and BaM at elevated temperatures, and also explored novel options. The primary function of a nucleation layer is to improve the crystalline quality of the overlying hexaferrite. This is achieved by providing a surface that improves the wetting and adhesion of the PLD seed layers, adjusting the lattice constant to a closer match to the hexaferrite, mitigating interfacial strain and controlling interfacial chemical reactions between the hexaferrite seed layers and SiC. In addition to providing a seed for hexaferrite deposition, nucleation layers are needed to protect the SiC substrate during the high temperature and potentially corrosive hexaferrite growth process. As such the nucleation/protection layers must be chemically stable and robust. To this end, traditional magnesium oxide and platinum, as well as the novel (with respect to BaM) aluminum nitride interlayers were studied. Our approach to achieving the nucleation and growth of protective MgO or Pt thin films is based on Atomic Layer Deposition (ALD). The advantages of this process include the ability to conformally coat structured substrates free from pinholes and other surface defects. Novel AlN layers were deposited by means of Metal-Organic Chemical Vapor Deposition (MOCVD). To study temperature stability of these nucleation layers, coated 6H-SiC wafers were annealed at temperatures between 600 and 900^{O}C, in air, oxygen, and nitrogen atmospheres. Further analysis included scanning electron microscopy (SEM), atomic force microscopy (AFM), X-Ray diffractometry (XRD), and surface resistivity measurements. As deposited nucleation layers had the thickness of about 30nm, surface roughness Ra of about 0.4nm, and high degrees of crystalline orientation. Pt nucleation layers mostly preserved their properties after annealing at 600^{o}C, but experienced boil off at temperatures approaching 900^{o}C. Although MgO interlayers on SiC substrates demonstrated much better thermal stability, BaM films grown on MgO faced a number of problems, including low density, delamination, and cracking. AlN interlayers are widely used in semiconductor manufacturing to reduce the tensile stress and cracks, but have never been used as nucleation layers for magnetic films. Our annealing study demonstrated that AlN on SiC retains its properties after annealing at elevated temperatures even in oxygen atmosphere. However, we were not able to grow high quality hexaferrite films directly on AlN due to poor epitaxy, poor adhesion, and cracking. Therefore, an additional layer of MgO has been introduced on top of AlN by means of ALD. Such heterostructures (MgO/AlN/SiC) exhibited excellent temperature stability, the surface roughness remained unchanged after the annealing at 900^{o}C and equaled 2.4nm (Figure 1). We were able to reliably produce high quality, perpendicularly textured BaM films on these structures under varying pulsed laser deposition conditions. Optimal PLD parameters can be found elsewhere [1-3]. As deposited 1.5um thick BaM films on MgO/AlN/SiC heterostructures have been rigorously tested and demonstrated excellent functional properties. Vibrating sample magnetometery (VSM), XRD, and pole figures confirmed a high degree of crystalline orientation ((00n) texture). The surface of these films, as well as ion milled holes, were analyzed by SEM and AFM, and appeared to have a near theoretical density. This conclusion was supported by the VSM analysis that revealed a near theoretical saturation magnetization and a low magnetic coercively of about 200 Oe. The FMR linewidths were measured by a coplanar waveguide connected to a Vector Network Analyzer (VNA) and equaled 500 to 600 Oe [4-5]. As demonstrated in prior art, microwave magnetic properties of as-deposited BaM films can be further improved by subsequent annealing in oxygen atmosphere.

While thin-film magnetic cores provide significant enhancement to integrated passive circuit elements, including inductors and transformers [1-10], often their operating frequency limits their applications to mainly power management [1-6]. The growing field of mobile electronics, however, demands higher inductances than achievable by air-core inductors [11], [12] and higher operating frequencies than previously achievable by magnetic materials. This work aims to meet the needs of radio frequency mobile applications, by providing high frequency inductors with large inductance enhancement due to a magnetic core, all in a small form factor. As illustrated by pervious works [7-10], the trade-off between inductance enhancement and high operating frequency is challenging to overcome. Although magnetic cores contribute high permeability for inductors, at the intrinsic ferromagnetic resonance (FMR) frequency of magnetic materials (typically between 1 and 2 GHz for large blanket films), the relative permeability drops to unity, thereby making the inductance enhancement due to the material negligible. Extending the operating frequency, however, by means of patterning the magnetic core and increasing the FMR frequency through shape anisotropy has the consequence of also decreasing the permeability. In this work, we analyze the most crucial considerations regarding material selection and the fabrication process as well as magnetic-core and device design in order to produce and inductor offering a magnetic enhancement over air core extending beyond 6 GHz, a low frequency inductance of 1 nH, and a peak quality factor of four at approximately 3 GHz [13]. Both air-core and magnetic-core solenoid inductors of the same topology, shown in Fig. 1, were fabricated and measured. First, a 40 μm thick polymer insulating layer (SU-8 2015) was formed on the silicon substrate to provide isolation of the inductor from the parasitic substrate. 3 μm thick bottom inductor windings were electroplated starting from a thin Ti/Cu seed layer. Planarization and insulation was completed using two layers of the SU-8 2002 polymer to first fill the gaps between windings for planarization and then provide an additional 1.5 μm insulation layer between the windings and the magnetic layer. The magnetic material $Co_{43}Fe_{43}B_{14}$, selected its excellent high frequency properties [14], [15], was sputter deposited with laminations such that 63 nm CoFeB layers were alternated with 6 nm SiO_2 insulating layers to form a total of 1 μm thick magnetic core. The core was then patterned into a narrow shape for high shape anisotropy and high FMR frequency, where laminations further improved broadband performance by reducing high frequency losses due to eddy currents. Finally, the vias and top inductor windings were again formed by an electroplating process. The comparison of measured inductance from the air-core and magnetic-core inductors of the same design provided a direct evaluation of the performance enhancement of the inductor due to the magnetic material. Fig. 2 shows the measured permeability of the blanket film as well as the calculated permeability of the patterned magnetic core used in the inductor. The shape anisotropy is seen to increase the bandwidth of the inductor by approximately 1 GHz. The inductance of the fabricated inductors, shown on the same graph, was approximately 1 nH for the magnetic-core inductor and 0.5 nH for the air-core version. Thus, incorporation of the magnetic core is seen to experimentally double the inductance of the air-core inductor well into the high frequency mobile electronics range. The decreasing inductance at higher frequencies and suppression of the ferromagnetic resonance peak is likely due to a combination of misalignment of the applied magnetic field during deposition of the cores [15], parasitic capacitances, and eddy currents along the length of the core. Nevertheless, these results show that, with continued optimizations, magnetic materials may indeed satisfy the needs of mobile electronics applications. Acknowledgement Research for this project was conducted with government support under FA9550-11-C-0028 and awarded by the Department of Defense, Air Force Office of Scientific Research, National Defense Science and Engineering Graduate (NDSEG) Fellowship, 32 CFR 168a. Part of this work was performed using the Stanford Nanofabrication Facility (SNF) and the Stanford Nano Shared Facilities (SNSF) at Stanford University.

I. Introduction Magnetic materials are the necessary components of the modern rf components. The demand for higher communication speed such as the upcoming 5G network requires higher operation frequency of rf components. For example, the future spectrum band of mobile network will be extended above 24 GHz [1]. Permeability measurements provide a basis for the design and characterization of magnetic materials and the development of RF devices. However, permeability measurement results and commercially available permeameters have been limited to 9GHz or below [2-7]. Conventional broadband permeameters use a vector network analyzer (VNA), and a pick-up coil or an electric short [2,3], or a broadband transmission line [4,6] for magnetically exciting the materials under test. Inductance changes are measured at zero magnetic field and at saturation magnetic field through a vector network analyzer for extracting the permeability spectrum. The bandwidth of Pick-up coil is limited to several hundred MHz. Transmission-lines [4-6] are widely used for broadband permeameters. However, the transmission-line type permeameters are noisy in the frequency range below 100MHz due to the low inductance. In addition, all these broadband permeameters based on vector network analyzers are expensive, and not reliable in measuring thin films or materials with low permeability because of the low signal to noise ratio (SNR). In this article, we demonstrate a new type of permemeter for ultra-wide band permeability measurements with significantly enhanced signal to noise ratio (SNR), and demonstrate the measurements on a 50nm FeGaB film up to 22GHz and an ultra-thin 2nm NiFe film. This permeameter enables the characterization of the complex permeability between 10MHz-26GHz, as well as many other typical magnetic parameters including linewidth, saturation magnetization, effective anisotropy field, Gilbert damping, and inhomogeneous linewidth broadening. In addition, the new permeability measurement system shows 40 ~ 50dB higher SNR over the conventional permeameters. II. Measurement and Results The proposed permeability measurement system is established from the broadband ferromagnetic resonance (FMR) spectrometer [8], which uses a microwave source without a VNA. Before measuring the permeability of magnetic films, the in-plane magnetic anisotropy field H_k and saturation magnetization $4\pi M_s$ of a 50nm FeGaB film are evaluated from FMR as 11.6Oe and 13934Gs, which are comparable to the reported results of FeGaB [10] measured by VSM. The complex permeability is defined as $\mu = \mu' + j\times\mu''$, where are μ' and μ'' the real and imaginary part of permeability respectively. The low-frequency permeability equals to the theoretical initial permeability as $\mu_{lowf}'=1+4\pi M_s/(H_k+H)$ when H is applied along the magnetic in-plane easy axis. One can calculate the low-frequency permeability from the saturation magnetization and anisotropy field that are determined from FMR characterization initially. The complex permeability as a function of frequency at fixed bias field is determined by the frequency-swept measurement, as detailed in Ref [8]. Fig.1 shows the measured spectrum of complex permeability of a 50nm FeGaB sample at zero bias field and 2000Oe bias field. The resonance shifts from 2GHz to 20GHz with the increase of bias field. The profile of the complex permeability agrees well with the theoretical permeability calculated from Landau–Lifshitz–Gilbert (LLG) equation, which validates the results. To further investigate the detection limit of the system, we measured the permeability on a 2nm ultrathin NiFe sample. NiFe is a commonly used ferromagnetic material with weaker magnetization than FeGaB. The saturation magnetization and anisotropy field are extracted to be 7735G and 7.5Oe following the same analyzing procedure for FeGaB sample. The resonance peak is near 700MHz that is lower than the resonance frequency of FeGaB because of the smaller saturation magnetization of NiFe. Again, there is a good agreement in profile and amplitude between the measured permeability spectrum and theoretical permeability from LLG equation. III. Performance Comparison A comparison between the reported permeability measurements on magnetic films is summarized in Table I. The new method presented in this study can measure samples through a much wider frequency bandwidth than any other permeability measurements using microwave transmission line or cavity with vector network analyzer. Moreover, our permeameter has shown much higher SNR, particularly in the low-frequency region (~100MHz). We analyzed the SNR of the real part of permeability for all the studies listed in Table I. The measurements on 50nm FeGAB film lead to S/N ratio of 72dB, indicating the highest sensitivity among all the permeability measurement techniques that we know. In addition, our system is able to detect a 2nm ultra-thin NiFe film with a SNR of 28dB, which is beyond the capability of other methods. IV. Conclusion A new permeability measurement system has been demonstrated with ultra-wide frequency band from 10MHz up to 26GHz. The measurements on 50nm FeGaB and 2nm NiFe thin films have shown excellent SNR, which is 40~50dB higher than conventional permeameters, and the measured permeability spectrum matches well with the theoretical permeability simulated by LLG equation.

CE-05. In-site measurement of permeability and magnetostrtriction constant of magnetic films deposited on Si wafers.

O. Mori[1], Y. Endo[2,3], Y. Shimada[1], S. Yabukami[4] and R. Utsumi[1]
1. Toei Scientific Industrial Co., LTD, Natori, Japan; 2. Graduate School of Engineering, Tohoku University, Sendai, Japan; 3. Center for Spintronics Research Networks, Tohoku University, Sendai, Japan; 4. Tohoku Gakuin University, Tagajo, Japan

1. Introduction This paper proposes a new technique to measure simultaneously and non-distractively both permeability and saturation magnetostriction constant of magnetic thin films deposited on Si wafers. Generally in order to evaluate permeability and magnetostriction of magnetic thin films, samples with adequate size and shape have to be prepared separately for each measurement. This new measurement technique allows for in-site measurement of these material properties for a magnetic thin film on a large-sized Si wafer substrate. 2. Experimental procedures In addition to permeability measurement using the microstrip line probe that was already reported[1)] this technique measures ferromagnetic resonance (FMR) of the same sample. In the FMR measurement, a Si wafer is bent with well controlled curvature radius giving uniaxial tensile stress to the magnetic film on the Si wafer. The FMR frequency ($f_{r\sigma}$) shifts due to the uniaxial anisotropy caused by magneto-elastic effect and the shift reflects the strength of magnetostriction of films. From dependence of fr_{σ} on an external magnetic field (H_{ex}) the saturation magnetostriction constant λ_s is available by graphical fitting and calculation. The following is an example of the measurement. The film to be measured is Co-Zr-Nb amorphous with thickness of 500 nm deposited on a 4 inch diameter Si wafer by RF sputtering. As shown in Fig. 1, the sample was set on a substrate holder with a curvature radius of 300 mm with the film surface upside. The film in this state is under a uniaxial tensile stress that induces uniaxial anisotropy through magnetostrictive effect. The resonance frequency shift is plotted as a function of H_{ex}. The relation between the resonance frequency and H_{ex} is $(f_{r\sigma}^2 - f_{r0}^2) / f_{r0}^2 = (3\lambda_s h_s E_f / 2rM_s) / (H_{kf} + H_{ex})$ (1) where $f_{r\sigma}$ and f_{r0} are resonance frequencies under tensile stress and in stress free state, respectively. r is curvature radius determined by position censor (278mm for the present sample), M_s is saturation magnetization, H_{kf} is other kind of uniaxial anisotropy field such as induced anisotropy, h_s is a substrate thickness, and E_f is Young's modulus. 3. Results and discussion The resonance frequency was defined as the peak frequency of resonance power loss profile, which was determined from s_{21} measured with a network analyzer. Fig. 2 shows $(1-s_{21})/ s_{21}$ which means an effective resistive component of resonance. The solid and broken lines are profiles under tensile stress and in stress free state, respectively. Under the stress, $f_{r\sigma}$ shifts to lower values and difference ($f_{r\sigma}– f_{r0}$) tends to decrease from 30 MHz to 4 MHz with increase of H_{ex}. Fig.3 shows plotting of $(f_{r\sigma}^2–f_{r0}^2)/fr_0^2$ as a function of $1/(H_{kf}+H_{ex})$. The value of λs was determined by fitting the plot with a linear line with proportionality $(3\lambda_s h_s E_f/2rM_s)$, that is, $-7.2x10^{-7}$. A film sample deposited on a thin glass rectangular substrate simultaneously with that of the Si substrate was measured with the optical cantilever technique and λs was found to be $-13x10^{-7}$. Table 1 summarizes the results of two methods of λs measurement for Co- Zr-Nb films with different compositions. They are in good agreement confirming that the technique proposed here is reliable for film characterization on Si wafers. Conclusion The experiments described here give good evidence that the technique proposed here has a high potential as a measurement method of in-site characterization of magnetic thin films on large size Si wafers. Compared to the conventional optical cantilever method, this proposed technique has the following advantages. 1. Permeability and saturation magnetostriction properties can be evaluated simultaneously and non-distractively. When the probe size is reduced in future, information on local distribution of these properties on Si wafers becomes available. 2. In the conventional optical cantilever method rotatable or bi-directional H_{ex} is needed. This limits the external field strength, while H_{ex} of the proposed method is unidirectional without limitation to the strength, making application to magnetically hard samples possible.

INTRODUCTION - This paper proposes a new application of skin effect suppression technology [1]-[4] for long wiring on high-speed & low-delay I/O board (typical wiring length; 200 to 1000 mm). This proposal will overcome the difficulty to further reduce the transmission losses on the I/O board with >50 Gbps data rate, which is currently performed by lowering dielectric substrate losses and surface smoothing of Cu conductor. A major challenge in this paper is to demonstrate the skin effect suppression by electroplated magnetic/conductor multilayer, instead of sputter-deposited thin film in literature [2]-[4], in order to meet coming cost-effective, thick (>5 μm), large area, and high throughput mass productivity requirements. High frequency (>10 GHz) estimation of complex permeability and measurements of low resistance devices are also investigated. *EXPERIMENTAL PROCEDURE* - Cu was selected as metal conductor material, and NiFe the magnetic material. The target frequency to demonstrate skin effect suppression is selected as 15 GHz. The Cu and Ni80Fe20 films are alternately electroplated to form the NiFe/Cu multilayer, as Shown in Fig. 1. The top and bottom surface layers of the multilayer are Cu layers. The skin effect can be suppressed in the multilayer provided that the real part of the relative permeability of NiFe, μ_r' is negative and the volume average of the relative permeability, μ_{rav}, becomes zero(refer equation (1) as inset in Fig. 1). The μ_{rav} can be zero when the ratio r of the Cu thickness t_N to the NiFe thickness t_F, equals $r = t_N/t_F = -\mu_r'$ ($\mu_r<0$). The imaginary part of the relative permeability μ_r'' must be small enough. Thicknes of each of Cu and NiFe layer is so designed not to exceed skin depth δ of the material (refer equation (2) as inset in Fig. 1). In order to design the film thickness ratio, r, complex permeability of NiFe film with thin Cu back layer was measured by a shielded-loop type thin film permeameter up to 9 GHz[5]. Static hysteresis loop was also measuerd. Then parametes necessary to estimate higher frequency comprex permeabililty by the known Landau-Lifshitz-Gilbert equation [6] were extracted as 4πMs=8000 G, Hc = 0.5 Oe, FMR frequency = 0.9 GHz, and damping parameter α=0.1. This calculation lead μ_r'= -2 at 15 GHz. Accordingly, Cu thickness t_N = 0.51 μm and NiFe thickness t_F=0.25 μm are targetted. Total number of layers is 21 and total thickness is 7.85 μm. Maximum size of electroplating area was 75 x 75 mm^2. Film-substrate bending was reduced by electric deposition parameters [7] and additives to solution. *RESULTS AND DISCUSSION* - Fig. 2(a) shows simulated cross-sectional current distribution at 15 GHz by a full wave FEM simulator (Ansis Co, HFSS) [8]. Within the multilayer, current density is high in Cu and low in NiFe because of the electric conductivity difference. Compared with Cu conductor, it is seen that the top and bottom surface curernt densities become low, and depth-center current density becomes slightly high for the multilayer, showing the skin effect is suppressed. The suppression is not perfectly because of large damping (α=0.1) and noticeable contribution from imaginary part of the relative permeability μ_r''. Accordingly it was estimated that the degree of transmission loss decrease at 15 GHz would be 5 %. In Fig. 2(b), this is clearly demonstrated in experiments. Provided a lower damping material with low imaginary part permeability, the degree of skin effecrt suppresion would be more significant.

CE-07. Angular dependence of single sideband generation in spin torque nano-oscillators.

R. Sharma[1], N. Sisodia[1] and P.K. Muduli[1]
1. Physics, Indian Institute of Technology Delhi, Delhi, India

Spin torque nano-oscillators (STNOs) [1-3] are useful to generate high frequency GHz range carrier signal for transmitting the low-frequency information signal through analog frequency modulation. [4-7] Recently a single sideband (SSB) generation [7], which uses transmitter power and bandwidth more efficiently, has been demonstrated in magnetic tunnel junction (MTJ) based STNOs using nonlinear dependence of STNO frequency and amplitude on the bias current (I_{dc}). The SSB generation is well described by nonlinear frequency and amplitude modulation (NFAM) theory. [5,8] This study shows a strong dependence of onset modulation frequency (f_{onset}) required for seeing the SSB on the STNO frequency (f_0) tunability with bias current at a fixed in-plane angle (ϕ = angle between fixed and free layer). Furthermore, macrospin simulation showed that field like torque, which is a device property, can manipulate the frequency tunability and thus the f_{onset}. In this work, we present macrospin simulations to show a strong dependence of SSB generation and f_{onset} on varying in-plane field angle, which is easy to control in the experiments. We show that ϕ strongly alters the red-shift of STNO frequency with the bias current, which changes the onset frequency for SSB generation. We performed the macrospin simulation for the same CoFeB/MgO/CoFeB based device used in Ref [7]. All the simulation parameters are same as in Ref [7]. Electrons are assumed to flow from fixed layer to free layer. Field angle is measured with respect to fixed layer which is pinned in x direction (ϕ=0°). Magnetization is initially aligned along the direction of externally applied field (H_{app}) and later relaxes in the direction of effective field (H_{eff}) according to the LLG equation. Here, the effective field (H_{eff}) contains contributions from external field, demagnetizing field and thermal field. The Slonczewski term is then added to the system to account for the torque generated due to spin polarized current. Figures 1(a-c) show the modulation spectra at H_{app} = 400 Oe and I_{dc} = 7 mA three in-plane field angles of 190°, 195° and 200°. The Fig.1 (a-c) shows that the onset frequency required to see the SSB generation (shown by white line) strongly depend on the angle between free and fixed layer even in a narrow range of 10°. In order to understand this behavior, free running STNO frequency is plotted in Fig. 2(a). It can be clearly observed that change in ϕ changes the STNO frequency red shift at higher dc bias current. The maximum frequency of operation of the STNO, f_{max} is shown by black dotted lines in Fig 2(a). Whenever upper sideband frequency [f_0 + modulation frequency (f_m)] lies above f_{max} only lower sideband is generated. Since red shift of STNO frequency with I_{dc} strongly depends on the ϕ angle [Fig 2(a)], SSB onset frequency (f_{onset}) also varies as a function of ϕ, which is shown in fig 2(b). In particular, frequency tunability is negligible at high in-plane field angle, which are not suitable for SSB generation. The value of f_{onset} is approximately equal to f_{max}-f_0. Another important factor for SSB transmission is the power generated by the STNO which is shown as a function of ϕ, in Fig 2 (c) at I_{dc} = 7 mA. At higher angles, power of the STNO becomes relatively low and STNO frequency reaches the f_{max} region (shown by red dotted lines). So, an optimum value of ϕ=210° is suitable for the SSB application. We will discuss these simulation results by the NFAM theory, which includes the nonlinear variation in STNO frequency and amplitude as a function of modulation current around the bias dc current at different values of ϕ. In conclusion, we present an angular dependence of SSB generation in MTJ-STNOs, which gives a liberty to the experimentalist to tune the SSB generation by an external parameter i.e. the in-plane field angle.

The magnetic nano-oscillator is a promising candidate for microwave generator due to its high tunability and wide range of working temperature. Usually the steady precession in the nano-oscillator is achieved by applying spin-transfer torque (STT) to cancel the intrinsic Gilbert damping of the magnetic oscillator. As an energy-efficient alternative to STT, the spin-orbit torque (SOT) can also be used to compensate the intrinsic magnetic damping and induce steady magnetic oscillation in the spin-Hall nano-oscillator (SHNO). However, there are few studies on tuning frequencies in SHNO without using external bias field, which is crucial for practical on-chip application. Here, we present a new control method of SHTO by using voltage-induced strain in a multiferroic system (i.e., coupled piezoelectric and magnetoelastic effects). A macrospin model is developed to simulate the piezoelectric/heavy metal/magnetoelastic structure. Applying voltage to the piezoelectric layer induces strain, which in turn generates an effective magnetoelastic field inside the magnetoelastic element (e.g., CoFeB). It is shown that both the frequency and amplitude of the oscillation can be tuned within wide ranges by tuning strain and the SOT current applied to the heavy metal layer. The strain-mediated SHNO provides a platform of a potential antenna system with wide-range frequency and amplitude modulation. Fig. 1a illustrates an array of strain-mediated STNO for antenna transmitter application. The magnetic nano-oscillators (shown in blue) are attached to a heavy metal thin film (e.g., Ta), which is then attached to a piezoelectric substrate such as PMN-PT or PZT ($Pb_y[Zr_xTi_{1-x}]O_3$). The SOT current is applied to the heavy metal to compensate the Gilbert damping, and the voltage is applied to the bottom of the piezoelectric layer to generate strain. The voltage-induced strain is estimated using a finite element model and input into the macrospin model to calculate the magnetic dynamics of a single magnetic oscillator. Each nano-oscillator is a CoFeB element with 50nm diameter and 1.5nm thickness. For specific ranges of strain/current combinations (as shown Fig. 1b and 1c), the SOT completely compensates the CoFeB's Gilbert damping and leads to steady out-of-plane magnetic oscillation. The upper left plot in Fig. 1a shows the temporal change of the perpendicular magnetization in a representative steady oscillation. It is shown that the amplitude of the perpendicular magnetization is invariant with time. Fig. 1b shows the oscillation frequency diagram with different voltage induced strains and current density values. For the strain and current range studied, the frequency can be tuned from 500MHz ~ 5GHz, which is within the microwave range. The minimum strain to initiate continuous oscillations is ~1000, while the minimum current density is ~1×10^6 A/cm^2. For the oscillating cases with fixed current, the applied strain has negligible influence on oscillation frequency. However, with fixed applied strain, tuning the current density causes large changes in oscillation frequency. More specifically, higher current density leads to higher oscillating frequency. When the current exceeds 3×10^7 A/cm^2, further increasing the current will increase the threshold strain, causing the oscillation more and more difficult to initiate. Fig. 1c shows the oscillation amplitude diagram with varying strain and current densities. The oscillation region is the same as in Fig. 1b. The color bar represents the amplitude of the perpendicular magnetization under a steady out-of-plane oscillation as shown in Fig. 1a. It is shown that both current density and strain have strong impact on the oscillation amplitude. For a given strain level, increasing the current will decrease the oscillation amplitude. In contrast, for a given current density, increasing the strain will increase the oscillation amplitude. Combining the frequency and amplitude diagrams in Fig. 1b and 1c, one can design the system to have a wide range of frequency and amplitude outputs by choosing a specific strain/current combination. In conclusion, the strain-mediated SOT control has a potential application of broadband antenna with large frequency-modulation (FM) and amplitude-modulation (AM) abilities.

Energy harvesting technologies offer a promising approach to capture energy from ambient sources, such as vibration, heat, and electromagnetic waves. Among them, the ambient radio-frequency (RF) electromagnetic signals provide an attractive energy source for applications in self-powered portable electronics in the "internet of things" era [1, 2]. However, currently available microwave detectors based on semiconductors do not meet the practical requirements for energy harvesting applications. The key challenges that need to be addressed are: (i) Miniaturization: Electromagnetic devices currently used for microwave energy harvesting could be efficient but are difficult to miniaturize, and (ii) Low input-power operation: Here we show the development of a *bias-field-free* nanoscale spintronic diode (NSD) based on a magnetic tunnel junction (MTJ) having a *canted magnetization* in the free layer, and demonstrate that this NSD could be an efficient harvester of broadband ambient RF radiation, capable to efficiently harvest microwave powers of microWatt and below. The stack composition of the MTJs is PtMn (15) /$Co_{70}Fe_{30}$ (2.3)/Ru (0.85)/$Co_{40}Fe_{40}B_{20}$ (2.4)/MgO (0.8)/$Co_{20}Fe_{60}B_{20}$ (1.65) (thickness in nm) patterned into ellipse-shaped pillars using electron-beam lithography and ion milling techniques. The free layer is composed of $Co_{20}Fe_{60}B_{20}$ capped by Ta and exhibits interfacial perpendicular anisotropy [3]. It is designed in order to have a tilted out-of-plane easy axis, due to the competition of shape anisotropy with the first and second-order magnetic anisotropies of the free layer. The perpendicular magnetic anisotropy (PMA) in the MgO/$Co_{20}Fe_{60}B_{20}$/Ta free layer is caused by an interfacial effect that arises from the hybridization between the O (of the MgO) and Fe (of the CoFeB) orbitals, and can be controlled by the CoFeB composition, the capping material, and the thickness of the free layer. We have measured the rectified voltage with an RF current in the absence of an applied magnetic field by applying an RF current to the device through a bias tee using a signal generator, while the rectification voltage V_{DC} across the MTJ is recorded with a nanovoltmeter. The frequency response of the NSD shows that a novel type of frequency behaviour, i.e. broadband response, is achieved. Figure 1 displays an example with a RF input power of P_{RF} = 10 μW, showing that the NSD rectifies a nearly constant voltage across a 100 to 550 MHz range. To evaluate the performance for energy harvesting applications, the rectified DC voltages obtained at a frequency of 500 MHz for several Schottky diodes and two spintronic diodes were compared. Figure 2 summarizes the calculated efficiency for a constant frequency of 500 MHz. The efficiency in the high-barrier Schottky diodes is extremely low (< 10^{-8}%), as expected [4]. The spintronic diode exhibits better efficiency than the low-barrier Schottky diodes at low input power (< 5 μW). For example, at an RF input power of 3.2 μW, the spintronic diode has a conversion efficiency of 0.005%, compared to less than 0.001% for low-barrier Schottky diodes. Therefore, our results suggest that the spintronic diode offers a prospective approach for energy harvesting applications.

CE-10. Intrinsic permeability of composites filled with nickel powders.

S.N. Starostenko[1], K.N. Rozanov[1] and A.O. Shiryaev[1]
1. Theoretical, Institute for Theoretical and Applied Electromagnetics, Moscow, Russian Federation

The microwave permeability of nickel (Ni) is reconstructed from constitutive parameter measurements of paraffin–binded composites filled with flakes or spheres of carbonyl nickel. The metal permeability is assumed to be equal to the intrinsic permeability of inclusions. The mean diameter of spheres is about 12μm, the mean diameter of flakes obtained from spheres by ball milling is about 50μm, the thickness is about 2μm. The shape and size are determined by microscopy and by laser particle sizer Analysette 22. The measurements of composite permittivity ε_{mix} and permeability μ_{mix} are performed with MS2028 VNA applying the reflection-transmission coaxial-line technique within 0.05-20GHz frequency band. The calculations are performed for isotropic mixtures filled with spheres and for plane-isotropic mixtures filled with flakes. The assumption of plane isotropy for flake-filled samples is reasonable as for the pressed washer sample the thickness (~0.8mm) is much smaller than the diameter (7mm). The effects of filling factor, particle shape and size on permittivity and permeability are analyzed. The reconstruction of inclusion permeability μ_{incl} is based on treatment of the measured dependence of ε_{mix} and μ_{mix} on frequency *f* and volume fraction of inclusions *p*.The procedure is based on generalized Sihvola mixing model [1] simplified for a plane-isotropic composite. The model is valid for wide range of susceptibility contrast and accounts for inclusion shape and geometric spectral linewidth [2] described by parameter *a* in equation (Eq.1). The dependence of composite susceptibility χ_{32} on frequency is defined by the corresponding dependence of inclusion susceptibility χ_{12}. The susceptibilities χ_{12} and χ_{32} are normalized by the corresponding constitutive parameter of a binder: permittivity ε_2 or permeability μ_2 of polymer. Equation (Eq.1) relates susceptibility of a composite χ_{32} to the filling factor *p*, inclusion susceptibility χ_{12}, inclusion depolarization factor *N* and mixture structure characterized by parameter *a*. $\chi_{m32}/\chi_{m12}=p(1+a\chi_{m32})/[1+ a\chi_{m32}+ N\chi_{m12}(1-p)]$ (1) Indexes 1, 2 and 3 relate to inclusion, binder and mixture. The inclusions are assumed to be identical spheres or identical oblate ellipsoids of rotation; their shape defines the depolarization factor *N* [3]. The similar equation (Eq.2) describes composite electric susceptibility χ_{e32}. As metal conductivity is about 10^8Ohm×m,thus $\chi_{e12} >>\chi_{e32}$ at practicable fillings, and Eq.1 may be simplified as shown below. $\chi_{e32} = p\chi_{e12}\ (1+a\chi_{e32})/[1+ a\chi_{e32} + N\chi_{e12}\ (1-p)] \approx p/[N\ (1-p)-ap]$ (2) The difference in electric and magnetic susceptibility of metals $\chi_{e12} /\chi_{m12} >>1$ makes it possible to estimate intrinsic permeability of metals at microwaves, where the measurements with bulk metals are impossible because of skinning. Moreover the mixing model (Eq.1) makes it possible to estimate from the measured data the spectral linewidth *a* as well. It is easy to show that for metal inclusions ($\chi_{\varepsilon12}\rightarrow\alpha\infty$) the inclusion depolarization factor *N* and percolation threshold p_c are related to linewidth parameter *a* as Eq.3 $a=N(1-p_c)/p_c$ (3) The parameters *N* and p_c are readily determined experimentally and are used in the generalized Maxell Garnett (Odelevskiy) equation to relate a composite susceptibility to that one of inclusion [4]. The measured at 50MHz quasistatic permittivity and permeability $\varepsilon_{mix}(p)$ and $\mu_{mix}(p)$ data are shown in Fig.1 by circles and squares correspondingly. As the imaginary permeability μ''_{mix} at 50MHz is comparable to real part μ'_{mix}, the value $\mu_{mix}(p)$ is presented by the absolute value of μ_{mix}. In the vicinity of percolation threshold p_c the samples become electrically conductive and the measured permittivity has poor reprodusability and jumps from high positive to negative values. The effect of negative permittivity is known [5] but we relate it to inductive resistance of long clusters similar to that of wire sections [6]. The dashed lines in Fig.1 present the permittivity curves calculated from Eq.2 with *N* and p_c as fitted parameters. The fitted values of depolarization factor N_{sph}=0.149 and N_{flk}=0.04 agree with microscopic measurements. The percolation threshold values are correspondingly $p_{c\text{-}sphere}$=0.56, and $p_{c\text{-}flake}$=0.19; thus Eq.3 gives a_{sphere}=0.111 and a_{flake}=0.167. The measured frequency dependence of microwave permeability for composites filled with flakes and spheres (the data in Fig.2 are selected for composites with approximately the same ε_{mix}-values) shows that the absorption peak shape and frequency strongly depend on inclusion shape and on thickness because of skinning. The absorption frequency is much lower than that of composites with carbonyl iron [1] and the permeability values measured at 50MHz are far from static ones. The reconstructed inclusion permeability at this frequency is also far from the static one as the loss tangent for spheres and flakes is close to unity, while the permeability real value is about 5 for both inclusion types; the value is about 2 times lower than the reported data [7]; the difference may be attributed to skinning and structural defects introduced in flakes while ball milling. The measured microwave constitutive parameters of composites show that Ni flakes and spheres both are promising fillers for interference suppressors and UHF-band absorbers similar to sendust powders [4].

One class of material that currently shows promise for spintronic and magnonic applications is Heusler compounds. Of importance is the fact that many of these compounds are half-metallic, meaning that one of the spin bands has a bandgap at the Fermi energy (i.e., insulating) while the other spin band is metallic in nature (i.e., conducting). This property leads to highly efficient generation of spin currents and large values of giant magnetoresistance, even at room temperature. [1,2] In addition, many half-metallic Heusler compounds are expected to have exceptionally low values of the damping parameter. We show that low values of the magnetic damping parameter can be achieved in sputter deposited poly-crystalline films of Co_2MnGe annealed at relatively low temperatures up to 400 °C. Such a low processing temperature for sputter deposited films is advantageous for many applications in spintronics that have limited thermal budgets. Measured damping values as low as 0.0014 are achieved with an intrinsic value of 0.0010 after spin-pumping contributions are taken into account. Of importance to applications is the low value of inhomogeneous linewidth that yields measured linewidths of 1.8 mT and 5.1 mT at 10 GHz and 40 GHz, respectively. The damping parameter is found to monotonically decrease as the annealing temperature increases, as shown in Figure 1. X-ray diffraction reveals that the increase in annealing temperature results in an increase in the B2 order of the films, suggesting that the damping parameter depends on the crystalline order of the CMG. This hypothesis was investigated via calculations of the damping parameter from density functional theory as implemented in the SPR-KKR code [3,4] combined with linear response theory. [5] Here, the damping parameter is calculated as the structure evolves from A2 to B2 to $L2_1$ orders as shown in Figure 2. The largest decrease in the damping parameter occurs during the A2 to B2 transition as the half-metallic phase becomes established. Finally, it is important to point out that our results show excellent *quantitative* agreement between the calculated and experimentally determined values of the damping parameter as the crystalline order is varied. Having the ability to quantitatively predict damping in materials can lead to the discovery of new materials with ultra-low values of the damping parameter.

CF-02. Enhanced magnetostatic and dynamic properties in Fe/Co substituted Ni-Mn-In alloy films.

R. Modak[1] and *A. Srinivasan*[1]
1. Department of Physics, Indian Institute of Technology, Guwahati, India

Multifunctional properties [1-3] and half metallic character [4] of Ni-Mn-In alloys have projected them as promising candidates for fabricating magnetoelectronic devices (MED) [5,6]. Since MEDs operating at microwave frequencies consume very little energy and are capable of achieving higher speeds, the search is on for new prospective materials for such applications. Understanding the magnetodynamic properties of thin films of these prospective alloys is very important for these applications. Substitution of magnetic elements in Ni-Mn-In is expected to enhance its magnetic properties. Here, Ni-Mn-X-In (X = Fe, Co) alloy films of thickness 500±5 nm were deposited on Si (100) substrate by dc magnetron sputtering from a $Ni_{48}Mn_{39}In_{13}$ alloy target. The fourth element (X) was introduced in the films by symmetrically placed 2 × 2 mm^2 X chips on the Ni-Mn-In target. As-deposited films were annealed *ex situ* at 550 °C under residual Ar gas pressure of 10^{-3} Pa for 1 h. Composition of the three annealed films were found to be $Ni_{49.2}Mn_{39.6}In_{11.1}$ (F1), $Ni_{49.1}Mn_{36.9}Fe_{2.9}In_{11.1}$ (F2) and $Ni_{49.0}Mn_{36.8}Co_{3.0}In_{11.2}$ (F3). The corresponding valence electron to atom (*e*/*a*) ratio of F1, F2 and F3 are 8.02, 8.09 and 8.08, respectively. Grazing incidence X-ray diffraction patterns of the films confirmed single phase austenite structure with $L2_1$ ordering (space group Fm-3m). Room temperature isothermal magnetization (*M-H*) curves recorded as a function of applied field showed paramagnetic behavior in all as-deposited films due to their amorphous structure. However upon annealing, ferromagnetic order was induced in the films with the formation of a polycrystalline structure (*c.f.* Fig.1(a)). It can be noticed from the figure that substitution of Fe or Co for Mn increases the magnetization upto ~120 emu/cc. It is evident from the typical *M-H* loops depicted as inset in Fig. 1(a) that the easy axis of magnetization is along the plane of the films. Room temperature ferromagnetic resonance (FMR) spectra recorded using an electron spin resonance spectrometer for different polar angles (θ_H) with applied magnetic field oriented along the film plane are shown in Fig. 1(b). The FMR spectra were analyzed using the well-known theoretical model discussed in Refs [7-9]. Effective magnetization ($4\pi M_{eff}$) and perpendicular effective anisotropy (K_1) have been extracted from the numerical fitting to resonance field (H_r) recorded from in plane orientation (90°) to out of plane (0°) of the film with respect to the applied magnetic field, using the above model. The analysis shows that H_r varies from a low to a higher value when the applied field is rotated in steps from in-plane to out-of-plane orientation. The saturation magnetization (M_s) of the films estimated from the H_r versus θ_H plots shown as inset in Fig. 1(c), are in good agreement with the dc magnetometry measurements. Fig. 1(c) represents the numerically fitted FMR linewidth (ΔH) data as a function of θ_H. It can be seen that the numerically modeled curves yield a good fit to experimental data with three crucial factors contributing to the observed linewidth. These are the (1) Gilbert damping term (ΔH_α) which is an internal property of the material, (2) 2-magnon scattering term ($\Delta H_{2\text{-}Mag}$), and (3) ΔH_0 term which depends on various extrinsic parameters related to the material nature. A careful look in Fig. 1(c) would reveal that with Fe (or Co) substitution, ΔH increased (or decreased) as compared to the ternary alloy film even though the Gilbert damping constant (α) remained almost invariant for both elemental substitutions. Through these studies, we show for the first time Co substituted Ni-Mn-In films with low Gilbert damping constant, higher saturation magnetization, high perpendicular anisotropy and easy axis along film plane which are very promising attributes for application in MED.

CF-03. Manipulation of Gilbert Damping Parameter by Annealing Sputtered Deposited Co/Pt Bilayer Thin Films.

A. Kumar[1], N. Pandey[2], D.K. Gupta[2], M. Gupta[2], S. Chaudhary[1] and P.K. Muduli[1]

1. Department of Physics, IIT Delhi, New Delhi, India; 2. UGC-DAE Consortium for Scientific Research, Indore, India

Ferromagnet/ heavy metal (FM/HM) systems have attracted considerable attention due to the presence of current-induced spin-orbit torques (SOT) at their interface. The SOT allows the manipulation of magnetization of the ferromagnet when sufficient high current density is used [1,2]. An important parameter for potential applications of these heterostructures is the Gilbert damping constant of the FM, which can be affected by the details of the interface. Here we study the damping constant of Co thin films in Co/Pt multilayers as a function of post-growth annealing. Such post-growth treatment is expected to affect the SOT and hence knowledge of the damping constant as a function of annealing temperature (T_A) is useful for applications. Co (10 nm)/Pt (5 nm) bilayer structure was prepared using DC magnetron sputtering on a Si (100) n-type substrate at 3 mTorr working pressure with base pressure of $<1\times10^{-7}$ mbar. The Si substrates were cleaned using RF cleaning with RF bias of 50 W for 15 min. We used 3-inch sputter targets with 99.99% purity for better uniformity over a large area of the substrate. We also performed pre-sputtering for 2 minutes before every deposition. Co and Pt thin films were sputtered at a very low growth rate of 5 Å/min and 25 Å/min, respectively. Structural characterization of as-deposited Co/Pt bilayers was performed using X-ray Diffraction (XRD) and X-ray reflectivity (XRR) measurements (Fig. 1). XRD spectra show the polycrystalline growth of Co/Pt bilayer thin film. XRR measurements show the high-quality growth of thin film with roughness <1 nm, this is further confirmed by atomic force microscopy (AFM). After growth, samples were annealed at zero field in a high vacuum chamber for 300, 400 and 500 °C with vacuum $<5\times10^{-6}$ Torr for 1hour. Figure 1 (c)-(e) shows AFM images for as-deposited and post-annealed samples. The AFM measurements show an increase of grain size with increase in annealing temperature, T_A, which predict high inter-diffusion of Pt and Co thin films with increase in T_A [3,4] Figure 2 (a) shows ferromagnetic resonance (FMR) spectra of as-grown Co/Pt bilayer thin films for 9 GHz RF frequency, the red line is fitted with derivative of the Lorentzian equation, fitting provides the value of linewidth and resonance field for a particular fixed frequency. Similar measurements are repeated for a frequency range of 6-12 GHz. The FMR linewidth vs. frequency was fitted to determine the Gilbert damping constant (α_{eff}). Frequency vs. resonance field was fitted with Kittle's formula to determine effective saturation magnetization (M_{eff}) [5]. Gilbert damping parameter is found to increases with increase in T_A while the effective saturation magnetization shows opposite behavior [Fig. 2(b)]. No FMR signal was observed for the sample annealed at T_A= 500 °C. These results can be understood by possible intermixing of Pt and Co at the interface. This study predicts that Gilbert damping constant of Co/Pt bilayer thin films can be manipulated by annealing the heterostructures at high temperature. We will show a detailed study of interface and inverse spin Hall effect measurements for understanding the possible effect on SOT due to annealing.

CF-04. Spin-orbit-torque and magnetic damping in ferromagnetic bilayers.

D. Lee[1], J. Kim[1], K. Lee[1], B. Ju[1], H. Koo[1], B. Min[1] and *O. Lee*[1]
1. Korea Institute of Science and Technology, Seoul, The Republic of Korea

Electrical manipulation of magnetization has been of great importance because of its scientific interest and potential application for low-power and high-speed spintronic devices. More recently, a number of works have demonstrated that in-plane charge currents generate spin-orbit torques (SOTs) that can directly switch the magnetization in hetero-structures with a strong spin-orbit coupling (SOC). For the practical use of SOT-MRAMs, it is required to reduce the write current density (J_c) significantly for minimization of Joule heat effect, low power consumption and CMOS compatibility. It is, hence, important to employ a multilayer system exhibiting a low resistivity, a large conversion efficiency from charge currents to spin currents (i.e. spin-Hall angle, θ_{SH}), a small magnetic damping (α) and a low demagnetization field (or effective out-of-plane magnetization) as much as possible to minimize J_c. Especially the achievement of a larger θ_{SH} and a lower α at the same time is of importance to implement successful SOT-devices. However, the recent spin-transparency model [1,2] suggests that the simultaneous achievement of a large θ_{SH} and a low α might be improbable. In the model, the interface transparency of the spin current between a heavy metal and a ferromagnetic layer plays an important role in determining both the effective magnitude of the spin-Hall angle and the increased amount of a magnetic damping due to the spin-pumping effect; e.g. θ_{SH}(Pt|Co)~0.11 vs θ_{SH}(Pt|Py)~0.05 but $\Delta\alpha_{sp}$(Pt|Co)~2 $\Delta\alpha_{sp}$(Pt|Py) from the Ref. [1,2]. This model indicates that the increase in θ_{SH} with a higher spin transparency will be counteracted by an increase in α so that the variation of the transparency would not be helpful for lowering J_c. Here we present one strategy to relieve this issue by utilizing ferromagnetic bilayers, consisting of Co and Py, instead of a single ferromagnetic layer, sandwiched between MgO and Pt layers [3]. We used DC/RF magnetron sputtering to deposit two series of multilayer films having different stack orders, Pt|Co|Py|MgO or Pt|Py|Co|MgO, on a thermally oxidized Si substrate at room temperature. The multilayers consist of, from the bottom to the top, Ta(1)/Pt(5)/Co(*t*)/Py(5-t)/MgO(2)/Ta(2) and Ta(1)/Pt(5)/Py(5-*t*)/Co(t)/MgO(2)/Ta(2) (thickness in nm) where the thickness of cobalt (t_{Co}) layer was varied from 0 to 5 nm. We considered Co|Py or Py|Co magnetic layers as a single ferromagnetic layer in our analysis because the total thickness of the bi-layers (5 nm) is comparable or less than the exchange length of each Co or Py. We, first of all, characterized the multilayer films by using our vibrating sample magnetometer (VSM). The saturated magnetization (M_s) monotonously increases with the t_{Co} as expected while the stack order (Pt|Co|Py|MgO or Pt|Py|Co|MgO) has little effect on the M_s. However the perpendicular magnetization anisotropy (PMA) is strongly dependent on the stacking order: Pt|Co|Py series have much stronger PMA than Pt|Py|Co|MgO series, resulting in the effective out-of-plane demagnetization field ($4\pi M_{eff}$) of Pt|Co|Py|MgO lower than $4\pi M_{eff}$ of Pt|Py|Co|MgO. We note that the magnitude of $4\pi M_{eff}$ is also one of the key material parameters in determining the switching current density for the anti-damping SOT induced magnetization switching. Next we utilized spin-torque ferromagnetic resonance (ST-FMR) method to investigate their spin-Hall angle's (θ_{SH}), magnetic damping's (α), inhomogeneous linewidth broadening's (ΔH0), and effective out-of-plane demagnetization field's ($4\pi M_{eff}$) as functions of their stacking order and relative thicknesses. Figure. 1 summarizes the measured $4\pi M_{eff}$, α, ΔH0 and θ_{SH} from the ST-FMR. The $4\pi M_{eff}$'s are in good agreement with the ones from the *M-H* hysteresis; the $4\pi M_{eff}$'s for Pt|Co(t)|Py(5-t)|MgO is lower than the ones for the Pt|Py(5-t)|Co(t)|MgO. Our results show that the value of θ_{SH} was determined by the type of interface mostly in contact to the Pt layer (Pt|FM), i.e. θ_{SH}(Pt|Co) > θ_{SH}(Pt|Py), which is consistent with the spin-transparency model. However we found that the FM|MgO interface also plays a substantial role in determining the dynamical dissipation parameters, along with the spin-pumping effect through the Pt|FM interface. The Co|MgO interface significantly increases both α and ΔH0 probably due to more developed two-magnon scattering process while the Py|MgO interface has a negligible effect on their enhancements. Figure 2 summarizes the determined α *vs* ΔH0 from all our ST-FMR devices having ferromagnetic bi- or tri-layers. Interestingly α increases with increasing ΔH0 quasi-linearly for samples with a Co|MgO interface, whereas for those with a Py|MgO interface, α remains nearly constant with increasing ΔH0, which is mostly distributed at low values. The measured data definitely indicates that a new magnetic relaxation channel is developed at the Co|MgO interface. We, based on the measured parameters, estimate the current density as functions of the stack order and the t_{Co} for the SOT induced in-plane magnetization switching. Overall for a low J_{c0} the multilayer configuration of Pt|Co|Py|MgO has more preferable material parameters than the stack of Pt|Py|Co|MgO. Our approach suggests one promising method to optimize θ_{SH}, α, ΔH0, and $4\pi M_{eff}$ by engineering both interfaces contacting to the Pt and the MgO layers. In this talk, we shall present the detailed our results for the various stacking order and thickness ranges. And we will discuss about possible mechanism to the magnetic damping from the interface with MgO layer.

CF-05. Tetragonally Distorted Ultrathin $Fe_{50}Co_{50}$ Epitaxial Film with High Magnetic Anisotropy and Gilbert Damping.

R. Mandal[1], J. Jung[1], Y. Takahashi[1], Y. Sakuraba[1], S. Kasai[1], T. Ohkubo[1] and K. Hono[1]
1. Research Center for Magnetic and Spintronic Materials, National Institute for Materials Science (NIMS), Tsukuba, Japan

Perpendicular magnetic anisotropy (PMA) thin films have attracted considerable interest due to their potential application in the field of spintronics such as spin transfer torque magnetic random access memory (STT-MRAM) [1]. To increase the capacity of STT-MRAM, high PMA material is required for both of the reference and free layers in order to overcome the thermal agitation problem. One of promising PMA materials is the tetragonally distorted FeCo alloy. Large PMA of 0.2 MJ/m^3 was reported for tetragonally distorted FeCo grown on Rh [2, 3]. To further investigate the potential of this material for the ferromagnetic layer in STT-MRAM, the estimation of Gilbert damping (α) is necessary. Here we report unusually high α of 0.04 in 1.0-nm-thick FeCo film grown on a Rh underlayer. Based on the microstructure observation, we conclude that large value of α is due to the Rh diffusion as well as the large lattice distortion. The $Fe_{50}Co_{50}$ films were deposited by ultra-high vacuum magnetron sputtering system at a base pressure of 2×10^{-7} pa. The stacking structure of the film is MgO/Rh (50)/$Fe_{50}Co_{50}$ (t)/Rh (3), where the numbers in the parentheses indicate the thickness in nm. The thickness (t) of $Fe_{50}Co_{50}$ was varied from 1.0-nm to 10.0-nm. The Rh buffer layer was deposited at room temperature followed by post annealing at 573 K. $Fe_{50}Co_{50}$ (t) layer and the capping Rh (3) layer were also deposited at room temperature (RT). The magnetization curves were measured using a vibrating sample magnetometer whereas the crystalline structure and microstructure were verified by using X-ray diffraction (XRD) and transmission electron microscopy (TEM) with energy dispersive spectroscopic (EDS) analysis. α was estimated by time-resolved magneto optical Kerr effect (TRMOKE) method based on an all-optical two-color pump-probe setup [5]. Here the pump pulse used as an excitation pulse to excite the magnetization whereas the probe beam used to measure the change of magnetization *w.r.t.* the time in phase sensitive manner. Fig. 1 (a) shows a cross-sectional STEM-HAADF image of 1.0-nm-thick FeCo sample. The zone axis is Rh [110] and FeCo [100]. From the lattice spacing in this image, c/a is determined to be 1.3, in agreement with that estimated by XRD data. No misfit dislocations are observed in this area of view, indicating that there is a large strain in the FeCo layer. Fig. 1 (b) and (d) shows an elemental mapping and the composition profile. Although the deposition of FeCo was carried out at RT, the serious interdiffusion of Rh is observed because of the good solubility in the Fe-Rh system. Fig. 1 (c) shows the magnetization curve of the perpendicular and in-plane directions of the 1.0-nm-thick sample. The film shows strong PMA and K_u is about 0.6 MJ/m^3 which is the highest value ever reported for FeCo [4]. With the increase of the film thickness of FeCo, the c/a, K_u and Rh interdiffusion decreases (data is not shown here). Thicker than 2.0-nm, the film shows in-plane magnetic anisotropy. The inset of Fig. 2 shows the typical TRMOKE signals for 1.0-nm-thick sample at various strength of external bias magnetic fields ($\mu_0 H$). Using the linearized LLG equation [6] α was estimated as a function of the inverse film thickness 1/t. We found that the value of α for t = 1.0-nm is 0.04, unusually high value for FeCo, and later α decreases to 0.01 at t = 10.0-nm-thick film. The value of α shows a linear trend as shown by the blue dotted line in Fig. 2 from in-plane to PMA samples. From the microstructure observation, we can conclude that the large α in 1.0-nm-thick FeCo PMA sample is due to the Rh diffusion as well as the large lattice distortion. Judging from the large PMA and α, 1.0-nm-thick FeCo film is suitable for the reference layer in STT-MRAM, because it has high PMA and α in the very thin region. However, it is not suitable for a free layer as its damping and magnetization are too large for low current STT switching.

Understanding and controlling magnetism in laterally confined micro/nano-structures has been attracted much attention because of both the fundamental magnetism and engineering applications such as magnetoresistive sensors and microwave oscillators. [1] One of the interesting magnetic domain structure is vortex core, being the most obvious example. [2] To understand and control the magnetism, the magnetization dynamics in the artificially confined magnets have been investigated using various techniques including time-resolve Kerr microscopy [3], Brillouin light scattering [4, 5] and electrical detection techniques. [6 – 10] Recently, control of the magnetization structure or dynamics using electric fields, spin currents or strain that is electrically induced via piezoelectric effect has been focused to achieve the electric control of magnetic characteristics in the spintronics devices. [11] One simple idea is creation of an artificial multiferroic materials induced by the heterojunction between ferromagnetic and ferroelectric materials. [12, 13] This idea has been tried by a number of researchers, and a considerable advance in knowledge and technique has been obtained. The study on magnetization dynamics in artificial nano/micro-magnets with the heterojunction is a significant important subject for many applications of magnetic materials, examples of which include nonvolatile magnetic random access memory, microwave-detector and oscillator. The electrical techniques allow the indirect detection of the resistance oscillation as a function of the input microwave signal. The homodyne detection using rectifying effect can provide an excellent probe for the intrinsic magnetization dynamics influenced by the additional contributions derived from the heterojunction in the nano.micro-magnets. In this investigation, we demonstrated ferromagnetic resonance of a Ni wire with magnetic anisotropy induced by the magnetoelastic effect derived from the heterojunction between the Ni layer and ferroelectric single crystalline $LiNbO_3$ substrate. We fabricated the 30-nm-thick Ni wire onto the $LiNbO_3$ substrate by means of electron-beam lithography and lift-off methods using a magnetron sputtering. [12, 13] The Ni wire is placed in the aperture between the conductive strip lines of the coplanar waveguide (CPW) comprising of a Cr (5 nm)/Au (80 nm). The wire prepared between the CPW strip lines is 5 μm in width and 100 μm in length as show in the inset of Fig. 1(a). In this study, the Ni wire is oriented perpendicular to the orientation flat (OF) direction of the substrate. The alignment allows the formation of zebra-stripe domain structure near the absence of external magnetic field. The rectifying spectra are dependent on the magnetic field strength, angle, and internal domain structure. In this study, we focused on the magnetic response for the microwave current excitation in the Ni wire with zebra-stripe domain structure under the external magnetic field. First, we measured the magnetoresistances (MRs) of the Ni wire in the application of magnetic field at θ = 0° (magnetic field // Ni wire) and 90° (magnetic field Ni wire) as shown in Fig. 1(b). In this study, we defined MR ratio as MR ratio = $[R(H)\text{-}R(H_{sat})]/R(H_{sat})\times 100$ %, where H_{sat} denotes the saturation magnetic field at which the MR was saturated. As shown in Fig. 1(b), focusing the MR behaviors of the cases : θ = 0 and 90°, we found the hysteresis and possibility of domain structure formation near the absence of magnetic field in both cases. Next, the field angle dependence of rectifying spectra are measured. The magnetic field was applied at angle *q* relative to the longitudinal axis of Ni wire. Figures 2(a) and 2(b) show the typical rectifying spectra in Ni wire oriented perpendicular to the OF direction in the application of magnetic fields at the angles θ = 0 and 90°, respectively. The clear rectifying signals are observed as shown in Fig. 2(a), while almost signals are independent of the magnetic fields in Fig. 2(b). Based on the analytical calculations of the rectifying spectra, we could estimate the uniaxial magnetic anisotropy derived from the heterojunction. Our results manifest that the electrical detection techniques of MR and rectifying effect are very useful for understanding and evaluating the magnetic properties induced by the heterojunction between ferromagnetic and ferroelectric materials. This study will open a door to develop the novel artificial multiferroic materials [14] and devices using the heterojunction.

Spin orbit torques have attracted interest for use in manipulation of magnetization of magnetic memory devices[1]. Tungsten-oxide (W(O)) is a new material to generate spin orbit torque which has highest spin hall angle up to -0.5[2] to date for conventional metal materials. Whilst much work has focused on improving the spin hall angle of new materials, there is much less work investigating the application of this W(O) material as the highly efficient spin orbit torque generator for memory devices. Here, we explore switching dynamics of the magnetic tunnel junction in use of spin obit torque in three terminal magnetic devices which use W(O) as the spin hall layer. We investigate the role of non-uniform micromagnetic states in achieving deterministic switching in a novel scheme where the magnetization of the magnetic element and spin polarization are non-collinear without external field. We also confirm the -50% spin hall angle of W(O) as the spin orbit torque generator in three terminal devices. Lastly, we show the potential of using this novel spin orbit torque scheme in non-volatile magnetic logic application

Spin Hall effect (SHE) is known to be a good way to generate spin currents taking advantage of spin-orbit (SO) interaction in non-magnetic (NM) materials [1]. Since the origin of SHE is based on SO coupling and SO coupling is expected to be larger for heavier elements, several studies on SHE have been conducted with heavy metals such as Pt [2]. Recent studies have also been carried out by adding NM impurities with strong SO coupling in light metals to enhance and tune the spin Hall angle θ_{SH}, a parameter allowing the quantization of the spin current generation efficiency of a material by SHE [3]. Besides, in direct contact with a ferromagnetic layer, the interfacial Dzyaloshinskii-Moriya interaction (DMI), introduced by broken inversion symmetry and strong SO coupling, can be arised. This phenomenon, which plays an important role in the creation of skyrmions [4], combined to the SHE should be understood for applications, particularly the behaviour of magnetic parameters with SO coupling variation in such systems. In this work, we study the effects on the DMI constant D_s and the Gilbert damping parameter α of the addition of Pt into a light metal Cu mostly used in spintronic devices nowadays. The structure of the studied films is Si substrate/ Py (5 nm)/$Cu_{1-x}Pt_x$ (6 nm)/MgO (1 nm)/SiO_2 (3 nm). We first studied the DMI using Brillouin light scattering (BLS) technique. The BLS data were analysed for ultrathin films leading to a Stokes (F_S) and anti-Stokes (F_{AS}) frequency difference: $\Delta F = F_S - F_{AS} = (2\gamma D_s k_{sw})/(\pi M_s t_{FM})$, with the saturation magnetization M_s deduced from VSM measurements, the ferromagnetic layer thickness t_{FM} and the gyromagnetic ratio γ ($\gamma/2\pi$ = 29.5 GHz/T for Py [5]). The slope d(DF)/dk_{sw} is given by $(2\gamma Ds)/(\pi M_s t_{FM})$ .The analysis of the BLS results leads to an increasing of the D_s values with the Pt concentration (figure 1a) due to the appearance of more strong SO coupling sites. We obtained an expected D_s value for the Py/Pt structure [5]. The full width at half maximum of the Stokes and anti-Stokes peaks was also measured (figure 1b) providing direct information of the α by their proportionality [6]. Ferromagnetic resonance (FMR) measurement were performed in order to extract α (figure 1c) and effective magnetization $4\pi M_{eff}$ (figure 1d) depending on Pt concentration. The addition of Pt into Cu induces a large increase of α until saturating at ~ 75% of Pt as also observed by BLS. This increase can be explained by the spin pumping contribution brought by the Pt. The Pt also induces a dead layer deduced from the M_s for different Py thicknesses. The reduction of Py thickness leads to a higher anisotropy H_a in line with the decrease of the $4\pi M_{eff}$ (= $4\pi M_s - H_a$) with Pt concentration. In our CuPt system, the DMI and the Gilbert damping parameter could be engineered depending on Pt concentration for different applications.

Similar to electrical currents flowing through magnetic multilayers [1,2], thermal gradients applied across the barrier of a magnetic tunnel junction may induce pure spin currents and generate 'thermal' spin-transfer torques large enough to induce magnetization dynamics on the free layer [3, 4]. The relation of spin current, charge current and heat current was theoretically described by Bauer et al. using Onsager's reciprocity rule [5]. According to Onsager's law, spin currents can be produced by bias voltages or thermal gradients and investigated in terms of spin-Seebeck effect in magnetic multilayers. First, Hatami et al. theoretically studied the spin-Seebeck effect in spin-valves and introduced the concept of thermal spin-transfer torques. They predicted that the thermally induced spin current creates an imbalance on the interface between non-magnetic and ferromagnetic layers due to collisions (electron-electron and electron-phonon interactions) [3]. Thermal spin-transfer torques were studied experimentally within asymmetric Co/Cu/Co nanowire spin-valves which exhibit switching field changes under varying a.c. currents causing Joule heating [6]. In magnetic tunnel junctions, it was theoretically predicted that temperature differences of around 10 K over an ultrathin barrier (1 nm) can create magnetization dynamics in Fe/MgO/Fe magnetic tunnel junctions [4]. The spin-Seebeck effect has been studied on CoFeB/MgO/CoFeB magnetic tunnel junctions using different heating methods such as Joule heating, heating with Peltier elements, as well as laser heating [8-14]. Recently, it was shown that using Co_2FeAl as a reference layer improves tunneling magneto-Seebeck ratio (TMS) in the magnetic tunnel junctions [7]. Here, we describe a novel experimental approach and setup to observe effects of thermal gradients within magnetic tunnel junctions with Heusler compounds by using the microresonator ferromagnetic resonance (μR-FMR) method under laser heating. Initially, microresonators (shown in figure 1) were introduced by Narkowicz et al. for electron paramagnetic resonance (EPR) experiments to achieve optimal sensitivity for small objects [8]. Detecting the FMR signal of nano- to micron-sized samples in conventional cavities (cm^3) is not possible, due to the too small ferromagnetic volume, and therefore low filling factor. A planar microresonator, by definition, is a two-dimensional structure, its diameter can be tailored to match the order of the sample's size (shown as a black ellipse in the microresonator loop in figure 1). Two stubs are attached to the inductive loop. The capacitive radial stub in first approximation may be viewed as an element to tune the loop to the operation frequency, while the rectangular stub matches the structure to the 50 Ω impedance of the microstrip feedline. We investigated magnetic tunnel junctions (MTJs) fabricated out of Co_2FeAl/MgO/CoFeB stacks. The sample and microresonator fabrication consist of multiple steps of lithography, ion etching, and lift-off processes. The sample is finally patterned into a 6x9 μm^2 elliptical shape using electron beam lithography (EBL) and ion beam etching is used to etch down the sample to the substrate. Microresonators are then fabricated around the sample using UV lithography. For laser heating, a continuous-wave (CW) laser at 532 nm wavelength and with tunable power up to 33 mW is focused on the sample. "Hot-FMR" measurements were performed on unpatterned multilayers between 300 K and 450 K (figure 2) to understand the effect of global heating. It is clearly seen that the FMR signal of Co_2FeAl exhibits a shift with increasing temperature. As seen in the inset graph, it is difficult to quantify the changes for the CoFeB signal, due to its small intensity. Subsequent, measurements in the presence of a thermal gradient were performed on 6x9 μm^2 MTJs, integrated into microresonator loops with an inner diameter of 20 μm. The MTJs were submitted to laser irradiation, up to a maximum power of 33 mW. Unlike the Hot-FMR measurements, the resonance field and linewidth did not show clear changes with increasing laser power. The results suggest that the laser power is neither sufficient to induce magnetization dynamics via thermal gradients across the barrier nor lead to significant changes of the magnetic parameters due to global heating of the sample. As a conclusion, the effect of a global temperature change on the resonance frequency and linewidth of Co_2FeAl was analyzed. With regards to the μR-FMR results, the higher laser power is needed to induce magnetization dynamics. Moreover, the lateral heat transport might reduce the vertical thermal gradients, thus similar measurements on smaller structures are required. This study was funded by the German Research Foundation (DFG) via priority program SpinCaT (SPP 1538). We thank H. Schultheiss for helping with the optical part of the experimental setup and S. Zhou for giving the access to the VSM setup.

Full Heusler alloys such as Co_2FeAl (CFA) are promising candidate for lowest damping among the Heusler compounds and the manipulation of the damping constant is the key requirement for the study of spin transfer torque [1-3]. In this work, the spin dynamics properties of CFA/Mo bilayer thin films grown on Si(100) substrate by the ion-beam sputtering system are analysed in detail. Ferromagnetic resonance (FMR) has been used to investigate the Mo(0-10nm) layer thickness dependence gilbert damping parameter enhancement (spin pumping) in CFA(8)/Mo(t_{Mo}) bilayer system. The spin pumping then confirmed by inserting various Cu layer thickness (For brevity Cu(1nm) is shown in Fig.1(d)) at CFA(8nm)/Mo(5nm) interface which terminates the spin pumping into the Mo layer. The gilbert damping is found to increase up to 0.0084±0.0003 which is ~68% enhancement of original Gilbert damping (0.0050±0.0002) of CFA(8nm)/Al(Al(4nm)) [Fig.1(c)]. This enhancememt of Gilbert damping is comparable to the Pt nonmagnetic metal. The experimental data have been analyzed using a model for spin pumping that includes the effective spin mixing conductance and the spin-diffusion length. The spin mixing conductance and spin-diffusion length were calculated and found to be 1.19×10^{19} m^{-2} and 3.5±0.35nm, respectively. PPMS VSM was used to measure the saturation magnetization. The thickness, interface width and the surface roughnesses were evaluated by the XRR and AFM respectively. From these These results are indispensable for Mo as spin pumping material in spin dynamic devices.

CF-11. Study of Static and Dynamic Properties of Dumbbell Shaped Structures.

P.N. Sherpa[1], S. Khanal[1] and L. Spinu[1]
1. Physics/ Advanced Materials Science Institute, University of New Orleans, New Orleans, LA, United States

Metamaterials such as magnonic crystals (MC) have been of great interest in the past years as its easily tunable magnetic properties provide new possibilities for exciting technologies. Information transformation, signal processing, spintronic devices, high-density data storage and sensors [1-4] are a few examples where MC show the promising application. MCs are also a perfect candidate for on-chip data communication, phase shifters, splitters, and non-linear networks as well as magnonic logic devices [5-9]. The unique non-reciprocal properties of spin waves have possible application in microwave devices such as isolators, circulators and microwave filters [10, 11]. The beauty of MC is that the static and dynamic properties can be easily tuned by simply the changing the shape, size, spacing, and symmetry of the structure. Saturation magnetization, anisotropy constant, exchange stiffness, and damping constant is no longer only intrinsic properties of the magnetic structure because of different boundary condition for different structures. Controlling these parameters in a systematic manner to achieve distinctive properties is highly important from a technological perspective. For this, extensive studies on structures such as nanowires, dots, rings, grooves, antidots, modulated wires, etc. have been performed. Periodic modulations on one or both sides of nanowires to study the effect on static and dynamic properties is shown in detail in reference [12, 15]. In this study, we combined two different structures, wires and dots in a dumbbell configuration, to study the static and dynamic properties collectively. Joining the planer symmetric structured dot to the non-planer symmetric wire should be interesting to study how static and dynamic properties would change from individual to a combined form of varying structures. Magnetic nanowires where magnetization reversal (MR) generally takes place by nucleation and propagation of domain walls are different from the dot structure where MR takes place depending on the aspect ratio as well as size [13]. Understanding MR on these combined structures and effect on both static and dynamic properties is main drive of this study. Magneto-Optic Kerr Effect (MOKE) and vector network analyzer- ferromagnetic resonance (VNA-FMR) were used to study the static and dynamic properties respectively. Ground-signal-ground (G-S-G) type coplanar waveguides (CPW) were prepared by the combined method of photolithography, DC sputtering and liftoff process. Titanium (Ti), copper (Cu) and gold (Au) having thickness 5 nm, 150 nm, and 10 nm, respectively, were deposited on silicon substrate. The dimensions and shape of CPW were designed by the CST MICROWAVE STUDIO to achieve the nominal characteristic impedance of 50 Ohm. Then periodic Ni80Fe20 (Permalloy - Py) arrays of dumbbell were fabricated on the top of the signal line of CPW with the help of electron beam lithography, sputtering and liftoff process. Six sets of samples are prepared on top of a CPW, three parallel and three perpendicular to the signal line (since the dot is symmetric, parallel and perpendicular refer to the orientation of the wire axis with respect to the signal line). The samples parallel to the signal line are named D-1-PA, D-2-PA, D-4-PA, which means the diameter of the dots are 1, 2, and 4 micrometers, respectively. D-1-PE, D-2-PE, D-4-PE refers to samples with dot diameter 1, 2 and 4 micrometers, oriented perpendicular to the signal line. In all samples, the wire has a length of 4 micrometers and a width of 1 micrometer. The thickness of all samples was 50 nm and the gap between individual dumbbell was kept more than 1 micrometer to ensure the structures did not interact with each other. MOKE was used to study static properties, such as collective magnetization reversal, sweeping the external magnetic field in different directions, for example. VNA-FMR was used to study the dynamic properties at room temperature. The ac magnetic field and dc applied field were always kept perpendicular to each other to satisfy the condition of FMR. The microwave frequency was swept from 1 to 15 GHz while keeping the dc magnetic field constant. The dc field was swept from 1500 to -1500 Oe with a step of 10 Oe. The scattering parameter transmission coefficient (S21) was collected as a function of frequency. The 3-dimensional contour plot of frequency, dc field, and S21, where the highest absorption of microwave field is shown in black, is presented in the figure. To better understand the experimental results, micromagnetic simulations were performed with graphics processing unit (GPU) accelerated micromagnetic simulation software Mumax [14] on LONI Queen Bee supercomputer, from LONI (Louisiana Optical Network Initiative - http://www.loni.org/), with a 1.5 Petaflop peak performance cluster containing 504 compute nodes with 960 NVIDIA Tesla K20x GPU's and over 10,000 Intel Xeon processing cores.

CF-12. Magnetization and FMR studies of Si/Ni multilayers with varying Ni layer thickness.

D. Singh[1], R. Roy[1] and M. Senthil Kumar[1]
1. Department of Physics, Indian Institute of Technology Bombay, Mumbai, India

Magnetic properties of ferromagnetic multilayers are influenced by their structure and composition. In ferromagnetic materials, the spontaneous magnetization is well explained by Bloch's law occurs from the spin wave theory for bulk ferromagnets[1]. In many cases the Bloch's law is also verified for ultrathin two dimensional ferromagnetic films with $T^{3/2}$ dependency[2]. The magnetic field dependent MH-loops and ferromagnetic resonance (FMR) spectra technique are extensively used as useful tools to determine effective spontaneous magnetization, Lande's factor, magnetic anisotropy effect ($2K/M_s$) and interlayer exchange coupling between ferro-magnetic layers separated by non-magnetic spacer layer[3] The Si/Ni multi-layers were prepared using a DC magnetron sputtering system at 300K. After achieving a base pressure of $2x10^{-6}$ mbar, the deposition was taken place on to the both glass and Si (111) wafer at $4x10^{-3}$ mbar of Ar pressure. The nominal thickness of the Si layer was fixed at 10Å and that of the Ni layer varied from 10 Å to 100Å. We have investigated the influence of the Ni layer thickness on the structural and magnetic field dependent magnetization, spin wave excitations and ferromagnetic resonance properties of the Si/Ni multilayers (ML). The GIXRD pattern obtained within the annular region 10° to 90° at 300K shows a strong texture along Ni (111) plane. There are no peaks originating from Si layer explaining that Si layer is amorphous whereas Ni layer is nanocrystalline. The field dependent in plane magnetization measurements were carried out at 300K, 200K, 100K, 77K, 10K and 4.2K with magnetic field up to 20 kOe. The variation in M_S with temperature T of the ML is shown in the Fig. 1 (a). To study the spin wave excitation, we have fitted the M_S versus T data using Bloch's equation i.e. $M(T) = M(0)(1-BT^{3/2})$. The spin wave constant (B) and stiffness coefficient (D) are related by the equation $B = 0.0587(g\mu_B/M(0))(k_B/D)^{3/2}$ [4]. Where g and μ_B are the spectroscopic splitting factor and Bohr magnetron respectively. It can be clearly seen in Fig. 1 (a) that M_S versus T data is well fitted using Bloch's equation. The deduced B parameter's values are much higher than that of bulk Ni ($7.5x10^{-6}K^{-3/2}$). The B values are found to increase from $18.4x10^{-6}K^{-3/2}$ to $132.4x10^{-6}K^{-3/2}$ by decreasing t_{Ni} from 100Å to 10Å, respectively. Furthermore, the B parameter is dependent with t_{Ni} through the equation $B(t_{Ni}) = B_{Bulk} - (B_{Surface}/t_{Ni})$ where B_{Bulk} and $B_{Surface}$ are the bulk and surface spin wave parameters [5]. It is evident in Fig. 1 (c) that the B parameters fit reasonably well to a straight line with respect to the t_{Ni}. The extrapolation to $1/t_{Ni} = 0$ is in good agreement to that of bulk for Ni which is equal to $5.8x10^{-6}K^{-3/2}\pm 0.6x10^{-6}K^{-3/2}$. From the slope of the linear fit of B versus $1/t_{Ni}$, is deduced to be $1.3x10^{-3}ÅK^{-3/2}$. The FMR study is carried out at 9.443 GHz. The FMR spectra of the Si/Ni ML were recorded at 300K in both parallel and perpendicular direction. The effective spontaneous magnetization (M_{eff}) is calculated using Kttlel's equations[6]. The variation in M_S and M_{eff} at 300K obtained from S-VSM and FMR spectra respectively is shown in Fig. 2 (a). The difference between the M_S and $M_{eff,}$ in Fig. 2 (a), could be due to the demagnetization field and interface magneto crystalline anisotropy. If the interface anisotropy is contributing towards the first order anisotropy energy K_1, then the perpendicular anisotropy (including demagnetization term) can be estimated according to the equation $K_{eff} = K_V + (2K_S/t_{Ni})$ Where K_S, $K_V = K_U-2\pi(M_S)^2$ and $K_{eff} = K_1-2\pi(M_S)^2$ are the surface anisotropy, volume anisotropy and effective anisotropy energies, respectively. We have report the t_{Ni} dependency of K_{eff} in Fig. 2 (b). The data fitted between $K_{eff}*t_{Ni}$ and t_{Ni} follow a well approximated linear line. The deduced K_V and K_S from the straight line fit of Fig. 2 (b) at 300 K are $-1.09x10^6$ erg/cm^2 and 0.12 erg/cm^2, respectively. The positive vale of K_S indicates that the surface anisotropy energy try to confine magnetization perpendicular to the film surface [1][7]. The negative value of K_V ascribes that the volume anisotropy energy tends to confine magnetization in the plane of the film. From Fig. 2 (b) the intersection on the x-axis is deduced to be 23 Å indicating that the major contribution to the anisotropy comes from the interfaces of the multilayer. Therefore in the low thickness regime (t_{Ni} < 23Å) the interface anisotropy dominating and favoring confinement of magnetization to the out of the film surface whereas with that of higher thickness (t_{Ni} > 23Å) volume anisotropy dominates indicating easy axis of magnetization along the film surface.

CG-01. An Improved Core-Loss Calculation Method with Variable Coefficients Based on Equivalent Frequency.

W. Jia[1] and X. Lan[1]
1. Nanjing University of Aeronautics and Astronautics, Nanjing, China

Abstract: A concept of equivalent frequency is proposed for arbitrary waveforms. A determination method of core-loss coefficients based on the equivalent frequency is established, together with an improved core-loss calculation method for electric machines. Finally, a doubly salient motor is used as a prototype to verify the improved core-loss calculation method. I. Introduction Due to the uneven distribution and local super-saturation of flux density, together with the high frequency of fundamental and harmonic components, the core loss of non-sinusoidal electric machines is prominent and difficult to predict. The core-loss prediction of non-sinusoidal electric machines is an important and challenging subject. Many calculation models has been proposed and improved in many researches [1-6].The most widely used one is the dynamic model proposed by D. Lin in [6], which has been used in ANASYS Maxwell. However, the core-loss coefficients varies with frequency and flux density, the calculation results with constant core-loss coefficients can only valid in a certain operating condition. Some core-loss calculation methods with variable coefficients have been studied in some researches [7-8]. However, most of them only consider the influence of frequency or flux density. Besides, if the time-domain dynamic model is used, only the fundamental frequency of a periodic waveform is considered. So, the core loss of electric machines cannot be calculated precisely, especially for aperiodic waveforms. II. The Equivalent Frequency of Arbitrary Flux Density In order to predict the core loss of arbitrary flux density precisely, the concepts of equivalent frequency and period are proposed, which are defined according to the equivalent values of average flux-density change rate. An arbitrary flux density can be deemed as a sinusoidal waveform with the amplitude equaling to half of the peak-to-peak value of the arbitrary flux density, and the equivalent sinusoidal waveform has the same average value of absolute flux-density change rate with the arbitrary flux density waveform. Fig. 1 shows an arbitrary flux density waveforms and the associated equivalent sinusoidal waveforms. For a sinusoidal flux density waveform expressed as $B=B_m\sin\omega t$ *T*he average value of the flux-density change rate for the sinusoidal waveform equals to $4B_mf$. For an arbitrary flux density waveform, the average value of the flux-density change rate can be expressed as $\sum(|\Delta B/\Delta t|)/(N\Delta t)$. Let the average change rate of arbitrary flux density equal that of the sinusoidal flux density, the equivalent frequency can be deduced as $f_{eq}=\sum(|\Delta B|)/(4B_{m.eq}N\Delta t)$, where $B_{m.eq}$ equals half of the peak-to-peak value of the arbitrary flux density. III. Improved Core Loss Model with Equivalent frequency Based Variable Coefficients According to the two-term model, the coefficients satisfy the expression below: $P_{fe}/(fB_m^2)=k_h+k_cf$ So, the coefficient k_h is the vertical intercept of the curves, which can be calculated by ignoring the nonlinearity of the curves during the low frequency. The coefficient k_c can be calculated according to the expression below: $k_c=P_{fe}/(f^2B_m^2)-k_hf$. By analyzing the changing pattern of k_c, it can be obtained that k_c changes with the frequency more obviously than with the flux density. Besides, k_c decreases with the frequency monotonously, which can be explained by the skin effect. By fitting the data of k_c, a mathematic model expressing the variations of k_c versus frequency can be shown below: $k_c=k_{c0}f^a\ln(f)+k_{c1}f^b$ where k_{c0}, k_{c1}, a, and b are flux density–dependent variables, which can be obtained by fitting the data of k_c with different frequency at every flux density point. The waveform of flux density can be deemed as a combination of many hysteresis loops, and each hysteresis loop contributes to the hysteresis loss independently. Therefore, the hysteresis loss of a electric machine can be expressed as $P_h=\sum[(m_i/T)\sum(k_hB_{m\_r.j}^2+k_hB_{m\_t.j}^2)]$ where m_i is the mass of the element i;$B_{m\_r.j}$ and $B_{m\_t.j}$ are the amplitudes of the radial and tangential flux density components of the jth hysteresis loop, respectively. The improved eddy loss of an electric machine with the time-stepping FEA method can be expressed as $P_c=\sum\{(m_if/(2\pi\Delta t))[(k_c(f_{eq},B_{eq})\sum(B_{k+1\_r.i}-B_{k+1\_r.i})^2+k_c(f_{eq},B_{eq})\sum(B_{k+1\_t.i}-B_{k+1\_t.i})^2\}$ IV. Experimental Verification In order to verify the improved core-loss calculation method, a DSEM is used as a prototype for core-loss calculation. Rotor-lock experiments are carried out and used for comparing with the calculated results. Fig.2 presents the core-loss comparison obtained from two different methods, i.e. the ANSYS results and the improved time-stepping FEA method proposed above. Obviously, the improved time-stepping FEA method can estimate core loss more accurately. V. Conclusions An improved core loss calculation method is proposed and verified. The conclusions can be obtained: 1)The proposed concept of equivalent frequency can be used to calculate coefficients in time-domain models so as to improve the accuracy of the core loss prediction. 2)A determination method of core-loss coefficients is established. By adopting the function-fitting method together with the looking-up table method, the influences of frequency and amplitude of flux density on core-loss coefficients are both considered. Besides, due to the effects of skin effects, the eddy-loss coefficient reduces significantly with the frequency. 3)The core loss with improved calculation method can predict core loss with high accuracy.

CG-02. Design of a High Power density Halbach BLDC Motor for Electric Vehicle Propulsion.

V.R. Bommadevara[1]
1. Electrical Engineering, IIT, Hyderabad, India

Abstract: Electric vehicles (EV) are the need of the day for future transportation. The electric drives used for vehicle propulsion need to be highly efficient and high power dense to improve the performance of EVs and make them competent in transportation applications. In the similar lines this paper proposes a Radial Flux BLDC motor with surface magnet rotor with a halbach array. The complete design of motor is carried out, nonlinear magnetic analysis carried out and arrived at performance characteristics. The proposed topology is compared with conventional BLDC motor and found an increment of 20% in torque density. The hardware is realized and tested for its performance I. Introduction: Improved power density topologies for electric drives are need of the day which will lead to energy efficient drives for critical applications. BLDC motors are commonly used as drive in EV propulsion applications due to their high power density and efficiency [1]. In BLDC family, axial flux BLDC with dual stator and dual rotor structure is capable of producing high torque densities [2]-[5]. In radial flux BLDC family dual rotor permanent magnet brushless DC motor (DR-BLDC) is proposed which is capable of producing high torque density [6]-[7].This paper proposes a high power density BLDC motor with radial flux configuration and rotor employing surface mount magnets forming a Halbach array. II. Proposed Topology: Fig.1 shows the complete construction and specifications of Halbach BLDC (HB-BLDC) motor. The motor is configured as radial Flux BLDC motor; rotor is employed with surface mount magnets forming a Halbach array. A. Magnetic design: The magnetic equivalent circuit of the motor is derived and solved for parameters like air gap flux density, flux density in stator core and flux density in stator teeth. The main magnet and auxiliary magnet is modeled as a current source and the circuit is solved. The equivalent circuit is given in Fig.2 along with equations and solved parameters. B. No-Load Magnetic analysis: The magnetic material characteristics are non-linear in nature and have to be taken care in arriving at magnetic parameters of the motor. Finite element(FE)analysis is carried out on the motor by taking the nonlinear B-H characteristics of the material into account. The magnetic parameters of the machine are derived at no load using the magnetic analysis and shown in table-I of fig.3.The flux density profile in the complete motor, rotor and stator is shown in fig.3. C. Load analysis: Once the no load magnetic design is completed to arrive at overall dimensions of the machine, the electrical design is carried out to arrive at important parameters of winding, current density, stator resistance and inductance. FE analysis is carried out to analyze the effect of armature reaction during peak load of the motor. The average flux density distribution in stator, rotor core is shown in fig.4 along with air gap flux density curve. The max. Flux density in stator core is 2.2T and rotor core is 1.95T. D. Current-torque characteristics: The machine is loaded with peak current density corresponding to 16A i.e. 50A/mm^2 and FE analysis is carried out to arrive at current-torque characteristics of the motor and is shown in fig.5.The characteristics of the both proposed and conventional configurations are compared and found that there is an increment of 24% in power density with the proposed halbach BLDC motor. D. Development of prototype and test results: The prototype is realized and complete developed stator and rotor are shown in fig.6. The hardware is tested for its performance and the results are in line with designed values. III. Conclusion: A halbach BLDC motor is proposed for high power densiyty application of EV propulsion. Complete design of motor carried along with non linear electro-magnetic analysis on no-load and load conditions. The Current-Torque characteristics of the proposed motor is compared with conventional motor and found an increment of 24% in the power density with same volume and weight. The hardware is realised as per the design and tested for its perfrroamnce. The proposed motor will be right choice for high power density applications like elecctric vehicles.

CG-03. High Frequency Characterization of Magnetic Rod Cores with Anisotropic Power Loss.

B.A. Reese[1] and C.R. Sullivan[1]
1. Dartmouth College, Lebanon, NH, United States

New low-loss magnetic flake composite materials are emerging which are well suited for high frequency (> 1 MHz) power electronic converters [1-4]. Much like laminated magnetic materials, magnetic flake composites have low eddy current loss only if flux travels through the long dimensions of the flakes (as opposed to through the thickness). Thus, in order to properly optimize the fabrication processes, a method of accurately measuring the power loss in each direction of flux travel is essential. Core loss is typically measured on a closed magnetic circuit, which is an ideal arrangement if the material can be easily formed into a closed shape (e.g., toroidal) and has low power loss in the two directions of flux travel. However, these conditions are not always met and a rod or bar core sample must be used. Forcing the magnetic field within a sample into only one direction can be accomplished with a high permeability return path as long as the power loss of the return path is significantly lower than the material under test. If the return path loss is on the same order as the test sample loss, then separating the two loss mechanisms becomes very difficult due to the nonlinear nature of the core losses. Since the goal of this work is to produce materials that will have power loss lower that typical high permeability materials, the magnetic return path is not a viable option. In this work we consider an open magnetic circuit characterization method so that the parasitic loss mechanisms can be more easily removed from the measurement. The key challenge for open circuit measurements is the flux fringing effect at the ends of the sample, which cause flux to travel in directions other than the intended measurement direction. This effect can be minimized by making the sample long compared to its diameter. However, a sufficiently large aspect ratio may also be difficult to achieve in a given process. Here we describe a core test fixture which properly aligns the field within a low aspect ratio rod core sample without introducing nonlinear power loss mechanisms. The magnetization at the center of a long solenoid inductor is $(\mu_r\text{-}1)NI/L$, where μ_r is the relative permeability of the core, N is the number of turns, I is the coil current, and L is the length of the coil. The end portions of the magnetic core can be emulated with additional solenoid windings, as shown in Fig. 1. In order to maintain constant flux through the core test sample, the emulation coils must generate a field equal to the magnetization of the core: $(\mu_r\text{-}1)N_x I_x/L_x = N_e I_e/L_e$ (1) Where the x subscript indicates parameters for the outer excitation coil and the e subscript indicates parameters for the core emulation coils on each side of the test sample. This arrangement is beneficial because the portions of the core which experience flux perpendicular to the intended measurement direction are now replaced with windings which have isotropic, linear, and predictable power loss. The excitation and core emulation coils should be connected in series to ensure the coil currents have the same phase. Since $I_x = I_e$, the currents drop out of (1). We then define an optimal turns ratio, a_{opt}, between the core emulation and excitation coils as $a_{opt} = N_e/N_x = (\mu_r\text{-}1)(L_e/L_x)$ (2) Fig. 2 shows finite element simulation results for different values of the turns ratio a, where the vertical axis is the amount of flux that is perpendicular to the intended measurement direction divided by the total amount of flux. The $a = a_{opt}$ line assumes that the fixture's turns ratio is changed for each permeability, according to (2). The perpendicular flux ratio reaches up to 0.5% because a nonzero gap between the core and emulation coils was assumed for the simulation. Since continually adjusting the turns ratio is impractical, we also consider using discrete values of a over restricted ranges. The $a = 0$ line, where only the excitation coil is connected, approaches 0% flux ratio at $\mu_r = 1$ and 15% at $\mu_r = 100$. When only the emulation coils are connected ($a = \infty$) the flux ratios become 21% at $\mu_r = 1$ and 1% at $\mu_r = 100$. A combination of the two configurations, where $a = 0$ is used for $\mu_r < 4.5$ and $a = \infty$ is used for $\mu_r > 4.5$ reduces the maximum flux ratio to 9.5%. Note that the best performing magnetic materials for high frequency (> 1 MHz) power electronics applications have permeabilities in the 15-40 range [5]. Thus, the core fixture must address the high flux ratio in this middle range. One way this could be achieved is to add a third configuration at the crossover point of $\mu_r = 4.5$ with $a_{opt} = 1.5$. This keeps the flux ratio to within 5%. Fourth and fifth configurations can also be added at the new crossover points of $\mu_r = 2.1$ and $\mu_r = 12.3$ (with a_{opt} of 0.5 and 5, respectively) to keep the flux ratio to within 2.5%.

CG-04. Freeze-Cast Magnetic Composites for High Frequency Power Conversion.

B.A. Reese[1], C.R. Sullivan[1] and U.G. Wegst[1]
1. Dartmouth College, Lebanon, NH, United States

While emerging thin-film magnetic materials [1] offer significantly lower power losses than ferrites in the 1-100 MHz range, they are very expensive to manufacture and difficult to scale up to higher power levels. Composite materials composed of magnetic flakes embedded in an insulating binder have the potential to achieve low power loss at high frequency [2-5], while maintaining lower cost and better scalability than thin-films. The flakes can have low eddy current loss due to their small cross sectional area; however, precise alignment of the flakes is required to minimize the loss. A common theme for reducing power loss in magnetic core materials is to interleave thin layers of magnetic material with thin layers of an electrical insulator. When a time varying magnetic flux passes through a conductor (including many magnetic materials), it generates eddy currents which lead to power loss. Thin laminations of magnetic material decrease the amount of flux passing through a conductive region, thus reducing the magnitude of induced eddy currents. Instead of continuous laminations, some cores are composed of small magnetic particles in an insulating binder. Commercially available powder cores are composed of individually insulated magnetic particles that are approximately 100 μm in size and offer lower loss than laminated tape wound cores but higher loss than ferrites. Several groups have made composite cores with magnetic flakes that have thicknesses in the 0.1-0.5 μm range. Since the cross-sectional area of these flakes is so small, they can potentially allow significant reduction of eddy current loss. However, the flakes must be precisely aligned with the magnetic field to have any benefit. Misalignment not only increases power loss, but could result in localized heating and thermal stress on the component. [2] formed the magnetic flake composite around a winding. The authors attempted to align the flakes with (a) a magnetic field generated from the winding and (b) applying pressure to the assembly. Pressure alignment achieved better alignment of the flakes than magnetic field alignment; however, there were still large regions which were not aligned correctly and the performance peaked at 4 MHz. [3] hot pressed bare cores (i.e., without an embedded winding) and achieved better alignment of the flakes. The permeability of this material started to roll of at approximately 10 MHz. [4] and [5] achieved very good, yet still imperfect alignment with hot pressing which led to permeability rolloff at 100 MHz and 1 GHz, respectively. These results show that the performance of flake composites is highly dependent on flake alignment and there is still some room for improvement. Thus, processes that can better control flake alignment could greatly extend the capability of magnetic components. A promising approach to achieve improved particle alignment is the use of the freeze-casting process for the manufacture of the magnetic composite materials. The process has been shown to produce highly aligned "brick-and-mortar" structures with alumina platelets in a polymer binder [6]. Figure 1 shows a schematic representation of the freeze-casting of the magnetic composite, where a water-based slurry (a) with magnetic flakes and an insulting binder (not shown) is directionally solidified. As the ice crystals grow, the flakes align along the freezing direction due to a shear flow between the dendritic ice crystals (b). The ice is then removed by sublimation (lyophilized) and a porous scaffold of the flakes and binder remains (c). Finally, the sample is compressed to collapse the pores (d). The binder provides isolation between the flakes to prevent eddy current conduction paths. A freeze-cast magnetic composite was fabricated with a slurry of nanocellulose from the University of Maine and 0.6 μm thick permalloy flakes from Novamet. The slurry was mixed in a shear mixer, directionally solidified, and then lyophilized. Scanning electron microscopy revealed that the majority of the magnetic flakes within the sample's pore walls were indeed aligned with each other, as shown in Fig. 2. Hysteresis curves were measured with a vibrating sample magnetometer, resulting in permeability of 11.0 and saturation flux density of 180 mT, both of which are comparable to commercially available high frequency (>1 MHz) magnetic materials.

CG-05. Electromagnetic Torque Analysis for All-Harmonic-Torque Permanent Magnet Synchronous Motor.

J.W. Zhang[1]
1. Changsha University, Changsha, China

I. Introduction With the advanced industrial development, such as robots and aerospace, the requirements for permanent magnet synchronous motors (PMSM) applied in these fields are increasing, especially the high torque density. There also have been a lot of research activities in developing new techniques for improving the torque performance of the PMSM, and the use of magneto motive force (MMF) harmonic components is approved effectively [1-5]. The torque is improved by >6% with the optimal third-harmonic-shaped rotor of interior PMSM [2]. The authors in [3] proposed to inject third harmonic into both the PM shape and current waveform of the five-phased PMSM is proposed, and consequently the torque could be improved significantly. This paper presents a novel all-harmonic-torque PMSM (AHT-PMSM) including special winding and commutation model. For this PMSM, the stator MMF (F_s) possesses the same harmonic components as the rotor MMF (F_r), and all the MMF harmonic components could be used to generate the effective electromagnetic torque. In theory, the electromagnetic torque of AHT-PMSM can be improved by 23% compared with that generated only by fundamental MMFs. The results of FE simulation and experiment show that compared to that of the normal sinusoidal PMSM, the torque of the AHT-PMSM is significantly improved by > 20% with the same size. II. Topology and Principle The rotor structure of AHT-PMSM is the same as the conventional PMSM, but the configuration of stator winding is quite different. The number of phases is decided by $Q/2p$, where Q is the number of slots and p is the number of pole pairs, and each slot under a pole is classified as different phase. Each phase winding is equipped with a hall sensor to detect the flux field position. Fig. 1(b) shows the phase winding distribution of a 24-slot/4pole AHT-PMSM. The configuration of the power supply for the 24-slot/4-pole AHT-PMSM is shown in Fig. 1 (a). Each stator phase winding is supplied by a half-bridge DC/DC converter which can supply positive or negative current. For AHT-PMSM, the conductors under the same pole are fed the currents with the same direction. In order to maintain the orthogonality between the F_s and F_r, when the rotor rotates from one slot to the next slot, a phase winding current would be commuted due to the hall signal of this phase. Fig. 1(b) shows the polarity of armature currents versus the position of PMs. The effective electromagnetic torque of PMSM is generated only by the interaction between the F_s and F_r harmonic components with the same order, and when the angles between them are $\pi/2$, the electromagnetic torque is maximum. For the conventional concept of the sinusoidal PMSM, the electromagnetic torque is produced only by fundamental MMFs, and the maximum electromagnetic torque could be calculated as $T_{esin}=K_{str}pF_{r1}F_{s1}$ where K_{str} is the structure constant, and F_{r1} and F_{s1} are the amplitude of fundamental components of F_r and F_s. The F_r of surface-mounted PMSM is a square wave, which includes all the odd order harmonics. For ATH-PMSM, F_s is approximated as triangular wave according to the Ampere's law, which also includes all the odd order harmonics. The waveforms also with fundamental and 3rd harmonics of F_r and F_s are shown in Fig. 1 (c). The angles between all the same order harmonics between F_s and F_r are the constant of $\pi/2$. So all the harmonic components of MMF can generate the maximum effective electromagnetic torque, which could be calculated as $T_{eAHT}=\pi^2/8{*}K_{str}pF_{r1}F_{s1}\approx 1.23T_{esin}$ It is obvious that the electromagnetic torque of AHT-PMSM is improved by 23% compared with that of normal sinusoidal PMSM theoretically. III. FE Analysis and Experiment A 2-D FEM model of a 24-slot/4-pole AHT-PMSM is used to verity the previous analysis. Fig. 2 (a) shows the flux density waveforms produced by PMs and stator currents separately, which agrees well with the theoretical analysis. Fig. 2 (b) shows the torque waveforms of the AHT-PMSM and normal PMSM versus the armature currents amplitude of 10A, 20A and 30A. The average torque values of the two PMSMs are 3.62Nm and 3.01Nm with 30A, 2.42Nm and 2.0Nm with 20A, 1.23Nm and 1.04Nm with 10A. It is obvious that the average torque values of AHT-PMSM are improve by > 20% compared with those of conventional PMSM. A prototype of AHT-PMSM according to the FEM models is manufactured, and the stator core with the stator windings is shown in Fig. 2 (c). The torque values with the armature currents of 10A, 15A, 20A, 25A and 30A of the AHT-PMSM and a normal PMSM with same size are measured. The test results are shown in Fig. 2 (d), which shows that the torque of AHT-PMSM is improved by at least 20% compared with that of the normal PMSM due to each stator current value.

CG-06. Performance Optimization of a Novel DC Fault Current Limiter Combining Different Magnetic Materials and Topologies.

H. Zhou[1], J. Yuan[1], L. Wei[1,2], P. Gan[1], F. Chen[1], Y. Zhong[1], C. Tian[1], B. Chen[1], Y. Gao[3] and K. Muramatsu[3]
1. School of Electrical and Engineering, Wuhan University, Wuhan, China; 2. Department of Electrical Engineering, Graduate School of Engineering, Kyoto University, Kyoto, Japan; 3. Department of Electrical and Electronic Engineering, Saga University, Saga, Japan

I. Introduction For future high voltage direct current (HVDC) grids, the dc protection system is often considered as one of the main challenges due to the difficulty in interrupting a large dc current and the stringent time constraint imposed by the fast rising fault current[1]. Therefore, a novel DC system fault current limiter based on saturable core reactor theory (DCSFCL) was proposed previously. In order to obtain better performance of DCSFCL that is unable to be accomplished by single magnetic material, mixed magnetic materials were applied to take advantages of different magnetic materials. Furthermore, magnetic valves were also added to original DCSFCL topology, which is a good way to optimize clipping performance and reduce the usage of both magnetic materials and permanent magnets (PM). ANSYS models were built and finite element analysis were carried out to verify the feasibility of these deductions. II. Configuration and Principle Study From previous studies, permalloy and nanocrystalline alloy are chosen to combine their fine magnetic characteristics and improve the performance. Fig.1 shows basic configuration and working principle of proposed mix material model with magnetic valve structure. According to Faraday's law of electromagnetic induction and the constitutive relationship between voltage and inductance, inductance of DC coils L_{fcl} can be calculated as: $L_{\mathrm{fcl}}=(4N_{\mathrm{dc}}^2)/(2R_{\mathrm{e11}}+2R_{\mathrm{e12}}+R_{\mathrm{e21}}+R_{\mathrm{e22}}+2R_{\mathrm{m}}+4R_{\mathrm{u}})$, where N_{dc} is turn number of DC coil, while R_{e11}, R_{e12}, R_{e21}, R_{e22}, R_{m} and R_{u} are magnetic resistance of both limbs, PM and iron yokes. Since magnetic valve are often used to generate iron-core reactor[2], fast responding material, i.e., nanocrystalline alloy, is added into original limbs and magnetic valve structure is applied to enhance the performance of DCSFCL. Given that two materials have different working points (1.51T for permalloy and 1.1T for nanocrystalline alloy), the limb structure needed to be properly designed based on the flux continuity theorem($B_{\mathrm{I}}S_{\mathrm{A}}=B_{\mathrm{II}}S_{\mathrm{B}}+f_{l\mathrm{II}}$, $B_{\mathrm{II}}S_{\mathrm{B}}=B_{\mathrm{III}}S_{\mathrm{C}}+f_{l\mathrm{III}}$), where $f_{l\mathrm{II}}$ and $f_{l\mathrm{III}}$ are leakage flux of iron core II and III, while B_{I}, B_{II} and B_{III} are flux density inside the core. In that case, two materials can desaturate simultaneously and therefore, clipping performance can be improved. On the other hand, magnetic valve means smaller cross-sectional area, which leads to larger flux density inside the valve. In that case, less PM and magnetic material will be needed to get the limb into critical saturation state. Therefore, this valve structure can also reduce the usage of both PM and permalloy, which is cost efficient. III. Simulation Results Fig.2 shows the electromagnetic models built in ANSYS and simulation results. Considering that valve structure is applied, it can be seen from Fig.2(a) and (b) that flux density distribution of the limb is not continuous along the limb and those two materials work at their own critical saturation point. The sunken part, shown in Fig.2(a), demonstrates the separate critical saturation state of different materials, which is a solid prove for effectiveness of magnetic valve structure. Hence, the inductance value of the coils, shown in Fig.2(c), is 31.9% larger than single permalloy model due to the fast desaturate speed of inserted nanocrystalline alloy. Clipping performance is shown in Fig.2(d). It can be found that the new valve model has 55.1% and 4.9% drop in fault current compared with fixed smoothing reactor and single permalloy model, respectively. Besides, usage of permalloy and PM decrease by 22.9% and 50.9% compared with single permalloy model. Therefore, proposed mixed valve model is both better in performance and economy. IV. Conclusion In this digest, a novel structure and material modified HVDC transmission system saturable core fault current limiter is proposed. The combination of different magnetic materials makes use of fine characteristics of those materials and applied magnetic valve structure further enhance the clipping performance. Detailed information and investigation will be shown in the full paper.

CG-07. Dynamic Modeling and Control of Three-Degree-of-Freedom Electromagnetic Actuator for Image Stabilization.

A. Heya[1], K. Hirata[1] and N. Niguchi[1]
1. Department of Adaptive Machine Systems, Osaka University, Suita, Japan

I. Introduction Recently, the demand of an environment recognition using cameras mounted on autonomous mobile systems such as an unmanned aerial vehicle and walking robot has been rapidly increasing. However, the decrease of the recognition accuracy attributed an image quality deterioration due to vibrations has become a problem [1-3]. In order to solve this problem, a lens-unit-swing system which consists of a lens and imaging device has been developed. This system can suppress camera shakes over wide rotation ranges around three axes. Nevertheless, the increase of the size and weight has become a problem because several motors and links are required. Three-degree-of-freedom (3-DOF) actuators are expected to become a solution for these problems. However, conventional 3-DOF actuators are large in size, and need a complicated control system [4-6]. We proposed a novel 3-DOF electromagnetic actuator for an image stabilization, and an electromagnetic field analysis using 3-D FEM was conducted to verify the dynamic characteristics [7]. However, the calculation time of a high-speed motion increases because the time step of the analysis is small. In addition, the image stabilization system requires a high robustness for disturbances, and a robust control system is required. In this paper, we propose a dynamic modeling method of the actuator for reducing the calculation time, and a robust control system using its dynamic model is created. The basic structure and operating principle of the actuator are described. The decrease of the calculation time is achieved using state equations. In addition, an attitude stabilization system is created using a sliding mode control. Finally, the impulse disturbance response of the actuator is calculated, and the effectiveness of the control system is verified. II. 3-DOF actuator for image stabilization The basic structure of the proposed actuator is shown in Fig. 1 (a) [7]. This actuator is mainly composed of an inner mover and an outer stator. The mover consists of six permanent magnets and an inner yoke. The stator consists of outer yokes and coils. The rotation angle around the x-axis and y-axis is ±25 deg., and that around z-axis is ±5 deg. The basic operating principle of the actuator is shown in Fig. 1 (b). A tilting torque is due to Lorentz force. The coils carrying currents generate tangential direction forces that cause the tilting torque, and the mover makes a tilting motion. Similarly, the panning and rolling torques are generated and the mover makes panning and rolling motions. This actuator can be controlled by only 3 sets of the coils. Therefore, 3-DOF motions can be achieved by a simple control system. III. Dynamic modeling In this research, the rotor attitude is expressed by XYZ Euler angles. The equations used for the derivation of the state equation is show in Fig. (a). The motion equation with a generalized coordinate q is given by (1), where τ is the output torque, c and s represent a cosine and sine, respectively, and the relationship of $I_1=I_{xx}=I_{yy}$, $I_3=I_{zz}$ is satisfied. The torque generation equation is given by (2), where K_T, K_D and D are the torque constant, detent constant and viscosity friction coefficient, respectively, τ_f is the friction torque, and I_a is the current. The circuit equation is given by (3), where R_c, L and K_B are the coil resistance, inductance and back-electromotive force constant, respectively. The state equation can be derived to couple (1), (2), and (3) with each other. The state equation is given by (4).The comparison of the dynamic characteristics calculated by the state equation and the dynamic analysis of an electromagnetic field analysis using 3-D FEM is conducted to verify the validity of the state equation. An AC voltage of an amplitude of 5 V and frequency of 100 Hz is applied. The analysis results are shown in Fig. 2 (b). From these results, it is found that both shows a good agreement with each other. In the steady response, the maximum amplitude error of the panning and tilting motions are 24%, and that of the rolling motion is 21%. These errors are caused by the linearization of the torque characteristics in the torque generation equation. In this analysis, the calculation time of the dynamic analysis using the state equation is 1.53 s, and that of the dynamic analysis using 3D-FEM is 66.7 h. From these results, the state equation could shorten the calculation time by 1/157000. IV. Comparison of control systems An attitude stabilization system using a PID control, optimal regulator and sliding mode control is compared in terms of the control performance for a disturbance. The impulse disturbance response of each control system are shown in Fig. (c). From these results, it is found that the attitude can be stabilized, and the sliding mode control has the highest convergence. V. Conclusion In this paper, a dynamic modeling method was proposed for reducing the calculation time, and a robust control system using a dynamic model was created. The state equation of the actuator was derived, and the decrease of the calculation time was achieved. In addition, an attitude stabilization system using a PID control, optimal regulator and sliding mode control was compared. It was found that the control system using the sliding mode control has the highest robustness. In the final paper, the detail of the state equation, the controller design method and the verified results for comparing a control performance will be shown.

CG-08. Investigation of a High Corner-Power Modular Fault-Tolerant Permanent-Magnet In-Wheel Motor.

Y. Tang[1], F. Chai[1], Z. Song[1] and P. Liang[1]
1. Department of Electrical Engineering, Harbin Institute of Technology, Harbin, China

I. INTRODUCTION To acquire high reliability and corner-power of electric vehicles, modular fault-tolerant permanent-magnet synchronous motors (PMSMs) are becoming promising candidates[1,2], especially for the vehicles adopting in wheel PMSM schemes[3]. In this paper, a novel three-phase modular fault-tolerant modular in-wheel is proposed and investigated. The motor consist of some sub-motors, and each sub-motor is controlled by an independent drive. The applicable slot/pole combinations and module number are recommended for the motor, and the 24-slot/16-pole and 4-modules scheme is selected for the wheel driver application in this paper. The electromagnetic structure was designed, and the fault-tolerant slot was optimized to obtain reasonable fault-tolerant performance and torque curve. The fault-tolerant ability was analyzed under some conditions, including one phase open-circuit of a sub-motor, one sub-motor open, one single phase short-circuited. The result indicates that the drive system can survive these fault conditions through proper current control strategies. The proposed scheme is proved to have satisfying electromagnetic and fault-tolerant performances. II. THE CHOICE OF ELECTROMAGNETIC SCHEMES The corner-power is proportional to the product of maximum speed and maximum torque, the proper maximum speed and maximum torque can get a high corner-power. Design for fault-tolerant motor to achieve electric isolation, effective magnetic isolation, effective thermal isolation and physical isolation, the ability to reduce the bad influence of fault sub-motor on the other normal sub-motors[4]. 1) The Choice of Winding Form The promising winding forms for fault-tolerant motor are double layer fractional slot concentrated winding and single layer integer slot distributed winding. The former has a shorter end winding and a higher winding factor than these of the latter, however, the latter have a better performance on electric-magnetic-thermal isolation. 2) The Choice of Slot/Pole Combination and Module Number: Each sub-motor should be an independent module, the slot and pole are integer multiples of module number. The pole should not be too much because of the high maximum speed. The slot number is determined by pole number and winding form. III. DESIGN OF MODULAR FAULT-TOLERANT MOTOR A. Model Design of the Motor In this section, 24-slot/16-pole double layer fractional slot concentrated winding is investigated. The motor model is shown as Fig.1. The maximum speed is 4100 rpm and the maximum torque is 1500 Nm. B. Shape of the Fault-Tolerant Slot The deep slot has large inductance but bad high speed performance. The stator slot obtains large leakage inductance adopting small slot opening and big tooth tip depth, the ability to limit short-circuit current, however the torque decreases. Design for slot has overall consideration about electromagnetic performance and fault-tolerant ability of the motor. C. Electromagnetic Performance of the Motor FEM is used to calculate the main working point, including rated operation, maximum speed operation and overload operation. The motor get the technical indicators and has a high corner. IV. FAULT-TOLERANT ABILITY 1) Open Circuit of One Phase in a Sub-Motor: Fig. 2 shows the average torque is 466 Nm and the torque pulsation get 12% under open-circuit of one phase in a sub-motor; the through the compensation measure, the average torque value is 507 Nm, with 4.8% pulsation. The average torque is a slightly decreased, but the torque pulsation is reduced dramatically, which demonstrates that the motor can work well under condition of one phase open circuit. 2) Open Circuit of three Phases in a Sub-Motor Under the condition, the average torque drops to 381 Nm, but the torque pulsation is a slightly decreased, which demonstrates that the motor can work well even though lack of a sub-motor. 3) Inter-Turn Short Circuit One Phase in a Sub-Motor: The amplitude of short circuit current is 163 A which is slightly bigger than the rated current. When the number of short-turn is one, the average torque value is 505 Nm, with pulsation 4.5%. V. CONCLUSIONS 1) The 24-slot/16-pole combination is selected for the wheel driven application in this paper, and the electromagnetic design shows that it can meets the requirements in EV application. 2)The fault-tolerant slot was optimized with FEM, and better torque curve and ability of suppression short-circuit current are achieved. 3)The fault-tolerant ability was analyzed under three fault conditions; research results indicate that the drive system can survive these fault conditions. 4)Through proper current control strategies, different fault-tolerant performances can be obtained.

CG-09. An Effective Method with Copper Ring for Vibration Reduction in Permanent Magnet Brush DC Motors.

J. Hong[1], S. Wang[1], Y. Sun[1] and J. Li[1]
1. Tsinghua University, Beijing, China

Abstract:This paper presents a new method by sticking the copper ring on the permanent magnet brush DC motor (PMDC) to reduce the electromagnetic noise. Firstly, the air gap flux density distribution and radial force density distribution are derived in detail and the principle of such electromagnetic noise reduction technique is presented. Then, finite element method (FEM) and experimental results are given to validate the proposed technique, by testing the vibration spectrum of the two prototype PMBDC. It is shown that the acceleration in modified motor has about one-third of that in the origin motor. 1 introduction Vibration and noise become important specifications for many applications, and research on vibration and noise keeps hot for long time. The electromagnetic vibration of motors is mainly caused by the electromagnetic exciting force [1-2]. Electromagnetic exciting force wave on the stator changes with time and space, causes deformation of mechanical structure, and excites the motor to vibrate [3-8]. Existing research mainly focused on PM motors, switched reluctance motors, and induction motors. Many literatures [9-12] studied the accurate predictions of the vibration and noise behaviors by modeling precisely the magnetic forces and the mechanical structures for PM motors. But few papers show the vibration reduction method of PMBDC. This paper proposed a novel method by sticking the copper ring to reduce the vibration and noise on the PMBDC motor whose cross section is shown in Fig.1(a). 2 analysis of magnetic field 2.1 magnetic field generated by permanent magnet When ignoring magnetic saturation, the flux density distribution in the air gap under no load can be expressed as $b(\theta,t)=\pm(B_\delta\Lambda_0+\sum B_\delta\Lambda_k\cos kZ(\theta-\omega_r t))$ $\theta\epsilon[-\alpha\pi/(2p)+j2\pi/(2p),\alpha\pi/(2p)+j2\pi/(2p)]$ Where Z is the number of rotor slots,Λ_0 andΛ_k are the amplitude of average and k-th harmonic magnetic permeability.α is the pole arc coefficient. When j=2m,m=0,1,2,.., the sign in the equation takes a positive value; When j=2m+1, the sign is negative. The term$B_\delta\Lambda_0$ represents the main pole magnetic field excited by the permanent magnets, which does not change with time, and the second term represents the additional magnetic field caused by periodically changing of the permeance due to slotted rotor. 2.2magnetic field inducted by eddy current in copper ring Fig. 1(b) shows the solving region, which is half length of the motor. The direction y is the circumferential direction, and the direction z is the axial direction of the motor. Region 1 is the copper ring portion covered by the stator, and Region 2 is the end of the copper ring. In order to simplify the analysis, let $k=\pi/\tau$ The high frequency magnetic field can be written as: $Hs=H_m\exp(j(wt-ky))$ Where w is the rotation frequency. The magnetic field induced by the eddy current in the coppering is: $H_r=H_p\exp(j(wt-ky))$ So, the magnetic field in the air-gap is the interaction between the two magnetic fields. $H_x=H_p\exp(j(wt-ky))+H_m\exp(j(wt-ky))$ The Maxwell's equation can be written as: $\partial E_z/\partial y-\partial Ey/\partial z=-\partial B_x/\partial t$, $J_y=\partial Hr/\partial z$, $J_z=\partial Hr/\partial y$ The magnetic field can be deduced: $\partial^2 Hp/\partial z^2-(k^2+j\omega\sigma_e\mu_0)H_p-j\omega\sigma_e\mu_0 H_{m=0}$ The general solution of the equation is $Hp=C_1\exp(\lambda z)+C_2\exp(-\lambda z)+CH_m$ Where, C,C_1,C_2 and λ are undetermined coefficients, which can be solved by the boundary conditions. 2.3 The eddy current in copper ring Some works have been done about the simulation of flux density in the air-gap in the different copper ring thickness. The results show that the copper ring is thicker, the stronger ability to weaken the high frequency magnetic field in the motor. The eddy current and the copper loss are also analyzed in detail. 2.4 analysis of radial force density The radial force density distribution under one pole shoe calculated by Maxwell stress tensor method is $p_n=b^2(\theta,t)/(2\mu_0)$ For different copper ring thickness, the radial force is carefully analyzed and compared. 3 Modal and vibration analysis It is important to complete the modal analysis or modal test of the structure of the motor. This will decide whether the resonance occurs on the motor. In the modal testing, the test DC motor is suspended by the elastic rope to simulate the free support-condition. The natural frequencies corresponding to the circumferential modes 1 to 5 are identified to be 474Hz, 1496Hz, 2498Hz, 4185Hz, and 5241Hz, respectively. In the 3D structural finite-element analysis, the harmonic responses are calculated by using the mode-superposition method, and Five different thickness of copper ring are simulated and analyzed. 4 Experimental results In order to validate this proposed method, experimental verification of two sample motors has been performed by measuring the acceleration. The motor is hanged on the bracket by elastic rope. Seven accelerometer sensors are evenly attached on the stator in the circumferential direction, and the average of the acceleration is adopted.Fig.2 shows the vibration result of the simulated and measured when the motor run at 1500 rpm. It can be seen that the measured acceleration of 36^{th} harmonic component of prototype is 1.81m/s^2, which is approximately 3-times greater than the modified motor, 0. 56m/s^2. 5 conclusions This paper presents a new method by sticking the copper ring on the permanent magnet brush DC motor (PMBDC) permanent magnet to reduce the electromagnetic noise. The aim of the proposed strategy is to decrease the vibration and acoustic caused by the rotor slot harmonics. The FEM and experimental results show that the vibration in the modified motor is only one-third of that in the origin one.

CG-10. High Transmission Capacity P.U.A. Wireless Power Transfer for AUV Using an Optimized Magnetic Coupler.

C. Cai[1], Z. Yang[1], M. Qin[1] and s. Wu[1]
1. School of Information and Electrical Engeering, Harbin Institute of Technology at Weihai, Weihai, China

The Autonomous Underwater Vehicle (AUV) is an important maritime equipment widely used. Its endurance is limited by space as well as battery technology, which leads to poor flexibility and concealment. Wireless power transfer(WPT) is a proper approach to solve this problem effectively. Nowadays, there are some problems AUV wireless power transmission facing as low coupling capacity, undesirable AUV shape change and insufficient energy density[1-2]. To solve these problems, inductively coupled power transfer technology(ICPT) is applied to propose an ε-type core with strong coupling capacity, large energy density and none changing shape needs,which can improve transmission capacity per-unit-area(p.u.a.). The power formula[3] and efficiency formula based on the mutual inductance model are given respectively: $P_{out}=V_{in}\,I_1k^2Q$(1) $\eta=R_r/(R_1+R_r)=R_{ac}/(L_sR_1/k^2L_p+R_{ac})$(2) where $V_{in}I_1$ is the input power, k is the coupling coefficient, Q is the quality factor, R_1 and R_r are the primary coil resistance and the secondary reaction resistance, L_p and L_s are the primary and secondary coil self-inductance, and R_{ac} is the AC equivalent impedance. Based on formula (1) and (2), the power and efficiency will be enhanced with the coupling coefficient k increased and other parameters fixed. In the magnetic circuit model, the coupling coefficient k is expressed as[4]: $k=0.25R_{E2}/(R_{E1}+0.25R_{E2})=0.25R_{E2}/(l/\mu_0S+0.25R_{E2})$(3) where R_{E1}, R_{E2} are the main magnetic resistance and leakage magnetic circuit reluctance, l is the gap length, μ_0 is the absolute permeability and S is the equivalent cross-sectional area. R_{E2} can be regarded as a fixed value, so the coupling coefficient k is affected by l and S. When the cross-sectional area S is fixed, reducing air gap l can increase the coupling coefficient k. Therefore, the coupling coefficient of coupling device needs to be increased as much as possible. The addition of magnetic core can significantly enhance the coupling capability[1]. In this paper, a new type of coupling device is proposed pointing at the shape characteristics of a cylindrical AUV. It consists of coils and an ε-type core that is closely fitted to the AUV arc surface, as shown in Fig. 1 (a). Moreover, the ε-type core significantly reduces the air gap and makes it uniform therefore its coupling coefficient k is higher than other cores'. When AUV thickness together with air gap is approximately 8mm, the ε-type core coupling coefficient k can be 0.55. By contrast, the E-type and U-type cores in similar situations are less possible to reduce due to arc shape obstruction. The tapered core in [2] has a very high coupling coefficient with a small air gap. However, a partial modification of the AUV is required and the coupling device needs to be precisely aligned during charging. Compared with the toroidal core, moreover, less ferrite is used in the ε-type core. Therefore, the ε-type core is superior to the current coupling device. Practical application should consider its dimension fitting specific application objects. The coupler design in [3] also involves the iteration approach. The specific design process is as followings. Firstly, core shape as well as the compensation circuit are selected. The maximum length and height of the core could be decided according to the AUV diameter. Secondly, the minimum dimension is calculated with the area product method (AP method). In this interval, the coupling coefficient is taken as the goal based on the main variables including the core length, window width and column height. Maxwell 3D simulation software is used to perform the finite element analysis(FEA). Besides, a core with a smaller Aw/Ae ratio is preferred. The edge flux is small, which will contribute to a high efficiency. After figuring out the dimension, the inductance of the winding is calculated in conjunction with the relevant formula. The re-iterate designed is required if the winding cross-sectional area exceeds the window area, or power and efficiency requirements fail. The final optimal solution could be chosen from the calculation. This paper is applied to AUV with a diameter of 300mm. According to the requirement that transmission power is 600W and efficiency ratio should be higher than 0.8, the minimum length is 65mm. In this interval, the core length, window width and column height are taken as variables, and parametric analysis is carried out in the simulation. The ε-type 200mm is selected to meet the requirements. To reduce the volume quality, the final length is set to 100mm by reducing its size gradually. Meanwhile the corresponding inner and outer curvature radius are 154mm and 200mm. The secondary side is symmetrical with the primary, and the optimal dimensions are shown in Fig. 1 (b). With this design, the 17 turns with an inductance of 107μH are selected. Following the 136nF capacitance is calculated when resonant frequency is 50kHz. The results of ε-type core hardware experimental verification are shown in Fig. 2. As the input voltage gradually increases, the output power reaches 600W, and the efficiency is stable at 0.86. More importantly, the ε-type core has strong coupling ability, small volume and light mass. Meanwhile the transmission capacity p.u.a. is approximate 0.2W/mm^2, which is greatly improved in comparison to 0.083W/mm^2 for the EV. The improvement of transmission capacity p.u.a. will facilitate the AUV with an intense surface area for WPT. At the same time, the ε-type core is valuable in other WPT system where there is curvature.

I.Introduction With the rapid development of the power system, the fault current becomes a big problem. The current limiting measures become more and more important. The saturated-core fault current limiter(SFCL) is one of the promising methods[1]. The most serious fault in electric power system is three-phase short-circuit fault, and the fault current is more likely to exceed the circuit breaker's capacity. The use of three single-phase current limiters at the same time will need a lot of ferromagnetic material and space. A compact three-phase SFCL was proposed in [2], but it cannot limit three-phase fault current[2]. So we propose a novel structure of Economical Three-phase Saturated-core Fault Current limiter(ETSFCL). The novel structure has good clipping performance at three-phase fault conditions. Compared to three single-phase SFCLs proposed in [3], it saves a lot of ferromagnetic material and reduces the AC flux through the permanent magnet. The stability of the permanent magnet is greatly improved and the risk of demagnetization is reduced. In this paper, the operating principle of the proposed structure is explained by analyzing its equivalent magnetic circuit and electrical circuit. FEA models were established in ANSOFT to verify the its effectiveness. II.Configuration and Working Principle The novel concept of ETSFCL studied in this digest is shown in Fig.1(a). It consists of an iron core, three-phase limbs, two permanent magnets (PM) and DC/AC coils. Six AC coils are in series with power system and conduct the current of it. They are wounded on the six outer limbs equally. And six DC coils are also wounded on the outer limbs for biasing the iron core into saturation. An inductance is connected in the DC circuit. The inner limbs with air-gap are used to provide paths for AC flux. Equivalent electric circuit of economical SFCL is shown in Fig.1(b). USi (i=A, B, C) are the three-phase voltage sources of the simple three-phase system. ZSi and ZLi are the system impedances and load impedances of three phases. Lf is the fault-limiting reactor. Ed is the DC voltage source. Nac, Ndc are the number of turns of the AC and DC coils. Idc is the current of DC coils. IA_ac, IB_ac and IC_ac are the currents of three-phase AC coils, respectively. I is the amplitude of load current of each phase. Equivalent magnetic circuit of ETSFCL is shown in Fig.1(c). Re1_i (i=A, B, C), Re2_i (i=A, B, C), Rm, and Rg refer to the reluctances of the left outer limbs, the right outer limbs, the PM and the air-gap branch, respectively. The reluctance of the unsaturated yoke (Ru) is small and can be ignored. Hc, mm, lm are the coercive force, permeability, and the length of PM respectively. Under normal conditions, six outer limbs are deeply saturated. Based on Faraday's law of electromagnetic induction and the constitutive relationship between voltage and inductance (U=Ndf/dt=Ldi/dt), inductance of the ETSFCL (Lfcl) can be derived: Lfcl=NI(1/3bc+2abRm+1/2ac)/[Res(1/3bc+2abRm+1/2ac)+1/6c2+acRm], where a=1/3Res+Rg, b=1/2Res+Rg, c=Res×Rg. Res, Rg and Rm is very large, so the impedance is very small under normal conditions, having little effect on power system. When the fault occurs, the two outer limbs of the fault phase(s) will turn out of saturation alternatively. The impedance of ETSFCL can be adjusted by changing the values of Lf. The increased impedance of the ESFCL can limit the fault current. ESFCL can normally work on any short-circuit fault conditions because of its Six discrete limbs. III.Comparative Study and Simulations To validate the effectiveness of CSFCL, a 220 V model was designed and established in ANSOFT based on the structure proposed above. The flux density distribution is shown in Fig.2(a). The comparison of change of magnetic flux in the permanent magnet is shown in Fig. 2(b). As is shown in Fig. 2(a), at normal conditions, the limbs are all in deep saturation, and at fault conditions the limbs can independently turn out of saturation, which means it can work at any fault condition. And when fault occurs, the AC flux through the PM is 0.01T, much less than 0.06T in the single-phase SFCL in [3]. Therefore, the loss and the risk of demagnetization can be further reduced, the stability of the permanent magnet is improved. Compared to the 120A in system without FCL, the fault current is limited to less than 70A at single-phase fault and two-phase fault condition with ETSFCL. When three-phase fault occurs, the current is less than 80 A. In this study, we compare parameters of the ETSFCL with three single-phase FCLs[3] when they have the similar clipping performance. The economical use a common yoke, and its compact structure reduces the length of the equivalent air gap, improving the utilization ratio of permanent magnet. So the ETSFCL saves about 39% silicon steel and 40% permanent magnet. IV.Conclusion This digest briefly introduces a novel economical three-phase fault current limiter and explained the basic operating principle. The proposed ETSFCL has a good performance in limiting three-phase fault current. Compared to three single phase SFCLs, ETSFCL saves about 40% ferromagnetic material The AC flux in PM is reduced to 1/6, which means the loss and the risk of demagnetization can be further reduced, the stability of the permanent magnet is improved. Detailed comparisons and experimental results will be shown in the full paper

CG-12. Electromagnetic Vibration Analysis of Surface-Mounted Permanent Magnet Synchronous Machine.

Z. Xing[1], X. Wang[1] and W. Zhao[1]
1. School of Electrical Engineering, Shandong University, Ji'nan, China

1.Introduction Because of its simple structure, high power density and high efficiency, the applications of permanent magnet synchronous machine (PMSM) gain continual expansion, and the low-noise and high-performance PMSM has also become one of the hot research spots. In [1]-[4], the analytical calculation of the air-gap magnetic field of PMSM is studied in detail, and the transient magnetic field distribution of the surface permanent magnet brushless DC machine is obtained. Accordingly, an analytical model of analyzing the radial electromagnetic force wave in fractional-slot PMSM is established, and the influence of stator slotting, etc. on electromagnetic force waves are calculated in [5]. In [6], the vibration characteristics of four different types of interior PMSMs are analyzed by the finite element method (FEM), and the influence of winding configurations on the vibration characteristics is obtained, however, it is difficult to distinguish the source of exciting wave. In this paper, a method of calculating radial electromagnetic force combining analytical method and FEM is proposed. With this method, the influence of slot size is considered, meanwhile, the integral expression of radial electromagnetic force wave is calculated accurately and conveniently. Further, the influences of slot opening width, skewed slot rate, pole arc coefficient, eccentricity on the electromagnetic force wave are analyzed, which lay the theoretical foundation for the weakening of electromagnetic vibration. 2.Electromagnetic force wave calculation principle Electromagnetic vibration is excited by the exciting force wave, the key to calculate the exciting force wave is calculate the air gap flux density accurately. The magnetic potential drop on the stator core could be ignored with the assumption that the permeability of the iron core is infinite. Thus, the air gap magnetic flux density along the circumference could be described as $B_{ag}(\theta,\alpha)=\mu_0 F(\theta)/\delta(\theta,\alpha)$, where μ_0 represents the vacuum permeability, $F(\theta)$ is the air gap magnetomotive force, $\delta(\theta,\alpha)$ is the effective air gap length. The air gap magnetomotive force is divided into two parts, one is the magnetomotive force generated by the PM, and the other is the magnetomotive force generated by the winding. Fig.1(a) shows the machine structure without slots. With this structure, the magnetomotive force generated by the PM can be calculated as $F(\theta)=B_0(\theta)\times\delta/\mu_0$, where the $B_0(\theta)$ is the magnetic flux density of the air gap when the stator slots are neglected. The magnetomotive force generated by the winding can be obtained directly by analytical calculation. As shown in the Fig.1(b), the length of the air gap corresponding to the tooth is uniform and the magnetic flux density is basically the same. Thus, in range of the entire tooth pitch, the magnetic potential drop on the air gap is basically unchanged, and it can be calculated as $F\approx F_{\delta t}=B_{\delta t}\times\delta/\mu_0$, where $B_{\delta t}$ is the magnetic flux density corresponding to the stator tooth, so the effective air gap length can be calculated as $\delta(\theta,\alpha)=\mu_0\times F/B_{\delta t}(\theta,\alpha)$, where the $B_{dt}(\theta,a)$ is the distribution of the magnetic flux density of air gap along the circumference in range of a tooth pitch. 3.Electromagnetic force wave analysis According to Maxwell's tensor method, the radial force density acting on the inner surface of the stator is $f_r=(B_r^2-B_t^2)/(2\mu_0)\approx B_r^2/(2\mu_0)$. the expression of radial electromagnetic force wave can be calculated accurately. For the 24-pole/72-slot machine studied in this paper, the minimum order of the wave force is 24. 4.Influences of machine structure parameters on electromagnetic vibration Based on the above analysis, this paper proposes to reduce the lower-order electromagnetic force waves through the reasonable choice of machine structure parameters. Changing the slot opening width can affect the alternating component of the air gap permeance, as shown in the Fig.2(a), the amplitude of the exciting force wave will increase with the increase of slot opening width. Adopting skewed slot structure will cause phase differences between the radial forces at different axial positions, so the average radial force acting on a line will decrease. As shown in the Fig.2(b), the amplitude of the exciting force wave will decrease when the stator adopts skewed slot structure. As shown in the Fig.2(c) and (d), when the skewed slot rate is constant, the amplitude of the 24-order exciting force wave decreases with the increase of the pole arc coefficient, but the amplitude of the 48-order exciting force wave increases firstly and then decreases with the increase of the pole arc coefficient. As shown in the Fig.2(e) and (f), When the polar arc coefficients are different, the law of change of low-order force waves with eccentricity is also different. So only in a specific pole arc coefficient can we change the eccentricity to weaken the electromagnetic vibration. 5.Conclusion In this paper, the radial electromagnetic force has been calculated accurately by combining the analytical method and FEM. The influences of machine structure parameters on the electromagnetic force wave are analyzed. The study found that the lower-order electromagnetic force wave can be decreased by decreasing slot opening width, increasing the pole arc coefficient and adopting skewed slot. Adopting eccentric magnet pole can only weaken the electromagnetic force wave with a specific arc coefficient.

CH-01. Reduced EMI Noise with the Consideration of Magnetic Material Design in the Grid-Connected Inverter for More Electric Aircraft.

Y. Liu[1], Y. Liu[2], H. Wang[1], G. Wang[1] and J. Peng[1]
1. Shenzhen University, Shenzhen, China; 2. Nanyang Technological University, Singapore, Singapore

1.Introduction The concept of more electric aircraft (MEA) is based on the increasing use of electric power to replace the non-electric subsystems in the traditional aircraft. It provides significant improvements in reliability, maintenance cost, fuel consumption and overall weight for the aircraft [1]. The LCL filter is widely used in the grid-connected inverter due to its harmonic attenuation performance and system stability [2, 3]. Compact and efficient magnetic components design in the power inverter results in its total size and weight minimization. Winding technology [4, 5], switching frequency [6] and core selection [7] are three important issues in the size reduction of magnetic components in the LCL filter. Furthermore, besides power quality of the power grid, another important issue is the conducted EMI which is mainly generated due to the high frequency transistor switching and parasitic components in the noise conduction path [8, 9]. The differential mode (DM) EMI is dominant compared with the common mode (CM) EMI in the inverter side, thus the LCL filter can be treated as an EMI filter [10] if the self-resonant frequency in the filtering inductor is high enough. Thus, if THD and EMI can be reduced at the same time with one filter, the power density would be increased pronouncedly. 2. LCL filter design The output LCL filter is a necessary part as shown in Fig. 1 (a) for the harmonic limit requirement [11, 12]. The LCL filter is expected to attenuate the grid side current complied with the IEEE 519-std as shown in [13]. To increase the power density, the silicon carbide (SiC) power module is employed in the grid-connected inverter so that switching frequency can be pushed to 60 kHz or higher [14]. The Low core loss, high saturation flux density, wider operation frequency and high operation temperature Amorphous core take advanced power conditioning applications with high power. 3D printing technology is adopted for the bobbin fabrication with the purpose of compactness. 4. Inductor winding design The Amorphous core with low loss and high saturation flux density is chosen for the filtering inductors design. The impedance of the two types of inductors with different winding technology that is measured by Hewlett Packard 4194A Impedance analyzer. In order to reduce the parasitic components at higher frequency range, the conventional copper wire for inductor winding is replaced by copper foil with an EE Amorphous core. The copper foil inductor has larger resonant frequency than copper wire inductor. Larger resonant frequency means that it has better noise attenuation for the conducted EMI noise in the range of 150 kHz to 30 MHz. Fig. 1 (b) and (c) show the commond mode (CM) and differential model (DM) EMI noise model with the LCL filter consideration. It can be found that larger impedance of L_i denotes the smaller noise voltage and the EMI filter requirement can be reduced. Thus, the weight of the copper foil inductor is smaller than the copper wire inductor in the system requirement for the inverter. Copper foil inductor has more efficient high frequency noise attenuation ability and save more space for the EMI filter design. According to above analysis, the copper foil inductor will be designed and applied in the experiment to verify its THD and EMI noise attenuation effect. 5. Experiment results The LCL filter design is verified in a 30 kW, 750 V (DC) and 230 V/400 Hz two-level three-phase grid-connected inverter based on the early works [15]. The SiC power module is employed to achieve a high switching frequency with the commercial product CAS100H12AM1 (1.2 kV, 100 A) from Wolfspeed. It achieves 97.9% energy conversion efficiency at 30 kW input power and 60 kHz switching frequency. Fig. 2 (a) shows the simulated flux distribution at full load by FEA software, in which the maximum flux in the core is 4/5 of the saturation flux 1.56T. Fig. 2 (b) shows the temperature distribution in the filtering inductor after one hour full load running, the maximum temperature is 155^{o}C which is lower than the its Curie Temperature. Fig. 2 (d) shows the experimental current in the inverter with foil-wound inductor. The LCL filter can not only reduce the THD but also reduce the DM EMI noise at higher frequency range. Smaller resonant frequency can lead to larger noise attenuation performance. Fig. 2 (c) compares the grid side current spectrum in the two kinds of LCL filter with copper wire and copper foil inductor. It can be found that the high frequency current spectrum in the LCL filter with copper foil wound is smaller than copper wire wound. Thus, the foil wound inductor is used in the high power density inverter that would result in a smaller EMI filter requirement. 6. Conclusion This paper proposes the LCL filter design in a grid-connected system using foil-wound, 3D printing and SiC-based power converter. The experimental inverter and grid side currents' spectrums are used to evaluate the noise attenuation comparison of the copper foil-wound and traditional copper wire-wound inductors in the LCL filter. Due to the higher resonant frequency, smaller EMI noise and less space requirement in the foil-wound inductor, it is highly recommended for the high power density inverter design.

CH-02. All-Metal Domestic Induction Heating Using Single-Frequency Double-Layer Coils.

W. Han[1], K. Chau[1], C. Jiang[1] and W. Liu[1]
1. Electrical and Electronic Engineering, The University of Hong Kong, Hong Kong, Hong Kong

I. INTRODUCTION In the past few decades, induction heating based on near-field magnetic coupling has been actively developed, aiming to improve the efficiency, controllability and safety. For traditional induction heating, the heating coil is energized by an AC power source to generate an alternating magnetic field, which in turn induces the eddy current in the workpiece to produce the heating effect [1]. Nevertheless, the workpiece made of non-ferromagnetic materials like stainless steel, aluminum and copper cannot be properly heated, which dramatically limits its application as compared with traditional open-fire heating. There was an attempt to heat the non-ferromagnetic workpiece using a strong magnetic field provided by superconducting windings [2], but it was not practical for domestic induction heating. By using low-frequency AC (around 20 kHz) to heat the ferromagnetic pan and high-frequency AC (over 70 kHz) to heat the non-ferromagnetic pan, the selective operating frequency technique was developed for all-metal domestic induction heating [3]. However, the corresponding switching and winding losses significantly increased, which inevitably resulted in low heating efficiency. In addition, the frequency selection caused serious electromagnetic interference and increased complexity and cost. Recently, the homogeneity and flexibility of induction heating has been improved by adopting the magnetic resonant coupling (MRC) mechanism [4]-[5]. In this paper, a new all-metal domestic heating system is proposed and implemented. The key is to employ double-layer coils and utilizes the MRC mechanism to induce a high current in the resonant coil when heating the non-ferromagnetic pans, thus successfully heating both the ferromagnetic and non-ferromagnetic pans at 30 kHz resonant frequency. Consequently, the advantages of simplicity, high heating efficiency and single operating frequency can be attained for all-metal induction heating. II. METHODOLOGY The proposed approach employs double-layer coils and utilizes the MRC mechanism in a new way. Fig. 1 shows the structure and equivalent circuit of the proposed induction heating in which two coils are laid on lower and upper sides of the ceramic glass plate concentrically, thus dubbed as lower and upper coils and the pan is regarded as the load coil. Unlike normal MRC for wireless power transfer, the resonant coil (the upper coil) not only serves to boost the power transfer from the transmitter to the receiver but also provides high current to strengthen the magnetic coupling and hence the dissipated power in the non-ferromagnetic pan. Since the equivalent impedances of the upper and lower coils are affected by the material of the pan, two sets of switched capacitors are introduced so that the coil inductances can be properly compensated when loaded with the ferromagnetic and non-ferromagnetic pans at the same operating frequency. Additionally, some ferrite slabs are placed beneath the lower coil to enhance the heating performance. Hence, the lower coil is directly excited by a low-frequency AC source which in turn excites the upper coil indirectly via the MRC mechanism. Given that the inductances of the coils are fully compensated by the capacitors, both high power factor in the lower coil and high resonant current in the upper coil are achieved simultaneously. Meanwhile, since the resistances of the coils which are made of Litz-wire are quite small, high power transfer efficiency can be achieved. Both the lower and upper coils transmit power to the pan and the upper coil plays a major role because of much higher current and stronger magnetic coupling. Firstly, theoretical equations based on the equivalent circuit are deduced to assess the currents flowing in two coils loaded with the ferromagnetic and non-ferromagnetic pans. Hence, the corresponding dissipated power and power transfer efficiency can be calculated. Secondly, the magnetic field and thermal field analyses of the proposed heating system when using the iron, stainless steel, aluminum and copper pans are carried out using finite element method based software JMAG. Finally, an experimental prototype has been constructed and tested to verify the feasibility and efficiency of the proposed all-metal domestic induction heating. As shown in Fig. 2, the thermal images of various metallic pans are captured by a thermal scanner (FLUKE TiS 40) after heating for 120 s in the proposed heating system. It illustrates that the average temperatures along the pan diameter of the iron, stainless steel, aluminum and copper pans are 105.1^{o}C, 102.5^{o}C, 108.5^{o}C and 104.1^{o}C, respectively, at the same operating frequency of 30 kHz. It confirms that all metallic pans can be heated successfully in the proposed induction heating system. More simulation and experimental results will be given in the full paper. III. CONCLUSION In this paper, an all-metal domestic induction heating system has been proposed and implemented. The key is to newly employ double-layer coils and utilizes the MRC mechanism so that both the ferromagnetic and non-ferromagnetic pans can be effectively heated. Theoretical analysis, numerical simulation and experimentation are given to validate the proposed system. This work was supported by a grant (Project No. SPF 201409176054) from the University of Hong Kong, Hong Kong.

1. INTRODUCTION For power-line monitoring, autonomous wireless power-line sensors are hung from overhead power-lines and transmit the data collected from measurement systems using internet-of-things technology. Since these sensors require a continuous power supply, some have proposed using self-powered monitoring devices to harvest magnetic energy using a current transformer (CT) with a toroidal core structure, as shown in Fig. 1a [1], [2]. However, those studies only focused on the power transfer efficiency of the CT without considering the effect of eddy-current loss in the CT and impedance matching for maximum power transfer to the load. Even though this device produces voltage drop and impedance changes in the power-line, no analysis of the CT impact on the power quality of the power-line has been done. The power quality is very important issue that power supplier cannot ignore. Impedance changes by CT in power-lines can induce power factor distortions in the electric power system. This paper presents analytical methods for calculating voltage drop and impedance changes in power-lines. Voltage drop and impedance change were found to increase as load impedance decreased under the impedance matching condition. 2. ELECTRICAL MODEL OF POWER-LINE AND ENERGY HARVESTING DEVICE A. COMPUTATION OF CURRENT DENSITY AND VECTOR POTENTIAL Unlike previous works which calculated the magnetic field distribution in the CT [3], [4], current density and vector potential are useful for calculating the impedances of the power-line and CT. In conductors, the current density J_z can be expressed as Fig. 2a from Maxwell's equation and Ohm's law. Assuming that the field emission in the air region is the transverse electromagnetic, the vector potential A_z can be expressed as Fig. 2b. The general solutions of these Helmholtz equations in cylindrical coordinates can be obtained as Fig. 2c. The current densities inside the power-line and CT can be expressed as Bessel functions and the vector potential of air regions is simplified by the logarithm function, where I_s denotes the current in the power-line, the current I_p in the CT and the coil turns N_p. The constants c_0, c_1, c_2 and c_3 can be determined by Ampere's law, while c_4 is not needed since it will be eliminated in computational procedure for the impedances. B. EQUIVALENT CIRCUIT MODEL Fig. 1b shows the equivalent circuit model. In a quasi-magnetostatic field [5], the scalar potential per unit length can be expressed as Fig. 2d. This is valid because the structure parameters in CT are much less than 1/4 wavelength (5×10^6m at 60Hz). The power-line impedances Z_{s_in}, $j\omega L_{s\_ext}$ and Z_{sc} can be obtained by applying the integral form of Faraday's law in Fig. 2d. The CT impedance Z_p consists of Z_{pc} due to the self-induced voltage in the coil and the wire wound resistance R_p, while Z_{pc} can be calculated by Faraday's law in the differential form and R_p is obtained from the resistance model of round wire [6]. The magnetic coupling between power-line and CT can be represented by M_{sp} in Fig. 2h, which not only makes the induced voltage for magnetic energy harvesting, but also causes the voltage drop in the power-line. M_{sp} can be obtained in a similar way to Z_{pc}. Z_{sc}, M_{sp} and Z_{pc} includes the losses due to the eddy-current inside the CT. 3. VOLTAGE DROP IN POWER-LINE As shown in Fig. 1c, the total impedance Z_{s_tot} viewed from the power-line referred to the primary side must include the effective impedance Z_{s_eff} due to magnetic coupling. Using I_s/I_p=j$\omega M_{sp}/(Z_{pc}+R_p+Z_L)$ [7], Z_{s_eff} is expressed as Fig. 2g. The inductance of the power-line without CT for magnetic energy harvesting is $\mu_0 h/8\pi$. Compared to the power-line with CT, the variation in impedance ΔZ can be expressed as Fig. 2i. To maximize power transfer by minimizing losses due to signal reflection from the load, the impedance matching circuit has the absolute difference between Z_L and Z_p, as shown in Fig. 2j. Under the condition of impedance matching, the denominator in Fig. 2i is doubled of Z_L. If there is no load connected to the magnetic energy harvesting device (open circuit or Z_L=inf), the voltage drop across the power-line is minimized since Z_{s_eff} is zero. Although there is no power dissipated at the load, a voltage drop still occurs on the power-line due to the eddy-current loss of CT ($Z_{sc}\neq0$). On the other hand, when Z_L is connected to the magnetic energy harvesting device ($Z_L\neq$inf), the voltage drop in the power-line increases as Z_L decreases. In order words, the power consumption of the load increases since Z_L decreases at P=$V^2/4Z_L$. When the structure parameters of CT are inner radius ρ_1=17.1mm, outer radius ρ_2=37.9mm, height h=45mm, coil turns N_p=90, permeability in the CT μ_c=50000 and conductivity in the CT $\sigma_c=2.2\times10^5$S/m, the voltage drop $\Delta V=\Delta Z\times I_s$ of the power-line is as follows. - I_s=60A, no load (Z_L=inf), ΔV = 0.54V - I_s=60A, Z_L=5Ω (impedance matching), ΔV = 5.12V - I_s=60A, Z_L=2Ω (impedance matching), ΔV = 13.33V

CH-04. Matrix formulation of Cauer Ladder Network Method for Efficient Eddy-Current Analysis.

T. Matsuo[1], A. Kameari[2], K. Sugahara[3] and Y. Shindo[4]
1. Kyoto University, Kyoto, Japan; 2. Science Solutions International Laboratory, Inc., Tokyo, Japan; 3. Kindai University, Higashiosaka, Japan; 4. Kawasaki Heavy Industries, Ltd., Akashi, Japan

1. Introduction Advanced power control often requires detailed eddy-current analyses of electric machines handling thin skin depth due to high frequency switching. The Cauer circuit [1][2] is a very efficient and exact representation of the eddy-current field in magnetic sheets and cylinders for wide frequency range, where magnetic and electric fields are optimally expanded by orthogonal polynomials. Recently, the Cauer circuit representation is extended to describe general eddy-current fields powered by the finite element method (FEM). This method is called Cauer ladder network (CLN) method [3][4] and still retains clear physical meaning based on the orthogonal function expansion. The generality of CLN method has a similarity to model order reduction (MOR) methods [5][6]. The relation between the CLN method and other MOR methods has not been clear yet because of the physics-based derivation of CLN method. This article derives a matrix formulation of CLN method for clear understanding of mathematical aspects of the CLN method. **2. Matrix based formulation of CLN method** In the matrix form based on the FEM, the governing equation of eddy-current field is given as $\boldsymbol{Ka} = \sigma\boldsymbol{e}$, $\boldsymbol{Ce} = -\,\mathrm{j}\omega\boldsymbol{Ca}$, $\boldsymbol{K} = \boldsymbol{C}^{\mathrm{T}}\boldsymbol{vC}$ (1) where $\boldsymbol{a}$ and $\boldsymbol{e}$ are the variable vectors representing vector potential and electric field, $\boldsymbol{C}$ is the edge-face incidence matrix [7], $\boldsymbol{v}$ is the reluctivity matrix, and σ is the conductivity matrix. The CLN method is described by the recurrence formulae below to generate orthogonal basis vectors as $\boldsymbol{K}(\boldsymbol{a}_{2n+1}-\boldsymbol{a}_{2n-1}) = \sigma\boldsymbol{e}_{2n}/\lambda_{2n}$ (2) $\boldsymbol{e}_{2n+2} - \boldsymbol{e}_{2n} = -\,\boldsymbol{a}_{2n+1}/\lambda_{2n+1}$ (3) where $\boldsymbol{a}_{2n-1}$ and $\boldsymbol{e}_{2n}$ are orthogonal basis vectors for vector potential and electric field and $\lambda_{2n} = \boldsymbol{e}_{2n}{}^{\mathrm{T}}\sigma\boldsymbol{e}_{2n}$, $\lambda_{2n+1} = \boldsymbol{a}_{2n+1}{}^{\mathrm{T}}\boldsymbol{Ka}_{2n+1}$. (4) The initial conditions for the recurrence formulae are given by $\boldsymbol{a}_{-1} = 0$, $\boldsymbol{Ke}_0 = 0$ (5) where it is assumed that a unit voltage is given as the boundary condition. As derived later, the eddy-current field is equivalently represented by the Cauer circuit shown in Fig. 1(a), where $R_{2n} = 1/\lambda_{2n}$, $L_{2n+1} = \lambda_{2n+1}$. (6) **3. Derivation of orthogonality** The orthogonality of basis vectors is derived by induction as follows. The multiplication of (2) and (3) gives $-(1/\lambda_{2k-1})\boldsymbol{a}_{2k-1}{}^{\mathrm{T}}\boldsymbol{K}(\boldsymbol{a}_{2n+1}-\boldsymbol{a}_{2n-1}) = (1/\lambda_{2n})(\boldsymbol{e}_{2k}-\boldsymbol{e}_{2k-2})^{\mathrm{T}}\sigma\boldsymbol{e}_{2n}$. (7) From (4), (5) and (7) with $n = 0$, $k = 1$, it holds that $\boldsymbol{a}_{-1}{}^{\mathrm{T}}\boldsymbol{Ka}_1 = 0$, $\boldsymbol{e}_2{}^{\mathrm{T}}\sigma\boldsymbol{e}_0 = 0$. (8) It is supposed that $\boldsymbol{a}_{2i-1}{}^{\mathrm{T}}\boldsymbol{Ka}_{2j-1} = 0$, $\boldsymbol{e}_{2i}{}^{\mathrm{T}}\sigma\boldsymbol{e}_{2j} = 0$ ($i < j \le n$). (9) From (4) (9) and (7), $\boldsymbol{a}_{2k-1}{}^{\mathrm{T}}\boldsymbol{Ka}_{2n+1} = 0$ ($k \le n$) (10) is obtained. By replacing (k, n) in (7) by (n+1, k), it holds that $-(1/\lambda_{2n+1})\boldsymbol{a}_{2n+1}{}^{\mathrm{T}}\boldsymbol{K}(\boldsymbol{a}_{2k+1}-\boldsymbol{a}_{2k-1}) = (1/\lambda_{2k})(\boldsymbol{e}_{2n+2}-\boldsymbol{e}_{2n})^{\mathrm{T}}\sigma\boldsymbol{e}_{2k}$. (11) From (4), (9) and (11), $\boldsymbol{e}_{2k}{}^{\mathrm{T}}\sigma\boldsymbol{e}_{2n+2} = 0$ ($k \le n$) (12) is obtained. Thus, the orthogonality below is proven by induction: $\boldsymbol{a}_{2i-1}{}^{\mathrm{T}}\boldsymbol{Ka}_{2j-1} = \boldsymbol{h}_{2i-1}{}^{\mathrm{T}}\boldsymbol{v}^{-1}\boldsymbol{h}_{2j-1} = \delta_{ij}\lambda_{2i+1}$, $\boldsymbol{e}_{2k}{}^{\mathrm{T}}\sigma\boldsymbol{e}_{2j} = \delta_{ij}\lambda_{2i}$ (13) where δ_{ij} is Kronecker's delta and $\boldsymbol{h}_{2i+1} = \boldsymbol{vCa}_{2i+1}$. The full paper will reveal the similarity to other MOR methods and will discuss the benefit of the CLN method based on comparison with the Lanczos algorithm. **4. Derivation of circuit equations** Electromagnetic fields are expanded as $\nu Ca = \boldsymbol{h} = \Sigma_n H_{2n+1}\boldsymbol{h}_{2n+1} = \Sigma_n H_{2n+1}\boldsymbol{\nu Ca}_{2n+1}$, $\boldsymbol{e} = \Sigma_n E_{2n}\boldsymbol{e}_{2n}$. (14) The substitution of (14) into (1) gives $\boldsymbol{K}\Sigma_n H_{2n+1}\boldsymbol{a}_{2n+1} = \sigma\Sigma_n E_{2n}\boldsymbol{e}_{2n}$. (15) $\boldsymbol{C}\,\Sigma_n E_{2n}\boldsymbol{e}_{2n} = -\,\mathrm{j}\omega\,\Sigma_n H_{2n+1}\boldsymbol{Ca}_{2n+1}$. (16) From (16), the electric field is given as $\Sigma_n E_{2n}\boldsymbol{e}_{2n} = -\,\mathrm{j}\omega\,\Sigma_n H_{2n+1}\boldsymbol{a}_{2n+1} - V_{\mathrm{S}}\boldsymbol{G}\phi$ (17) where V_{S} is the source voltage, $\boldsymbol{G}$ is the node-edge incidence matrix corresponding to the grad-operator, and ϕ is the variable vector representing scaler potential satisfying $\boldsymbol{e}_0 = -\,\boldsymbol{G}\phi$. (18) Multiplying (17) by $(1/\lambda_{2k})\boldsymbol{e}_{2k}$ gives $(1/\lambda_{2k})\boldsymbol{e}_{2k}{}^{\mathrm{T}}\sigma\,(\Sigma_n E_{2n}\boldsymbol{e}_{2n} - V_{\mathrm{S}}\boldsymbol{e}_0) = -\,\mathrm{j}\omega(\boldsymbol{a}_{2k+1}-\boldsymbol{a}_{2k-1})^{\mathrm{T}}\boldsymbol{K}\,\Sigma_n H_{2n+1}\boldsymbol{a}_{2n+1}$. (19) From (13) and (19), it holds that $E_0 = V_{\mathrm{S}} - \mathrm{j}\omega\lambda_1 H_1$, $E_{2k} = -\,\mathrm{j}\omega(\lambda_{2k+1}H_{2k+1} - \lambda_{2k-1}H_{2k-1})$ (k = 1, 2, …). (20) Multiplying (15) by $-(1/\lambda_{2k+1})\boldsymbol{a}_{2k+1}$ gives $-\,(1/\lambda_{2k+1})\boldsymbol{a}_{2k+1}{}^{\mathrm{T}}\boldsymbol{K}\,\Sigma_n H_{2n+1}\boldsymbol{a}_{2n+1} = (\boldsymbol{e}_{2k+2}-\boldsymbol{e}_{2k})^{\mathrm{T}}\sigma\Sigma_n E_{2n}\boldsymbol{e}_{2n}$. (21) From (13) and (21), it holds that $-\,H_{2k+1} = \lambda_{2k+2}E_{2k+2} - \lambda_{2k}E_{2k}$ (k = 0, 1, …). (22) Eqs. (20) and (22) represent the Cauer circuit in Fig. 1(a). Inversely, the substitution of (20) and (22) into (15) and (17) results in (2) and (3), which confirms the equivalence of the CLN and the eddy-current field. **5. Computation example** To demonstrate the efficiency and accuracy of the CLN method, a sample eddy-current problem is solved. A square iron bar [Fig. 2(a)] has the conductivity and permeability of $2*10^6$ S/m and 0.01 H/m. The unit electric filed is imposed at the surface of iron bar. The analytical solution is given by the Fourier expansion, which is represented by the Foster circuit shown in Fig. 1(b) where (m, n)-th R-L pair corresponds to the ($2m-1$, $2n-1$)-th sinusoidal basis function. Fig. 2(b) compares the frequency dependence of admittance per unit length. The Cauer circuit with only 3 or 6 R-L pairs accurately reconstructs the wide range of frequency dependence whereas the Foster circuit requires a large number of R-L pairs. The magnetic flux distributions due to $\boldsymbol{a}_1$, $\boldsymbol{a}_3$ and $\boldsymbol{a}_5$ are shown in Fig. 1(a). Using expansions (14) with these distributions, the CLN method can reconstruct the magnetic and electric fields. In the full paper more practical application will be presented.

CH-05. Design of Rotary Transformer Based on Transient Field-Circuit Coupled Model.

H. Zhong[1], Y. Wang[1], B. Peng[1] and Y. Yang[1]
1. Electrical Engineering School, Shandong University, Jinan, China

I. Introduction It is necessary to transmit electrical power from a stationary source to a rotating load or circuit in many industrial applications such as wound-rotor synchronous[1], doubly fed induction generator[2]-[4], radar power supplies[5] and so on. Although using of the brushed equipments is a simple, compact and low-cost solution, the presence of brushes and slip rings increases the maintenance costs and limits the machine only to non-explosive environments due to the mechanical wearing. To make a contactless maintenance-free solution, different brushless structures are proposed. This paper presents a novel rotary transformer for power supplying rotatable parts of electrical applications as a robust alternative to sliding contacts. The stator winding of the electrical machine is directly connected to the power grid while the stator(primary) winding of the rotary transformer is connected to power grid through power electronics converters and integrated control unit. This configuration can realize the indirect control of the torque, speed, power factor and current of induction by controlling the amplitude, frequency and phase of the rotary transformer primary winding voltage. The rotor winding of the electrical machine is electrically connected to the secondary winding of the transformer; consequently their currents have the same electric frequency. II. Structure Design of Rotary Transformer The structure of the rotary transformer in the plane is shown in Fig.1. One design challenge of the rotary transformer is the air gap of radial freedom to allow a small axial movement without affecting the electrical characteristics too much. The possible designs are limited by the constructive constraints such as the axial length l_{ax}, the outer diameter d_{out}, the desired air gap length c or the rotational speed n. A 3kVA rotary transformer parameters are designed using the core geometry Kg approach. Structural parameters and efficiency are two of the most important design specifications of the rotary transformer. Following with the traditional transformer design procedure and taking into account the characteristics of the rotary transformer, a transient calculation method coupling field-circuit mehtod is used in the design flow. The dimension calculation is performed by accurately analyzation the size and distribution of the magnetic field in the transformer core silicon steel laminations. The effect of the air gap is considered in the design to ensure that sufficient core area provided to prevent the core from saturation. III. Transient Nonlinear and Anisotropic Field-circuit Coupled Method A transient calculation method coupling field-circuit is presented considering nonlinear anisotropic magnetic properties of ferromagnetic materials in the transformer core silicon steel laminations. Transient calculation method coupling field-circuit has been improved compare with the traditional calculation method. The expressions of FE discretization are deduced in 3D transient eddy current field coupling field-circuit considering the electromagnetic characteristics of different materials such as anisotropy and isotropy and nonlinearity respectively. Nonlinear algebraic equations are solved by Newton-Raphson method which is common method to solve these equations, calculation accuracy of magnetic field of the rotary transformers can be improved greatly using this method. The field control equation is described as equation (1), where W_t is the turns of the transformer windings, S_t is the cross-sectional area of windings, A is the vector magnetomotive force. The discrete matrix is obtained by the Galerkin finite element method as equation (2), where j is the scalar magnetomotive force, N_j is the basis interpolated function, J_s is the source current density. The derivation of the nonlinear isotropic coefficient matrix by complex coefficient Newton - Raphson method was presented in [5]. Followed the similar derivation, the nonlinear anisotropic coefficient matrix of the field coupled equations is derived as equation (3), where c_e is determined by lamination coefficient c, shown in equation (4). Defined f_j as equation (5), the element of unit Jacobian matrix [J] is shown in equation (6). IV. Analysis and Verification The rotational speed of the rotary transformer is set to be 1200r/min in the calculation. The transient magnetic field of transformer core, distribution of loss density of no-load and the difference and size of exciting current change with time are analyzed. Magnetic flux density and no-load loss of the transformer model is calculated and analyzed. The validity and the correctness of the field-circuit coupled method is verified compared with the experimental results.

CH-06. Benefits of Synthetic Polymer Bonded Soft Magnetic Composites for Inductive Wireless Power Transfer Receivers in Electric Vehicles.

D. Barth[1], B. Klaus[1] and T. Leibfried[1]
1. Institute of Electric Energy Systems and High-Voltage Technology (IEH), Karlsruhe Institute of Technology (KIT), Karlsruhe, Germany

Abstract This paper displays the application of synthetic polymer bonded soft magnetic composites (SMC) as an alternative to ferrite backplates in inductive wireless power transfer (WPT) receivers. We analyze the influence of different shapes and the materials relative permeability on the coupling factor. Proximity effect loss and material processing are taken into account. Introduction Wireless charging is a crucial technology to increase the consumer acceptance of electric vehicles. Several publications present the investigation of WPT systems with a nominal power of several kilowatts, e.g. [1][2]. To increase coupling, the coils do usually have a high-permeable ferrite backplate or ferrite bars [3]. Soft magnetic ferrites are brittle, thus they are difficult to shape. Embedding the coil windings and the ferrite in a plastic housing keeps them in place. A soft magnetic polymer combines the magnetic benefits of ferrites and the structure and fabrication of synthetics. For this purpose, high-permeable ferrite is powdered and added to the polymer. The material must be compound to reach the desired permeability. It also has to be injection-moldable to receive the advantage of unlimited shaping. [4]. An existing application of such material is the flux guide in electrical machines [5]. For WPT systems, a similar approach to combine ferrite and concrete is presented in [6]. Analysis We use the magnetic resistance to describe the requirements of a good shape for the SMC. Assuming a current linkage Θ is given, the magnetic flux in a magnetic circuit is $\Phi=\Theta/R_m$, where R_m is the magnetic resistance. We can rewrite the magnetic coupling factor of two coils: $k = \mathrm{sqrt}(\Phi_{12}\ \Phi_{21}/\Phi_{11}\Phi_{22}) = \mathrm{sqrt}(R_{m,11}R_{m,22}/R_{m,21}R_{m,12})$ Because of symmetry, the magnetic circuits through both coils are identical, so we get $R_{m,21}=R_{m,12}=R_{m,h}$. The equation shows that increasing the coupling factor means decreasing the magnetic resistance of the main flux $R_{m,h}$ without decreasing the magnetic resistances of the stray flux. Figure 1 presents the proposed shape of the receiver unit ferrite. The figure is rotationally symmetric to the z-axis and shows two identical receiver coils with ten turns. While the coil on the top has a pure ferrite backplate, the second one contains SMC. Covering the windings with SMC from all sides would decrease the coupling factor, for it offers a path of low magnetic resistance for the stray flux. If the downside is left open, the SMC operates as a shielding in all directions besides towards the transmitter unit. Thereby it increases the coupling factor. Simulation The SMC is modeled as a distributed air-gap with an equable relative permeability [7]. To compare its shape to a ferrite backplate with varying permeability, we place the two receiver coils in figure 1 above the same transmitter coil. The coupling factor is calculated depending on the relative permeability of the receiver ferrite. Figure 2 shows that in this setup, the SMC with μ_r=30 achieves a better coupling factor than any possible backplate made of pure ferrite. Additionally, the coupling factor in this setup is already 94% of the maximum value that can be reached with μ_r>10000. Synthetic Polymer Bonded Soft Magnetic Composites, which allow complex shaping, do not have to be high-permeable as pure ferrites. The coupling factor increases only slightly if the permeability exceeds 100. The complex shaping of ferrite material has another advantage in high-power WPT systems. The SMC separates the windings. A layer of a material with μ_r>1 between the windings causes the magnetic flux not to be conducted in the windings and reduces the proximity effect loss. The external proximity effect loss that describes eddy current loss in a winding, caused by an external magnetic field, can be calculated using [8]: $P_{p,ext}=2*G*H_{rms}^2*l$ where G is the specific proximity effect factor depending on the conductor design and the frequency, H_{rms} is the average magnetic field strength (rms) in the winding and l is the length of the winding. To compare the setups in figure 1 regarding the average magnetic field strength in the conductors, the receiver designs must achieve the same coupling factor to have equal conditions. We choose μ_r=30 for the SMC and μ_r=3000 for the ferrite backplate. The average magnetic field strength in the conductor is about 30% less if we use the SMC. The equation above indicates that the external proximity effect loss reduces by more than 50%. Conclusion and details to come Synthetic polymer bonded soft magnetic composites can improve the performance and reduce proximity effect loss in inductive WPT systems although the relative permeability is low compared to pure ferrite. It is lightweight and its shaping is inexpensive using die casting. In high-performance applications, it can be combined with a ferrite backplate to maximize coupling. The full paper will contain a further analysis of the ferrite shape and how to optimize it, based on FEA-simulation. The saturation flux density and the coupling factor in case of coil misalignment will be included. Experimental validation of the simulation results is to come. The manufacturing of coils, embedded in ferrite composite, is in process. Due to the lack of SMC material that is purchasable, we will test only one product with μ_r=8.

CH-07. Winding Losses Analysis of a 4 KVA High Frequency Coaxial Transformer Used in the Bi-Directional DC-DC Converter.

W. Water[1] and J. Lu[1]
1. Griffith University, South Brisbane, QLD, Australia

ABSTRACT This paper examines the winding losses characteristic of a 4 kVA high frequency coaxial transformer used in the bi-directional DC-DC converters. With consideration of nonlinear behavior of the magnetic material, the winding losses of the transformer can now be estimated more accurately. Three-dimensional (3-D) simulation techniques, in conjunction with the Finite Element Method (FEM) technique, were deployed. These techniques significantly improve the calculation accuracy of the winding resistance under any specific condition. Prototypes were built to validate the effectiveness of the simulation and computation results. The simulation result and the measurement result are consistent with less than 10% error. I INTRODUCTION The most common type of high frequency coaxial transformer (HFCT) only has a two cylinder copper winding within a stacked core tube, which is composed of numbers of ring cores [1]. A similar design was introduced by replacing the inner copper tubes with Litz wires as shown in [2]. This makes it suitable for MHz range and high power applications, but there are not too many advantages when implemented in lower power and middle frequency range applications. The improved structure HFCT with symmetrical multi-turns winding deployment was introduced in [3]. This enables the HFCT to operate at a lower frequency range of 100 to 300 kHz while having a scalability with a power range from hundreds of watts to dozens of kilowatts. Much research has been undertaken to study the HFCT, such as structural optimizations, magnetic and electric field simulations, and the analysis of the Faraday shield [4], [5]. However, a comprehensive winding loss analysis of the HFCT has not yet been conducted. This is mainly due to the complex geometrical structure of the HFCT and the nonlinearity characteristics of the magnetic materials. The analysis and simulation of the HFCT performance requires more comprehensive modelling and computation and it is now presented in this paper. II APPLICATION AND PROTOTYPES A.Application The introduced HFCT can be used in many applications that operate at high frequencies and high power conditions while requiring the galvanic isolation for safety purposes. An example of this is the ongoing project involving the high power density on-board Electric Vehicle (EV) charger. This bi-directional four-quadrant DC/AC converter has many functions, such as battery charging and discharging, power factor correction, active and reactive power compensation and uninterrupted power supply [6]. B.Final Transformer Prototype Two prototypes have been built to validate the design's effectiveness. To reduce the common-mode noise propagating to the secondary side, one prototype was built with the Faraday shield. The final prototype (right) weighs about 820 grams with a volume of 84.5 mm x 52 mm x 99.5 mm. In comparison, the HFCT without the Faraday shield is 10 mm lower in height and 30 grams lighter. III WINDING LOSS ANALYSIS A.Eddy Current Simulation Result It can also be justified from the result shown in Fig. 3 that the winding structure of the HFCT is optimal because of the evenly distributed current. Hot spots are observed on the turning corner of the windings, where the end region and coaxial section windings are connected. However, the variation of peak current density is relatively small at about 26.2% to 37.8% when compared with the average value. B.Winding Losses Breakdown With the assistance of the 3-D FEM technique, the HFCT winding losses breakdown can be obtained (results will be showed in full paper). Under the condition of 400 V and 10 A, the eddy current losses of different regions of the HFCT can be analyzed across a broad operating frequency range. The thickness of the Faraday shield is 0.1 mm, which is equivalent to 0.485 skin depth at 100 kHz. However, it still contributes approximately 21.6% loss to the overall loss under full load conditions. The eddy current loss of the Faraday shield is largely due to the coaxial. The AC/DC resistance ratio at 100 kHz is 3.9 for the round conductor implemented according to *Dowell's* equations [7]. However, the resistance AC/DC ratio of the secondary and the primary winding are 5.65 and 5.91 respectively in the simulation result. It can be justified that the proximity effect and eddy current effect are contributing an additional 44.8% to 51.54% in losses. C.Winding Resistance Measurement The impedance measurements were conducted with the use of a high frequency Microtest Transformer Analyzer. The ambient temperature is stable at roughly 20 to 25°C, and both the open circuit and short circuit calibrations were conducted prior to testing. As expected, the winding resistance increases with the increased operating frequency. Results of the winding resistance comparison are shown in Fig. 2. The winding resistance does not increase dramatically until the operating frequency is above 200 kHz. Grounding or ungrounding of the Faraday shield had little effect on winding resistance. A comparison of the winding resistance measurement result with the simulation result indicates that they are consistent whereas the variation in difference is only 3.5% to 7.2% for the non-shielded case and 0.3%~2.3% for the shielded case. V ACKNOWLEDGMENT The work was supported by the *Advance Queensland Research Fellowship Program* from the Queensland Government, Elevare Energy and Griffith University.

CH-08. Leakage Flux based turn-to-turn Fault Detection for Shunt Inductor.

B. Chen[1], *J. Dong*[1], C. Tian[1] and Q. Chen[1]
1. Wuhan University, Wuhan, China

I INTRODUCTION Dry-type iron-core inductors in urban high-voltage substation reactive power local balance and reasonable control of voltage fluctuations plays an important role [1]. As its number of applications and uptime increase, the amount of failure must also increase. The most common events of dry-coil devices are interturn faults, which can damage the insulation of the coil and even burn the device when a large current generated in the short-circuit loop. Right now, the low-voltage dry-type iron-core inductors lack a special inter-turn fault detection method and generally use overcurrent protection and temperature detection protection. The zero-sequence and negative-sequence power direction protection are mostly used for ultrahigh-voltage inductors protection[2-3]. Therefore, this paper proposes to use the difference of the distribution characteristics of space magnetic field in normal operation and inter-turn fault as the criterion of on-line detection algorithm for turn-to-turn fault [4-5]. In this paper, a field-circuit coupled finite element model of a three-phase iron-core inductor is established. The distribution characteristics of the spatial magnetic field under normal operating conditions and different inter-turn fault conditions are simulated and analyzed. This result provides a theoretical basis for the inductor on-line detection algorithm of non-contact turn-to-turn fault. II SIMULATION RESULTS UNDER NORMAL CONDITIONS In this paper, field-coupled finite element model of BKSC-5000/10 parallel core inductor is simulated. Fig.1 (a) shows a half-length longitudinal cross-sectional view of a dry core inductor and its simplified simulation. Fig.1(b) shows the amplitude of magnetic flux density, the radial component BX and the axial component BY curve in the axial path from the outermost layer of inductor A phase winding 10mm. The calculated path is the same height as the windings in Fig.1 (a), with coordinates of 0-1550 mm from bottom to top. The axial component of magnetic flux density on this path is symmetrical about the horizontal axis L1, and its value is approximately the same in the middle section of the winding but varies greatly at the end. The radial component BX of the magnetic flux density is odd-symmetrical about the horizontal axis L1. The component direction of the field at the symmetry point of the horizontal axis L1 is opposite and the value of the end position is larger. The amplitude curve of the magnetic flux density is symmetrical about the central axis L1, and the strength of the leakage magnetic field at the end of the winding is significantly greater than that of the mid-section. III INTERTURN FAULT SIMULATION RESULTS Fig.2 (a) shows the core inductor windings occur in different turns of the inter-turn short when the reference path of the magnetic flux density curve. As the number of shorted turns increases, the magnetic flux leakage flux of the path increases as a whole. Meanwhile, the degree of asymmetry of the path along the horizontal axis L1 gradually increases, and the field asymmetry Diff1<Diff6 <Diff10 <Diff13. Fault detection algorithm can be based on changes in the degree of asymmetry of the magnetic field to determine the occurrence and severity of inter-turn short circuit. Fig.2 (b) shows the induced voltage curves of two symmetrical induction coils on the measurement path outside the winding when turn-to-turn fault occurs in the iron-core inductor windings. From Fig.2 (b), under normal operating conditions (0-20ms), the induced voltage of the coil is approximately zero. After the inter-turn fault occurs in the winding (20-100ms), the induced voltage Vfault of the coil at the fault position and the symmetrical position coil Induced voltage Vsys phase opposite and greater amplitude, Vout coil output voltage in series, much larger than the measured values under normal conditions. IV CONCLUSION In this paper, based on the field-coupled finite element simulation model, the distribution of magnetic field in the iron-core inductor under normal operating conditions and inter-turn fault conditions is analyzed. The following conclusions are drawn: under normal operating conditions, the leakage flux density of core reactors is small, and their spatial magnetic fields are longitudinally symmetrical. Under asymmetrical turn-to-turn conditions, the asymmetry of the magnetic field increases with the increase of short turns. The asymmetry of the space magnetic field under the inter-turn fault can be used as the criterion of the interturn fault detection algorithm.

I. Introduction The start current can reach up to as high as 4-7 times of the motor's rated current when high voltage motors start directly. For super large capacity motors (voltage above 6 kV, power above 10000 kW), the direct start current could reach 5000 Ampere or more[1]. Such large start current will not only have a huge impact on the motor itself but also cause a sudden decline of the grid voltage[2]-[3]. The main way is the step-down start method such as auto-transformer soft start and magnetic control soft start. However, the secondary impact exists during auto-transformer soft starting and the cost of magnetic control starter is too high[4]. This paper proposed a novel auto-transformer and magnetic control (ATMC) soft start method of super large capacity and high voltage induction motor. Firstly, the basic working principle of the proposed method is analyzed. In addition, the calculation formulas of cost for magnetic control soft starter and ATMC soft starter are deduced, and specific examples are analyzed and compared. Finally, simulation results verify the effectiveness of the proposed soft start method. II. Basic Principle Fig.1 (a) shows the topological diagram of auto-transformer and magnetic control soft starter. The starting procedure can be divided into the following three parts. At first, thyristor T of the magnetic control reactor (MCR) is turned off, the winding N_1 of MCR and the additional winding N_2 constitute an auto-transformer to reduce motor terminal voltage. After it, motor terminal voltage is gradually increasing, disconnect from the winding N_2 and the motor is connected in series with MCR. By controlling the turn-on angle of the thyristor T, the DC control current is generated, so that the core of the reactor is magnetically saturated, and the equivalent reactance value is reduced to achieve constant current start. When the motor is approaching the rated speed, disconnect the soft starter. III. Cost Comparison Here are the calculation formulas of C_1(cost for magnetic control soft starter) and C_2(cost for auto-transformer and magnetic control soft starter): $C_1=xk_{set}^2I_n^2(((U_1/(k_{set}I_n))^2\text{-}R_k^2)^{0.5}\text{-}X_k\text{-}X_s)$ (1) $C_2=(xk_{set}^2I_n^2(R_k^2+(X_k+X_s)^2)^{0.5})/k+(xk_a^2U_1^2X_{L2})/(R_{ck}^2+(X_{ck}+X_s)^2)$ (2). Take 12500kW/10kV motor for example, we get the comparison diagram for C_1, C_2 and C_1-C_2 versus start current multiple k_{set} when the tap ratio of auto-transformer k_a is equal to 0.8 shown in Fig.1 (b). When k_{set}=1.25, C_1 minus C_2 reaches the maximum which is 0.91×106x, C_1 is 32% higher than C_2. Therefore, we can get the conclusion: the choice of auto-transformer with appropriate tap ratio can greatly reduce the cost of ATMC soft starter compared with the cost of magnetic control soft starter under the same starting requirement. IV. Simulation Results and Conclusion According to the conclusion of the cost calculation, the total cost of the auto-transformer and magnetic control soft starter is reduced as much as possible by selecting the appropriate tap ratio of the auto-transformer. Motor parameter setting is given as follows: rated power is 18MW, rated voltage is 10kV, rated current is 1.039kA, rated speed is 1500r/min. The simulation results for three start methods, namely direct start, auto-transformer soft start and auto-transformer and magnetic control soft start, are shown in Fig.2. Fig.2 (a) shows that when the motor starts directly, the stator current reaches as high as more than 5000 A. It is about 5 times of the rated current. Such large start current will be harmful to the grid and the motor. The starting current can be reduced to about 2.5 times of the rated current when using ATMC soft start method. Fig.2 (a) and (b) show that there is obvious secondary current and torque impact during auto-transformer soft starting. Fig.2 (c) shows that start time of ATMC soft starter is about 15s which is 5s less than auto-transformer soft starter. Therefore, the auto-transformer and magnetic control soft start method can effectively reduce the starting current, eliminate the secondary impact, have fast response speed and starting performance is smooth and stable. In addition, more detailed analysis and experimental studies will be analyzed in the full paper.

I. INTRODUCTION Power electronic devices have been widely applied such as in consumer devices and electrical vehicles, and improvement of their efficiency is strongly required. One of the main factors of energy loss in the devices is the magnetic core loss in inductors and transformers. Therefore, simulation technology that realizes accurate energy loss estimation based on magnetic characteristics of the materials has been highly demanded. For this reason, we have been developing large-scale magnetic field simulation technology by combining micromagnetic models and the finite element method (FEM) [1]. One the other hand, structural design optimization for devices with complicated shapes requires huge man-hours, and it is difficult to judge whether the designed shape is sufficiently optimized. Genetic algorithm (GA) is widely used in various optimal design problems for its excellent global search capabilities. However, GA generally requires large numbers of simulations, and it takes a long time to search the optimal solution. To solve this problem, neural networks (NN) are applied as surrogate models instead of physics models to reduce computing time in some previous work [2]. In this work, we perform shape parameter optimization of an EI-shaped inductor using GA and NN surrogate models designed from magnetic simulation results. Magnetic loss and volume of the cores are chosen to be objective functions. Few previous works have been reported on optimization studies with magnetic core loss as an objective function [3]. Here we solve multi-objective optimization problems, and Pareto optimal fronts for various inductance values are obtained. We also show that experiment that employs one of the optimal design parameters presents good agreement within 10% with the simulation results. II. METHOD Fig. 1 shows a structure of the EI-shaped ferrite core. In general, larger inductance value can be realized by expanding the cross-sectional area of a magnetic flux flow under the condition of fixed external dimensions. However, it also causes increase in magnetic loss and volume (mass) of the core. Therefore, in this work, magnetic loss and volume are set as objective functions under constraints of various inductance values (lower limit) as well as external dimensions and minimum coil winding space. In magnetic simulation, we employed the FEM that includes the dielectric effect at grain boundaries in ferrite material to take account of the size effect at high frequency [4]. For magnetic hysteresis modeling, we adopted the play model [5] and fitted parameters of the model by using experimental results of B-H curves of a Mn-Zn ferrite toroidal core measured at a low frequency (10 kHz). The average magnetic flux density in the center pole of the E-shaped core was set to be 200 mT at the driving frequency of 100 kHz. For multi-objective optimization search, we employed SPEA2 (Strength Pareto Evolutionary Algorithm-II) combining with NN surrogate models designed using magnetic simulation results. To design the surrogate models of inductance and magnetic loss, one thousand magnetic simulation data with randomly generated six shape parameters were used. The number of the intermediate layer and its size was set to 1 and 10, respectively. As a result of the NN design for both inductance and magnetic loss, we obtained the coefficient of determinations R^2 of more than 0.999 between magnetic simulation results and NN outputs. Volume of the core is calculated from shaped parameters. III. RESULTS Fig.2 shows the results of multi-objective optimization for minimum magnetic loss and volume of the core. For optimization settings, number of population and generations are both set to 50, while crossover rate and mutation rate are set to 0.7 and 0.3. In addition, lower limit of inductance value L_{LC} is set to 41, 43, 45, 47 and 49 μH. The black plots and the red plots show Pareto optimal fronts obtained by the NN surrogate models and the magnetic simulation, respectively. One optimal search takes about 0.1 hours by the NN surrogate models, while it needs 83 hours by the magnetic simulation. As can be seen from the figure, the Pareto optimal fronts are obtained for each L_{LC} by the NN surrogate models. When L_{LC} becomes smaller, the Pareto optimal fronts become wider and the degrees of freedom in the design for minimizing both magnetic loss and volume become larger. It is also confirmed that the Pareto optimal fronts obtained from the NN surrogate models and the magnetic simulation at L_{LC} = 49 μH are reasonably similar. We conducted experiment in one condition of the Pareto optimal fronts at L_{LC} = 49 μH to verify the simulation results. As a result, the inductances evaluated from the experiment and the simulation are 48.6 μH and 48.8 μH (+0.4%), respectively, and the losses evaluated from the experiment and the simulation are 3.68 W and 3.34 W (-9.2%), respectively. These results show good agreement, and we also found that the error in the loss is reduced by using finer mesh in the FEM model of core. In further simulation studies with more shape parameters, we found that the reduction of the volume while keeping the loss can be achieved by cutting off the four external corners, where magnetic flux density significantly decreases compared to the main magnetic flux paths.

1. Introduction In recent years, the conditioning of cortical excitability has attracted attention as a valuable function to the recovery of motor function after stroke. Motor cortical excitability can be altered by transcranial magnetic stimulation (TMS), and by peripheral stimulation [1-3]. This study focused attention on the effects of peripheral stimulation on cortical excitability because TMS is not provided for all patients. Many studies of peripheral stimulation have not focused on the inhibition of cortical excitability. This study investigated the possibility that peripheral stimulation has an adjustment effect of motor cortical excitability, by examining the inhibition of cortical excitability induced by peripheral stimulation. This study used magnetic stimulation as peripheral stimulation, because the eddy currents induced by magnetic stimulation stimulate deeper tissue regions. 2. Methods A total of 26 healthy participants (right-handedness) were enrolled. The experimental paradigm was divided into three phases. In the first phase, TMS (0.1 Hz, 105% of each participant's resting motor threshold) was delivered to the left or right primary motor cortex to evoke motor evoked potential (MEP) from the contralateral first dorsal interosseous muscle. The measured MEPs in this phase were used to evaluate the effect of the peripheral stimulation as a baseline. In the second phase, peripheral stimulation (1 Hz magnetic stimulation, 100 pulses) was applied over the contralateral or ipsilateral forearm for the target motor cortex, immediately after the first phase. Finally, in the third phase, TMS was performed according to the same set up as in the first phase, and MEPs induced by TMS were also recorded. The effects of peripheral stimulation on motor cortical excitability were evaluated by comparing the mean MEP amplitudes recorded in the first phase and third phase. 3. Results Fig. 1 shows the normalized average MEP amplitude. Because there were individual differences in the MEP amplitudes induced by TMS, we performed normalization using each control condition (before peripheral stimulation). For the contralateral forearm for the left motor cortex, the average MEP amplitude after peripheral stimulation was significantly decreased compared with the average MEP amplitude before peripheral stimulation ($n=13$, $p<0001$). In contrast, no significant difference was observed in the contralateral forearm for the right motor cortex ($n=12$, $p=0.3$). The mean decrease in average MEP amplitude was approximately 65 %. For the ipsilateral forearm for left and right motor cortex, the average MEP amplitude after peripheral stimulation was significantly increased compared with the average MEP amplitude before peripheral stimulation (for the left motor cortex: $n=15$, $p<0.01$, for the right motor cortex: $n=11$, $p<0.05$). The mean increases in average MEP amplitude were approximately 142 % (left motor cortex) and 154 % (right motor cortex). 4. Discussion Previous TMS studies have reported that the inhibition of motor cortical excitability elicited by suprathreshold repetitive TMS may be based on afferent feedback activation related to peripheral muscle twitch induced by TMS [4,5]. This study provided magnetic stimulation of the forearm to induce the inhibition of motor cortical excitability. This study found an alteration in MEP amplitude following peripheral stimulation. Because MEP amplitude is used to evaluate the excitability of the corticospinal tract [6], changes of the MEP amplitude observed in this study may have an influence on motor cortical excitability. In the contralateral forearm for the left motor cortex, a decrease in MEP amplitude was observed after peripheral stimulation. This result suggests that the inhibition of cortical excitability of the left motor cortex was induced via peripheral stimulation over the contralateral forearm. A previous rTMS study incorporating functional magnetic resonance imaging (fMRI) suggested that the afferent feedback from muscle movements induced by supra-threshold rTMS may represent the dominant input to the motor system via the primary motor cortex [7]. Thus, we expected that the afferent feedback due to muscle twitch such as suprathreshold rTMS caused inhibition of cortex excitability due to the peripheral stimulation. In contrast, in the contralateral forearm for the right motor cortex, no significant changes in mean MEP amplitude were observed after peripheral stimulation. In this result, it should be noted that all participants in the current experiment were right-handedness. Right-handed has been associated with distinct anatomical asymmetry of the left hemisphere [8]. Thus, this study speculates that handedness-related cerebral asymmetry may be associated with the differences in cortical excitability observed in this study. Next, in the ipsilateral forearm for each motor cortex, increases in MEP amplitude were observed after peripheral stimulation. This increased MEP amplitude suggests that peripheral stimulation may have affected the facilitation of motor cortical excitability. The stimulation due to peripheral stimulation for the ipsilateral forearm may be caused by excitatory information to the cerebral cortex of the dominant side, and then transmitted to the cerebral cortex of the non-dominant side through the corpus callosum. The results of this study suggested that peripheral stimulation may have an adjustment effect on motor cortical excitability by the change of the stimulation site.

Transcranial Magnetic Stimulation (TMS) is a non-invasive and outpatient treatment for Major Depressive Disorder (MDD)[1]. It has also proven to produce beneficial effects for other neurological and psychiatric disorders including: Parkinson's Disease (PD), Obsessive Compulsive Disorder (OCD), Anxiety, Post-Traumatic Stress Disorder (PTSD) and Schizophrenia [2]–[6]. Recently, researchers have shown interest in investigating the effect of TMS in neurological disorders which have not been explored by utilizing animal studies [7]. Animal studies are required to test the efficacy and safety of the treatments before using the new treatment in human subjects. Furthermore, animal studies can reduce research cost and speed up the development of new TMS treatment procedures. That is why it is important to have flexible and tunable hardware/coil solutions that allow tenability of power, current, and the shape of the signals needed for experimentation. TMS is based on the principal of Faraday's law of induction, in which time-varying magnetic fields are used to induce an electric field in the brain. Substantial research has been published related to the improvement of coil designs, using head models and clinical studies. However, few publications are available on TMS stimulators and even less on TMS stimulators for use on small animals such as rodents and mice. Current commercial TMS stimulators are very expensive and they have limited usage due to the coil's unique geometry and size. Perhaps an important contrasting is that commercial coils are large enough to stimulate the entire body of the small animal, so studies needed to focally stimulate part of the brain are impossible. Hence, in this article a novel design for a small size TMS stimulator has been proposed. TMS stimulator has been designed for the stimulation of small animals, namely mice and other rodents. This new design was created to focally stimulate parts of rodent brain instead of stimulating their whole body when a commercial coil is used. This will provide researchers an opportunity to choose small TMS coils since commercial TMS stimulators do not support small inductive loads [8]. Mice brains are very small in size when compared with human brains that consist of approximately 2 cm^2 surface area, whereas human brains have about 100 times more surface area [9]. This small area allows the distance between the coil and the surface of the brain to be small hence the field needed to stimulate the brain to initiate action potential is about 0.1Tesla [7]. This means the circuit designed has to be capable of handling current more than 300 A. In addition, the proposed design provides additional flexibility, so that the coil can be changed to match the required specification of other coil designs for different locations of stimulation. Figure 1 shows the TMS stimulator and a coil positioned on a mice model.

CP-03. Effects of Pulsed Magnetic Field on the Flowing Red Blood Cells using Microvascular Model.

Y. Jo[1], H. Ahn[1], K. Shin[1] and *H. Lee*[1]
1. Sangji University, Wonju, The Republic of Korea

Introduction:It is known that red blood cells (RBCs) aggregation would significantly impede the blood flow and increase the vascular flow resistance contributing to peripheral vascular diseases. For many years, the use of pulsed magnetic field (PMF) was proposed as an alternative non-invasive medical treatment for influencing human physiology, via inducing electric current in deep tissue with the rapidly changing field of the magnetic impulses. Since various cardiovascular diseases such as hypertension, diabetes and thrombosis are also highly correlated to RBC aggregation, many researches concerning the effects of magnetic field on biological systems, especially, on the blood circulation were done. [1] However, the exact physiological role of disaggregation and mobility of RBCs in the blood microcirculatory network has not been clearly elucidated yet. The aim of the present study was to investigate the effects of PMF on the changes of blood flow in the microvascular model, simulated the human capillary. Since the capillaries represent the major site of oxygen delivery from RBCs to tissues, it is very important to know the velocity of blood flow of RBCs, blood viscosity, and shear rate in microvascular model for the microcirculation system. In addition, it is necessary to explore how the magnetic field affects hemorheology of RBCs. Experimental Method: PDMS(DC-184A/B,Dow Corning) was used for microvascular device model because of its blood compatibility, its transparency, and ease of use. The devices are fabricated with nano wire and mounted on a glass slide by 2 days dried at 25^{o}C. The channel diameter is 10~15 μm. All blood samples were collected by venipuncture in New Zealand white female rabbits, weighing 1.5–1.8 kg and 10 weeks of age, and anticoagulated using EDTA. Our PMF stimulator system consisted of single layered coil of 10 turns with an elliptical shape of 12.0 x 4.5 cm. The maximum intensity is 0.27 T at a transition time of 0.102 ms, with pulse intervals of 1 Hz. Images of blood flow are obtained with video camera attached to the microscope. In order to see the improvement of rouleaux formation of RBCs before and after PMF, erythrocyte sedimentation rate (ESR) was measured. To see how the magnetic field affects the oxygen transport capacity of RBCs, using free radicals, tBHP, oxidative stress was induced in the erythrocyte membrane to observe changes in blood flow. Results and Discussion: Fig.1 shows ESR with time before and after PMF. Preliminary study in our group has showed that PMF improved the rouleaux formation of RBCs with comparison of aggregation morphologies before and after stimulus. [2] The larger the value of ESR, the faster the erythrocyte sedimentation starts and sedimentation speeds up. The value of ESR is small after PMF stimulus, which proved the rouleaux formation of RBCs were improved. Fig.2 shows microscopic observation of flowing RBCs using microvascular model (a) before and (b) after PMF. The velocities of blood cell in microvascular model are 15.5 μm/s and 19.2 μm/s, before and after PMF stimulus, respectively. According to Einstein's theory, large rouleaux formation of RBCs is main factor affecting the viscosity of blood. And the blood viscosity along the flow direction is significantly reduced by the use of high magnetic field of 1 T [3]. Our results have demonstrated that PMF might reduce blood viscosity, and blood flow faster. It was also observed that the blood velocity of erythrocytes exposed to oxidative stress increased from 8.3 μm/s to 12.2 μm/s after PMF. In this study, PMF stimulus is proposed to achieve improvement of RBCs aggregation, increase of blood velocity, and reducing blood viscosity. Since non-Newtonian character of blood play a role in the microcirculation, for expanding our results, we need more experiments in diverse microvascular model in the size of 5 to 100 μm and inlet pressure and injection rate of blood.

Transcranial Magnetic Stimulation (TMS) has been gaining popularity for the treatment of Major Depressive Disorder (MDD) due to its non-invasive, painless and out-patient nature[1]. It also under investigation as a therapeutic tool for treating other psychiatric and neurological disorders such migraines, Schizophrenia, Parkinson's disease, and Post Traumatic Stress Disorder (PTSD). TMS is based on the principal of Faraday's law in which a large amount of current is passed through coils to generate time varying magnetic fields, thus inducing electric fields in the brain. There are several coils commercially available for both clinical and research studies which provide stimulation profiles that are characteristically unique in both stimulation intensity and focality. Understanding how stimulation characteristics differ between coils is important for researchers and clinicians as they attempt to choose a coil whose stimulation profile is best for a specific use case. Differences in coils have been characterized in detail in both spherical models, and in a single heterogeneous head model, but never with a population-based modeling approach [2][3]. It is well known within the TMS community that anatomical variability, including brain-scalp distance, cerebrospinal fluid, and gyral anatomy, exists between individuals and thus contributes to varying stimulation profiles[4–6]. Population-based modeling approaches that utilize many head models, can illustrate the effects of this anatomical variability in order to see group average stimulation characteristics. Here, we use population-based modeling with 50 unique, heterogeneous head models to calculate the induced electric field in TMS from 15 coil designs. The models used in this study were taken from the Population Head Model repository [5], and contain anatomical components for skin, skull, cerebrospinal fluid, grey matter, white matter, cerebellum, and ventricles. Simulations utilizing low-frequency magneto-quasi-static solvers were used in SEMCAD X to calculate the induced electric field from various coil designs. Parameters were calculated in post-processing describing stimulation intensity (both in brain and scalp), spread (both surface and volumetric), and "hot spot" location are used to illustrate similarities and differences between these coils. Figure 1 illustrates four coils positioned on the vertex of a MRI derived head model. In this study, simulations were ranboth over the vertex and dorsolateral prefrontal cortex for all subjects and all coil designs to give perspective from two different locations of stimulation. The results described in this study will serve as a guide for both researchers and clinicians wanting to understand the differences between coils stimulation profiles.

CP-05. Magnetohydrodynamic Approach to Effective Blood-Flow Control Utilizing ELF fields.

H. Nakagawa[1] and M. Ohuchi[1]
1. Department of Electrical and Electronic Engineering, Tokyo Denki University, Adachi-ku, Japan

Abstract To describe the broad potential opportunities in magnetohydrodynamic (MHD) studies for magnetic therapies, we examined the MHD effects of extremely low frequency (ELF) magnetic fields produced by a prototype diverted from an existing alternating magnetic therapy apparatus (AMTA), employing functional near-infrared spectroscopic (fNIRS) analyses. Experimental Five healthy male subjects ranging in age from 33 to 68 (two subjects each in their 30 s and 40 s, and one subject in his 60 s) took part in this experiment. For ELF stimulations to the subjects, we used a prototype equipped with two additional coils for twisting the ELF field of a commercial AMTA (NIKKEN, Biobeam 21). The flux-density (B_{eff}) distribution from the AMTA is shown in Fig. 1. The maximum density was revealed as 60 mT at each center of the internal iron core. We were able to obtain the B_{eff} of 60 mT on the coil surface, under a constant current of 0.34 A. Then the field frequencies of all the coils were fixed at 50 Hz, and the sinusoidal waveform signals from the additional coils were synchronized in phase in accordance with the axis of a part of the human body. All measurements on fNIRS (Hitach HOT121B) were carried out while the subjects were sitting on a chair in a quiet room at a temperature of 23°C and humidity of 50%. Discussion Our experimental results showed the fact that the proper twisted ELF fields induced from the prototyped machine were able to control the autonomic nervous system, depending on the field strength. We therefore estimated that the mechanism of blood-flow accelerations induced by ELF stimulations is due to a little temperature increase generated by an induced eddy current, and the following joule-heat gradient of the current. Consequently, the blood flow is probably accelerated in the process of human bioactivity via the autonomic nervous system [1–4], in order to reduce the induced fever and/or the heat gradient. On the other hand, there were no significant differences across the two mounting positions (Fig. 2A and 2B) in the behaviors of arterial/venous blood flows. It is quite probable that the arterial blood flows (Fig. 2A) could not generate an eddy current necessary for activations of the autonomic nervous system, although the flows grasping as a pulsating flow might induce an electromagnetic induction phenomenon in a fluid. We firmly believe that MHD effects for a virtual magnetic therapy are induced by moderately swept turbulence in the blood.

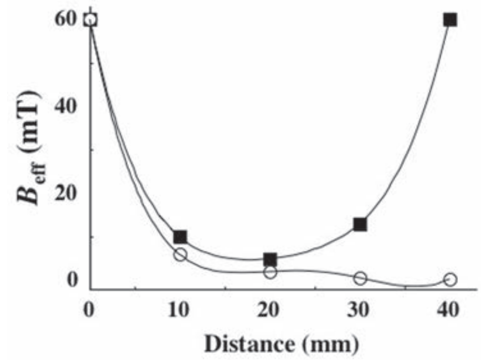

Fig. 1. Magnetic flux distributions from internal coil cores in Biobeam 21. The flux density (B_{eff}) was measured every 10 mm vertically (○) and horizontally (■) from the center of the coil surface. The maximum density was revealed to be 60 mT at each center of the iron cores. The densities at the horizontal points were measured within the space between the two internal cores (40 mm).

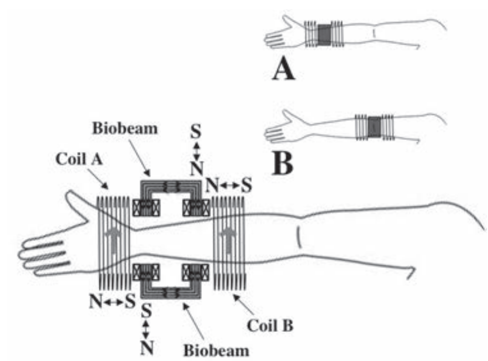

Fig. 2. Arrangements of additional coils and AMTA. Two additional coils were equipped at both ends of the Biobeam. The field frequencies of both the coils were fixed at 50 Hz out of phase along the axis of each subject's forearm.

CP-06. High Focality Stimulation on Primary Auditory Cortex.

Transcranial magnetic stimulation (TMS) is a non-invasive neuromodulation method that can be used to depolarize cortical neurons. TMS is used as a therapy for many neurological disorders, in fact TMS treatment has already been FDA approved to treat major depressive disorder. This is achieved by applying high current pulses through TMS coils to produce sufficiently high electric fields across the neuronal membrane. Even though the manifestation of auditory hallucinations are complex, there is evidence that the Primary Auditory Cortex plays a role as studies by Shi et. al.1 As the Primary Auditory Cortex is relatively small, the need for a coil that can stimulate small regions of the brain without stimulating neighboring regions is an apparent need for many researchers. The induced electric field depends on the coil geometry, which can be modified to suit specific applications. For example, two coils with very different geometry, the Figure-of-Eight (FOE) and the H-coil, while both FDA approved do not provide focused stimulation however, there is another coil design that claims to provide higher focused stimulation than the FOE. The Quadruple Butterfly coil (QBC) introduced by Rastogi et al. showed that there was improvement in focality over the dorsolateral prefrontal cortex in 50 head models.2 In the current work the authors have compared the volume stimulated (defined as the total volume of grey and white matter with at least half the maximum electric field calculated in the brain) by both the FOE and the QBC in 15 healthy head models and 15 Schizophrenic head models. The healthy models were created from MRI scans of healthy patients, while the Schizophrenic models were fabricated from the scans of Schizophrenic patients obtained from the SchizConnect database. Each model consists of 7 distinct anatomic structures: the skin, skull, Cerebrospinal fluid, grey matter, white matter, cerebellum, and ventricles. Simulations were performed using Sim4Life, a finite element tool used for the calculation of induced electric fields on GM.3 Electrical conductivities for each anatomical layer of the models were assigned based on Lee et al.4 In the computer modeling, the coils were placed 5mm from the scalp as shown in Fig 1, this displacement accounts for the insulation thickness around the coils. Additionally, the current in the QBC was scaled down relative to the FOE so that the maximum induced electric field on the cortex of each model were nearly identical. The results have shown that the QBC coil has 35 percent less stimulation volume than the FOE coil on average for the same induced electric field on the surface of the cortex. On each model the QBC proved to have lower volume of stimulation than the FOE. These results can be seen in Fig 2 for 15 models. Even with the reduced stimulation volume the QBC maintains the same depth of penetration as the FOE coil.

Transcranial Magnetic Stimulation, TMS, has been gaining considerable traction as a viable therapy for many neurological disorders. TMS utilizes a large capacitance that is charged to a high voltage to be discharged into a coil that is held on the scalp. The resulting magnetic field induces electrical current in the brain greater in magnitude to the currents produced chemically. In practice the level of voltage applied to the coils is derived on a per-patient basis using Resting Motor Potential, RMT. The RMT is defined as the minimum dose required to evoke at least 50 microvolt MEP's, motor evoked potentials by stimulation over the motor cortex. This is measured using electromyography on the muscle group stimulated. Once the RMT is established this voltage level is used in all areas of the brain under the assumption that the excitability of neurons elsewhere in the brain is similar to that of the motor cortex. For example, in Mehta et al.1 RMT was established as described above to investigate Mirror neuron activity of Schizophrenic patients in the inferior frontal gyrus, IFG, and related areas. In this study the authors have received T1 weighted MRI scans from over 50 schizophrenic patients who have received TMS stimulation over their IFG as well as the RMT's used during stimulation. Using the MRI scans, head models were created of the patients consisting of 7 distinct anatomical structures. These include: the skin, skull, Cerebrospinal fluid, grey matter, white matter, cerebellum, and ventricles. Simulations were performed using Sim4Life, a finite element tool used for the calculation of induced electric fields in the brain.2 Electrical conductivities for each anatomical layer of the models were assigned based on Lee et al.3 In the computer modeling, the coils were placed 5mm from the scalp as shown in Fig 1, this displacement accounts for the insulation thickness around the coils. To measure the excitability of cortical neurons the authors have used Sim4Life to calculate the maximum induced electric field in the brain, and the volume of stimulation on the IFG. Where the volume of stimulation is defined as the volume of the brain with induced electric field above half the maximum induced electric field in the brain as seen in Fig 2. If RMT is indeed proportional to the excitability of neurons in all areas of the brain, the value of the maximum induced electric field should be proportional to the RMT. The authors have found that a higher maximum electric field was calculated in models with correspondingly low RMT's. This is as expected due to the fact that a lower RMT is directly related to higher excitability of cortical neurons. The authors plan to further solidify this conclusion by running simulations on a total of 50 anatomically accurate MRI derived heterogeneous head models.

CP-08. Simulation study of Magnetic Response of Magnetic Nanoparticles for different temperature under different selection gradient field.

J. Zhu[1], X. Lu[1], S. Wei[1], Z. Wang[1] and W. Yang[1]
1. School Electronic, Electrical and Communication Engineering, University of Chinese Academy of Sciences, Beijing, China

INTRODUCTION In the past ten years, magnetic particles (MNP) have been developed into functional materials of therapeutic platform for integrated diagnosis of disease diagnosis, targeted drug delivery and magnetic thermal therapy [1, 2]. The thermal effect of MNP under alternating electromagnetic field can be widely used in targeted magnetic thermal therapy [3, 4]. Quantitatively obtain of the distribution of the magnetic nanoparticales temperature is one of the current challenges of magnetic nanoparticles based cancer hyperthermia. Besides, the current commonly used invasive methods, such as infrared optical fiber temperature measurement, not only cause damage to the tissue, but also difficult to obtain the temperature distribution of the lesions. In 2009, John B.Weaver and his partners offered a direct method for temperature measurement based on MNP [5].They found that the magnetic response of MNP has monotonic linear relationship with temperature and therefore it can detect the temperature of MNP itself. However, this method has limitations in obtaining the temperature distribution. In 2016, Christian Stehning and his partners presented a simultaneous imaging and temperature mapping method using a 'multi-color' reconstruction approach by applying a field free point (FFP) selection [6]. However, it is still unclear how the implied gradient field for FFP will impacts the temperature detection. In this study, we proposed to simulate the MNP magnetic response of the 3rd and 5th order harmonics under different temperatures in the presence of an applied gradient field. METHOD In this study, according to the Langevin function, the non-linear response of one dimensional MNP solution was simulated according to Equ (1). $M(t)=\int\Phi(x)*(\pi/6)*M_s*D^3*L(\pi/(6kT)*Ms*D^3*H(x,t))\,dx$ (1) Where $\Phi(x)$ is the distribution of the MNP concentration distribution and D is the diameter of the MNP.Ms is the saturation magnetization of the magnetic nanoparticles. H(x,t) is the applied selection and drive field.k is the Boltzmann constant and T is the temperature(K). L is the the Langevin function. The radius of magnetic nanoparticle is 20nm. The selection field is an infinite one-dimensional gradient magnetic field, and the field-free point (FFP) is the center point of the solution. The gradient of selection field is taken at 0T/m, 1T/m, 2T/m and 3T/ m. The drive field amplitude is 20 mT and the frequency is 25 khz. To show the relationship of the gradient and the harmonics, the Fourier transform was implied to obtain the first 10 harmonics. To study the relationship between the the gradient and temperature, the peak of each harmonic was detected by finding local max of the data and then the peak of the 3rd and 5th harmonic was subdivided to obtain a ratio for temperature detection. RESULTS AND DISCUSS As shown in Fig 1, we found that even order response exists when adding background selection gradient field, and the harmonics are lower than those with no gradient field. Considering the 3rd and 5th order harmonics, they all decreased when gradient increased. Furthermore, we studied the ratio of 3rd and 5th order harmonics with different temperatures by adding gradient field. It is shown in Fig 2 that this ratio has linear relationship when the gradient of selection field is 2T/ m. This linear relationship offer the basis for the feasibility of temperature distribution detection. The basic theory of magnetic particles imaging mention that by adding gradient field the magnetization response produced by magnetic nanoparticles under the alternating current electromagnetic field only reflects the information of magnetic nanoparticles in unsaturated space. It implies gradient field helps to spatial localization, which offers the possibilty of detection for temperature distribution. Meanwhile the slope of the line is deeper when adding 2T/m gradient field compared with that with no gradient field. So we can deduce that an additional selection field can further increase the sensitivity of temperature measurement. In the future studies, more detailed theoretical studies will be implied for better understanding the mechanism and the detecting system will be setup and experiments will be carried out for the validation of the simulation results. CONCLUSION In this study, aimed for a better understanding for the temperature distribution detection of the magnetic particles for hyperthermia, based on the Langevin function, a simulation study for the relationship of temperature and implied gradient field for field selection was studied. The results show that increased selection gradient strength will improve the detection sensitivity of the temperature detection of the MNPs. ACKNOWLEDGMENT This work was supported by the NSFC 51607169.

CP-09. Gradient/ELF magnetic Field Affects Metamorphic Behaviors in T_4-Administrated Axolotls: Regulation of Amphibian Metamorphosis Depending on Field Strength and Exposure Timing.

H. Nakagawa[1] and M. Ohuchi[1]
1. Department of Electrical and Electronic Engineering, Tokyo Denki University, Adachi-ku, Japan

Introduction Juvenile axolotls (*Ambystoma mexicanum*) can be readily metamorphosed to mature salamanders by a function of thyroxine (T_4) [1]–[5]; therefore, the experimental applications utilizing axolotls must be favorable for a direct examination with respect to aquatic-terrestrial transformations. But, there are almost no previous studies of the observations of axolotl metamorphosis under exposure to magnetic fields. The purpose of this study is to investigate the influences of a gradient or an extremely low frequency (ELF) magnetic field on the T_4-inducing forced metamorphosis of axolotls. Materials and Methods Thirty-six axolotls (about 120 mm) were bred under the same condition as group feeding. Before performing this experiment, all the axolotls were individually kept in 0.85-L square boxes containing dechlorinated water (0.7 L) without aeration under an illumination of 250 $mEm^{-2}s^{-1}$ on a 12 : 12 h L : D photocycle. The water temperature was also strictly controlled at 24°C, employing an original water-renewing system equipped with siphonage (siphon effect) and temperature controls (Fig. 2). After the adaptation of the axolotls to our experimental environment at least a week, they were kept in 0.32–0.80 mM T_4 and were exposed to a gradient magnetic field of 250 mT or an ELF magnetic field of 5.0 mT at 10 Hz. The gradient/ELF exposure was continued up to the morphological completions of all the T_4-administrated axolotls. The axolotls had become accustomed to being given food rotating of a solid / a tubifex worm. The morphological changes of the axolotls influenced by the presence of the T_4 were monitored every day, and the changes were evaluated minutely based on the reported method [1]. Discussion To begin with, we will discuss the influences of an ELF field of 5.0 mT at 10 Hz on axolotl metamorphosis, from the viewpoints of a metamorphic rapidity and a morphological change. The earliest completion of axolotl metamorphosis in a control experiment was observed at Day 13, and the remaining axolotls completed their metamorphoses by Day 17. However, none of the metamorphoses were completed by Day 14 under exposure to the ELF field. Moreover, there were morphological delays of up to 26% compared with a control. Concerning the timeframe of the morphological changes in the axolotls under our experimental conditions, we detected no particular change in connection with the ELF field. On the other hand, we found that the initiation timings of gradient-field exposure did affect the survival rates of the salamanded axolotls. Our data greatly support the idea that gradient/ELF exposures might modify axolotl metamorphosis minutely, depending on the exposure timing, the field strength, and the frequency, and so on.

CP-10. Reaserch on Influence of the Electric Vehicle on Body During the Wireless Charging Process.

S. Jiang[1]
1. Tianjin Polytechnic University, Tianjin, China

I. INTRODUCTION In recent years, the development of electric vehicles (EV) is becoming more and more rapid, but the current charging method of plug-in has the disadvantages of time consuming, unsafe, the interface that is not unified and so on. Therefore, a new energy supply mode-wireless power charging is proposed[1.2]. The advantages of wireless charging are high space utilization, high security, more convenient, stronger user experience compared to the plug-in charging. As the research hotspot of the new charging mode of EV, wireless charging has attracted more and more attention and research at home and abroad. For the development of EV charging, the effect of charging on life safety is the most important factor. The safety influence to the carrying life is also more important, but it is still in its infancy in our current research. Hunter H.Wu et al[3] designed a 5kW inductive wireless charging device for EV. The experiment was used to measure the magnetic induction intensity of 4 different positions at the man of 1.5 meters high. The result accorded with the ICNIRP electromagnetic safety standard. Omer C et al[4] measure the magnetic induction of the floor, seat, and head occipital positions when the transmitted and received coils are position offset. The measurement results conform to ICNIRP. The research of this topic not only provides a theoretical foundation for the safety analysis of the EV's wireless charging life, but also conducive to the future application development and promotion. In this study, the actual EV model, the adult model and the coils model are built. Under the condition of transmission frequency and output power of 85kHz and 15.2kW respectively, the magnetic induction intensity and electric field intensity of the human body in different positions are obtained. An experimental prototype of EV wireless charging and a measurement method for electromagnetic exposure on EV are set up to confirm the reliability of the simulation results. Finally the electromagnetic safety evaluation of EV charging system is carried out from the perspective of molecular biology. II. SIMULATION ANALYSIS The structure of the EV wireless charging system is to install the transmitter on the ground or underground, and the receiver is installed on the chassis of the car. When the EV needs charging, the transmitter and the receiver need to put the correct position. The electrical energy through the primary coil (TX) is transmitted to the secondary coil(RX), which realizes non-contact power transmission. At present, resonant coupling mode is applied in the EV charging. so the system can work normally when TX and RX are in a certain degree of dislocation, which improves the flexibility of the power supply. In order to reduce the leakage inductance, the volt ampere capacity of the system, and improve the system performance, Series- Series compensation is generally applied to the structure. The model of wireless charging system of EV is built by using finite element simulation software. The charging frequency, output power and distance between TX and RX are 85kHz,15.2kW,20cm respectively. The magnetic induction intensity and electric field intensity distribution sectional graph of the coils can be obtained. According to the same method, the contour that meets the international electromagnetic safety limit can be obtained by making sections in the two diagonal space of the charging device, as shown in Fig.1. The magnetic induction intensity of the green line represents the safety value of 27μT. Outside green area, space magnetic induction is less than 27μT, according to ICNIRP electromagnetic safety limit. The value of magnetic induction intensity and the electric field intensity are calculated and analyzed on the different positions at the top of the charging device center. The results show the magnetic induction intensity in some regions is not satisfied with the safety limit, and electric field intensity in all regions is satisfied, as shown in Fig.2. III. EXPERIMENT AND DISCUSSION A prototype of the EV wireless charging device is built, including power supply, transmitter, receiver, rectifier receiver and load. A three-dimensional electromagnetic radiation analyzer is used to measure the setting points. The measured values of the experiment are in close agreement with the simulated values. The experiment results verify the correctness of the simulation. A total of 12 healthy mice divided into the control group and the experimental group are selected in the experiment. The control group is placed in a thermostat at 37 degrees without magnetic field radiation. The experimental group is placed in the location below the long edge of the wireless charging device. It is exposed to electromagnetic radiation for 30 days, and 2 hours every day. Other experimental conditions remain unchanged. Results the changes of blood routine and blood biochemical indexes of mice are observed. The statistical analysis software of SPSS is used to make a significant analysis of the above data. The experimental results show the $P>0.05$ of each index. There is no significant difference in biochemical index between the control group and the experimental group in the wireless charging space. According to the analysis of the experimental data, it can be considered that the electromagnetic field of the EV in this paper is not harmful to the body.

Elaborate materials and systems found in living organisms provide a basis for generating biomimetic technologies in newly developing industries. Among these, micro crystals discovered in body surfaces and eyes of various aquatic organisms have been found to possess unprecedented optical functions [1]-[3] with potential application in biocompatible micro electro-mechanical systems (MEMS) and biomedical diagnosis and treatment. We previously investigated the remarkable camouflaging ability of the marine copepod *Sapphirina*, whose body produces various colors enabling it to vanish into the background. This brilliant coloring appears to be controlled by the structural arrangement of regular hexagonal guanine crystals and cytoplasm alternately situated beneath the dorsal cuticle [4]-[8]. We also investigated the iridescent eyes of the scallop, which are situated on the mantle tissue. We surmised that a multilayer guanine crystal structure in these eyes plays an important role in gathering and amplifying external light [9]-[11]. Guanine crystals are a type of biogenic photonic crystal with very high refractive index (n = 1.83) [12], [13]. Although the crystals themselves are colorless, they emanate iridescent colors whose value is determined mainly by the quantity of light transmitted, reflected and/or optically disrupted, factors which can be attributed to the thickness of the crystal, or, in the case of *Sapphirina*, the cytoplasm [8]. Therefore *Sapphirina* and the scallop may serve as reasonable models for further investigating biological optical coloring and light gathering properties. Extending our investigations to include the behavior of guanine crystals derived from various other marine animals, we found that fish-derived guanine crystals (dozens of micrometers in size) suspended in water have a highly-functional magnetic response, aligning themselves along the direction of the magnetic field [14]-[19]. By further examining the relationship between different crystalline structure arrangements and optical coloring, we hope to clarify the mechanism of brilliant colorization in animal camouflage utilizing natural light. In the present study we investigated the optical and magnetic properties of guanine crystals obtained from *Sapphirina* and the scallop. Guanine crystal suspensions enclosed within a cuvette were fixed between two opposing electromagnets and illuminated by halogen light. Guanine crystal behavior, with and without application of the magnetic field, was observed from directly above with a real-time, charge-coupled device (CCD) microscope and high-resolution spectrophotometer. Electron microscopy showed the distinctive honeycomb-like guanine crystals from *Sapphirina* to be overlapped or scattered. Scallop suspensions, on the other hand, were found to contain a majority of micron/submicron angular and spherical shaped crystal granules. Reflection intensity of both types of guanine crystals increased when exposed to a 0.5T magnetic field, and remained so throughout exposure. When the magnetic field was turned off again, reflection intensity returned to its original state. These changes were seen to occur instantaneously. Although in a previous study we mentioned that no such responses were observed with guanine crystals from *Sapphirina* [20], in the present study we increased the guanine crystal concentration of *Sapphirina* and enclosed suspensions in a thicker vessel. Although the shape of the crystals from these two species were different, magnetic response and light reflection switching properties were the same, and corresponded to those previously observed with the larger fish-derived guanine crystals. *Sapphirina* crystals in particular displayed a sort of flickering structural color. This was most noticeable when ultrasonic cleaning was performed before centrifugation. But cleaning also tended to reduce the intensity of structural color and the amount of reflected light. Time-series spectroscopic analysis quantitatively confirmed the CCD microscope results. This paper also describes the diamagnetic rotational energy of guanine crystals under magnetic exposure. In conclusion, guanine micro crystals were seen to enhance light reflection upon exposure to a magnetic field, a response that was not dependent on size or shape. Biogenic microcrystals seem to be new candidate optical materials, and should lead to new insights into various optical MEMS and biomedical applications, such as a convectional tracer for micro fluidic circuits, a highly sensitive optical biosensor for bacterial detection combining a light-gathering element, as well as stem cell manipulations for traumatic bone regeneration utilizing the diamagnetic rotational properties of guanine crystals. CP-12. Numerical investigation of biconical transcranial magnetic stimulation coil.

Y. Wu[1] and *Z. Liu*[1]
1. School of Materials Science and Engineering, South China University of Technology, Guangzhou, China

Transcranial magnetic stimulation, also known as TMS, is rapidly developed as a no-invasive, non-painful and safe tool for studying the physiology of human brain and brain therapy [1,2]. TMS is based on the principle of electro-magnetic induction of an electric field in the brain, which is of sufficient magnitude and density to depolarize neurons. Depending on the parameters of stimulation, TMS pulses can decrease or increase the cortical excitability even beyond the duration of the train of stimulation, and this produces behavioral consequences and prospect therapeutic potential [2-4]. Since electric field induced is an important parameter in stimulation process, this work investigates the 3-dimensional electric field distribution in human brain using the finite element method. Fig 1 shows the cross section of two-layer human head model and the investigated biconical TMS coils. The human head is modeled with harnpan and tissue fluid, and TMS coils consisted of two separated cones. The model is located in a solution region, in which the solution is generated and the mesh is refined, with proper boundary condition applied to determine the unique solution of the electromagnetic field. The magnitude of the induced electric field in the head is used for evaluating the stimulation effect. By investigating the influences of the distance between two cones, included angle, current frequency and the location of the coils, the optimized TMS coil sep-up for deep stimulation and good stimulation accuracy has been obtained. Fig 1. TMS model of biconical coil model Simulation result shows that high current frequency is beneficial for effectively deep stimulation, with 0.2V/m as threshold for effective electric field. Since the distribution of electric field is determined by the projection of TMS coil on the human head, decreasing the distance between two cones of biconical TMS coil can increase the magnitude of electric field along the symmetric axis, which is directing to the human head. The higher electric field means that the deeper tissue in the human head can be stimulated, as shown in Fig 2 a). Electric field in tissue fluid is decaying in an exponential form, which leads to a slightly improved stimulation depth by decreasing the distance between two cones. On the other hand, the decreasing the distance can also stimulate the human brain with a shaper peak of the magnitude of electric field, as shown in Fig 2 b) shows, which gives a better stimulation accuracy. The included angle between two cones has also been investigated, and the smaller angle generally leads to the larger electric field induced along the symmetric axis directing to the human head. In addition, to get good stimulation, TMS coil should be as close to the head as possible in the desired stimulation region. Fig 2. Influences of distance between coils on the magnitude of electric field on the distribution of the magnitude of electric field along symmetric axis directing to human head (a) and distribution of the magnitude of electric field in tissue fluid parallel to the connection of the center of the two cones (b).

Abstract: Sleep disorders, particularly insomnia, affect a great percentage of the population. Electroacupuncture (EA) and transcutaneous electric stimulation (TES) have been introduced into clinical practice to treat insomnia. Magnetic stimulation has more advantages than electric stimulation. In this paper, magnetic stimulation was used to stimulate acupuncture points (acupoints), 32-channel electroencephalography (EEG) signals were recorded before and after stimulation. Brain functional networks were constructed based on EEG data to determine whether magnetic stimulation at acupoints could treat insomnia or not. The results suggested that magnetic stimulation at acupoints might be an effective treatment for insomnia. Keywords: magnetic stimulation, brain network, acupuncture point, insomnia I.Introduction Magnetic stimulation has the advantage of being less painful and uncomfortable than electric stimulation, and it is possible to convey impulses toward the deep tissues without attenuation of the stimulus intensity [1]. And now, transcranical magnetic stimulation (TMS) offers promising non-invasive, surgery-free medical treatment of neurological ailments [2]. Peripheral magnetic stimulation has been gradually developed [3]. II.Materials And Methods Eighteen right-handed (9 insomnia, 9 healthy) subjects were chosen, with consent obtained before the study. Magnetic stimulation was used to stimulate PC6 (Neiguan), HT7 (Shenmen) and SP6(Sanyinjiao) acupoints, respectively. Frequency of stimulation was 1Hz. Intensity of stimulation was 80% of the maximal (2.2 T). Each insomnia subject was stimulated 6 minutes each time for 3 days. 32-channel EEG signals were recorded before and after magnetic stimulation. Brain functional networks at different stages were constructed and analyzed to explore the effects of magnetic stimulation at acupoints. III.Results Compared to healthy subjects, insomnia subjects' brain functional connections between frontal and other lobes decreased, and the efficiency of brain information transmission were reduced. For insomnia subjects, after magnetic stimulation at acupoints, the connections and the information transmission efficiency of corresponding brain regions were improved, as shown in Fig.1 and Fig. 2. IV.Discussion For insomnia subjects, after magnetic stimulation at acupoints, the correlation between different cerebral cortex regions was strengthened in contrast with that of before stimulation. The results indicated that after magnetic stimulation at acupoints, the synchronization of each relevant cortex functional regions was increased. Temporal synchronization of cerebral electrical activity plays an important role in brain function [4]. It suggested that magnetic stimulation at acupoints might be an effective treatment for insomnia. Transcranial Magnetic Stimulation (TMS) is a neuromodulation technique which is capable of non-invasively activating the neurons in the brain. TMS has been an approved method of treatment for major depressive disorders by the US Food and Drug Administration (FDA) since 2008. The major principle in TMS is electromagnetic induction. The time-varying magnetic field generated by the TMS stimulator induces an electric field in conductive brain tissues which activates neurons by depolarization. However, limited studies have reported the effects of the magnetic fields used in TMS on individual neurons and in cell cultures, especially on neuronal cells grown in a three-dimensional extracellular matrix (3D ECM). The main function of a 3D ECM is to provide the biochemical and structural support to the surrounding cells that is found in vivo. The protein collagen is the major component of the ECM that plays an important role in giving cells strength and structural integrity. Hyaluronon is a polysaccharide found in the ECM of all vertebrates. It is known to provide support and protection to the cells within the ECM. Poly-D-Lysine (PDL) is a positively charged amino acid polymer used to help cells bind to substrates such as glass and plastic. Based on these theories, we investigated the effects of magnetic fields generated by a monophasic TMS stimulator using a 90 mm circular coil on the N27 rat dopaminergic neuronal cell line grown on two-dimensional (2D) and in three-dimensional (3D) ECMs. In our experiments, collagen-coated functionalized glass cover slips and PDL coated cover slips were used as 2D ECM for cell growth. Images of both, stimulated group and non-stimulated group, were captured at five time points from the stimulation time (0 hour) to 72 hours. Cells were counted, averaged and plotted. The results of our experiments showed that the magnetic stimulation decreased the growth rate of the N27 cells in comparison to the non-stimulated control group. However, it was observed that the collagen coating helped the cells to be more resistant to this negative effect caused by magnetic stimulation. We concluded that the magnetic stimulation used in our study decreased the proliferation of N27 dopaminergic neuronal cells and that collagen plays a role in protecting the cells from adverse effects of strong magnetic fields. Experiments currently underway are studying the effects that magnetic fields have on N27 cells within 3D ECM of collagen and 3D ECM of collagen/hyaluronon.

Department of Neurosurgery, Virginia Commonwealth University Health System, Richmond, VA, United States

Patients of Parkinson's Disease (PD) suffer from debilitating symptoms and complications, including bradykinesia, resting tremor, shuffling gait, and rigidity as well as non-motor symptoms including speech and swallowing difficulties. [1] [2] [3] PD patients often receive deep brain stimulation (DBS) surgery, in which one or two electrical leads are inserted into the subthalamic nucleus (STN) or globus pallidus internus (GPi), and current is continuously delivered to these nuclei from a battery pack inserted into a chest pocket.[4] [5] [6] DBS has been shown to effectively eliminate motor symptoms in patients of both PD as well as Essential Tremor. [4] [5] [7] However, one of the more crippling symptoms of PD that is not treated by DBS is hypophonic speech and swallowing difficulty (dysphagia). The mouth motor area of the primary motor cortex is thought to play a role in the pathophysiology of these symptoms and manipulation of this cortex through repetitive Transcranial Magnetic Stimulation (rTMS) has been proposed as a treatment option. [2] [8] [9] [10] [11] [12] rTMS is a non-invasive neuromodulation therapy which utilizes time-varying magnetic fields to induce electric fields in the patient's brain, thus stimulating neurons in the targeted region. [13] [14] [15] However, the potential for electromagnetic interference from the magnetic fields of rTMS with the conductive leads of DBS has prevented serious consideration of the combination therapy. Primarily, there is concern regarding eddy currents, which are induced on conductive surfaces caused by time-varying magnetic fields. It is hypothesized that B-fields from rTMS may induce such currents on the surface of any conductive part of the lead, and this current would travel along the lead down to the contacts, in turn stimulating the deep brain nuclei which the contacts target. We posit that this issue has yet to be studied with proper models and parameters. The objective of this study is to calculate induced current and temperature increase from TMS in DBS leads that have been implanted in the patient's brain. We have developed a novel, highly complex DBS lead in SolidWorks, using parameters from commercially available Medtronic lead 3387. It is composed of the insulating sleeve, four independent wires with wire insulation, and 4 contacts at the lead tip. Additionally, we use newly-developed head models created using MRI images of real patients, downloaded from the online database ADNI PPMI. These models include separate geometries for grey matter, white matter, cerebrospinal fluid, skin, skull, and cerebellum.[16] We perform simulations using the Finite Element Analysis software known as Sim4Life, which has been developed by Zurich Medtech for the purposes of simulating the effects of EM fields on biological tissue. Using simulation results, we calculate voltage values in the DBS lead, as can be seen in Figure 1. Note that in all cases the induced voltage values are on the order of mV, three orders of magnitude below the typical voltage values of DBS stimulation (about 1 V). For this reason, it is clear that our simulations show that for a DBS lead positioned medially in the patient's head, TMS in the mouth area of the primary motor cortex is safe and will not induce a voltage comparable to DBS stimulation. Additionally, thermal simulations were performed for t = > 30 min, with TMS being in the "on" state from t = 20 min to t = 50 min. The initial time of 20 minutes was given for the simulation to bring all tissue to their respective initial conditions, which place various parts of the brain between 37 and 37.3° C. TMS was then switched on, and left on for 30 minutes, until t = 50 min. Cooldown was then observed. The results show that although there is slight increase in temperature in the tissue close to TMS coils (T_{max} = 37.45° C)as well as the DBS lead (T_{max} = 37.3° C), maximum temperature does not exceed 37.45° C in any part of the brain, which is a negligible increase in temperature. Temperature variation over time on the gray matter surface can be seen in Figure 2. Therefore, our simulations suggest that TMS in the presence of DBS leads is safe, both in terms of electromagnetic interference as well as temperature increase. However, experimental verification is required to be certain that TMS/DBS combination therapy will not cause any harm to the patient in a real-world scenario.

I. INTRODUCTION Mutations in the K-Ras gene are more common in primary lung adenocarcinoma than others. The effects of chemotherapy and radiation therapy to K-Ras mutation lung cancer are not ideal. Decades of research have proved that there are significant differences in electrical characteristics between cancer cells and normal cells. According to this phenomenon, the positive effect of electromagnetic stimulation on cancer treatment is receiving increasing attention [1]. The electric field could change the direction of dipoles within the target cells and lead to tumor cell apoptosis [2]. Clinical trials lead to Food and Drug Administration approval for the Tumor treating field treatment of recurrent glioblastoma. However, the electric field could not penetrate into biological tissues very deeply due to the various of impedance. Because of the disadvantages of the electric field, the biological effect of magnetic field stimulation is receiving increasing attention. For a similar relative permeability, the magnetic field can easily reach the position deep inside the tissue, avoiding the problems that were caused by an electric field. Previous studies have shown that the extremely low-frequency magnetic field significantly inhibited cell growth and induced apoptosis of prostate cancer cells in vitro [3]. Based on the A549 lung tumor cell experiment that was carried out in our preceding study, the initial frequency for tumor suppression was also studied [4]. Although the principle has not been fully discovered, magnetic field stimulation suggests a new way of tumor inhibition. In this research, a variable magnetic field stimulation system and a pair of stimulation coil were designed to find the inhibition effect of magnetic field stimulation on K-Ras-driven lung cancer in mice. The magnetic field distribution was calculated by the finite element method. The biological experiments were carried out to verify the inhibition of cell growth. The western blotting result showed that the magnetic stimulation inhibited the K-Ras-driven lung cancer cells noninvasively. II. SIMULATIONS AND MAGNETIC STIMULATION SYSTEM During the experiments, as shown in Fig. 1(a), stimulation coils were set on both sides of the holder. Mice holder can provide a dark environment at the end of the other side; the mouse keeps calm and peace during the magnetic stimulation. Based on the sensitive frequency and the intensity of the A549 cell line, the stimulation coil is designed by FEM calculation. The stimulation coil can be regarded as many single-turn coils of different radius. The magnetic flux density generated by the single-turn coil current can be determined by Biot-Savart's law. In the animal experiment, the RMS voltage of the stimulation coil is 30V. According to the previous study on the magnetic flux density calculation, the maximum magnetic flux density at the position of the lung in mice is 2.2 mT by programming. The visual simulations were carried out in Fig.1 (b). As shown in Fig. 1(a) and (c), the system consisted of a signal generator and a pair of stimulation coils. The signal generator was composed of a microchip, a keyboard, and an H-type circuit. The frequency of the magnetic stimulation could be changed easily by changing the value of the timer on the microchip. The stimulus intensity could also be adjusted by regulating the voltage of the H-type circuit. III. EXPERIMENTS AND RESULTS Experiments: All the tumors in mice were activated by using adenovirus-based delivery of Cre recombinase into lung epithelial cells. After four weeks, mice with tumors were ready for magnetic stimulation. The selected 20 mice were divided into the stimulation group and control group. Stimulation group is given 2 hours' magnetic field stimulation every day and none of the control group. Results: Nuclear factor erythroid-2 related factor-2 (Nrf2) is a redox-sensitive transcription factor that confers cytoprotection against oxidative stress and apoptosis in normal cells [5]. After two weeks, the dimension of tumor in stimulation group is 13.7% lower than that of the control group. As shown in Fig. 2, the Nrf2 gene was suppressed in lung tumor cells, and measured by western blotting. Therefore, the growth of K-Ras-driven lung cancer has been slowed down. IV. CONCLUSION In this paper, a magnetic stimulation system with stimulation coil for K-Ras-driven lung cancer in mice was proposed. The principle of magnetic stimulation on cancer cells is analyzed. The parameters of stimulation coils were calculated and optimized for animal experiments. The magnetic flux density at lung of mice was simulated by numerical calculation and the finite elements method. The biological experiments were conducted by two week's stimulation. The animal experiment results showed that the expression of Nrf2 had been suppressed. This approach could also suggest another way to treat cancer noninvasively.

CQ-01. Measurement of tilted magnetic anisotropy of quasi-perpendicularly magnetized Ta/Pt/CoFeB/Pt multilayers.

S. Guddeti[1] and P. Kumar[1]
1. Department of Physics, Indian Institute of Science, Bangalore, India

In the field of ultra thin film magnetism, the study of domain wall dynamics in perpendicularly magnetized systems has garnered significant attention. These offer improved functionalities like lower energy consumption for data storage technologies than current TMR based MRAM and possible three dimensional storage [1]. In such systems where the magnetization reversal is mediated by the Spin Hall effect, the chirality of the domain wall becomes critical [2,3,4]. However, due to the stochastic nature of nucleation, domain wall of either chirality is equally likely. An external biasing magnetic field is required to deterministic generation of domain wall of particular chirality leading to deterministic reversal. Recent studies on quasi-perpendicularly magnetized Pt/Co/Pt trilayers with tilted anisotropy have shown it is possible for deterministic reversal thereby eliminating the need for a biasing field [5]. In the present paper, we have studied tilted magnetic anisotropy in quasi perpendicularly magnetized Ta/Pt/CoFeB/Pt system using vibrating sample magnetometry (VSM). We also performed Magneto-Optic Kerr Effect (MOKE) microscopy to study the effect of the tilt in the anisotropy on the domain wall motion mediated reversal. Ta/Pt/CoFeB/Pt is well known perpendicularly magnetized system [6]. A tilt in the anisotropy can be obtained with a thickness gradient in CoFeB layer. We have grown quasi-perpendicularly magnetized Ta/Pt/CoFeB/Pt multilayer films on SiO_2 substrate using oblique-angle sputter deposition technique. We perform detailed investigations on two sets of multilayer thin films of Ta(3 nm)Pt(3 nm)CoFeB(x nm)Pt(1 nm) corresponding to with and without thickness gradient in CoFeB layer. In order to have uniform thickness of the layers, the substrate is rotated in-situ using stepper motor. Polar-MOKE measurements indicate perpendiculary magnetized films for x varying from 0.6 nm to 1.5 nm. There is no ferromagnetic hysteresis at room temperature for films below thickness 0.6 nm of CoFeB layer. Above 1.5 nm thickness of CoFeB layer, films show in-plane anisotropy. High field in-plane and low field out-of-plane M-H measurements are performed to calculate the anisotropy constant 8.93 x 10^5 J/m^3 for Ta(3 nm)Pt(3 nm)CoFeB(0.7 nm)Pt(1 nm) thin film. For the set of samples with thickness gradient in CoFeB layer, we calculate the tilt in anisotropy in quasi-perpendicularly magnetized films using Kerr microscopy by applying an additional biasing in-plane field H_x. Component of H_x along the tilted anisotropy axis acts as a bias field, $H_{tilt} = H_x \sin(\theta)$, where θ is the tilt angle. H_{tilt} contributes to shift in the hysteresis loop observed in Kerr microscopy. The shift in hysteresis loop is shown in Fig 1. The effect of tilt is captured by the slope of shift(H_{tilt}) vs in plane field (H_x) as shown in Figure 1. The effect of the tilt can be maximised by rotating the sample in-plane such that the in-plane component of the tilt axis lies along the direction of in-plane field. Figure 2 gives the variation of slope with azimuthal orientation for Ta(3 nm)Pt(3 nm)CoFeB(0.6 nm)Pt(1 nm) sample, from which the tilt is estimated to be 0.7°. To capture the effect of tilt on domain wall motion, Ta(3 nm)Pt(3 nm)CoFeB(0.6 nm)Pt(1 nm) thin film is patterned into a wire of width 10 um with an extended pad for domain wall nucleation as shown in Figure 2. The devices are patterned using optical lithography and ion beam etching. After patterning the switching fields are increased due to possible degradation of sample during etching. Preliminary current induced reversal measurements using a pulsed current density of 5.9 x 10^{11} A/m^2 of 100 μs pulse width indicate partial switching of the wire as shown in Figure 2. Due to the limitation of applying out-of-plane fields not higher than 150 Oe in the in-house instrumentation, the device is partially reversed. In conclusion, we report estimation of tilt in anisotropy of quasi-perpendicularly magnetized Ta(3 nm)Pt(3 nm)CoFeB(x nm)Pt(1 nm) thin films and preliminary measurements of current induced domain wall dynamics.

Domain wall based devices such as racetrack memory have been proposed as promising candidates for high capacity, non-volatile information storage [1,2]. In these devices, multiple domain walls can be propagated through nanowires at speeds of many hundreds m/s using spin transfer torque, thus allowing data to be written, read and processed. One of the main challenges towards the commercial realization for domain wall memory is the stochasticity of domain wall motion. In thin film systems, where domain wall motion is the dominant reversal mechanism, the magnetization reversal does not happen in a controlled fashion but instead forms zig-zag domains extending over several micrometers in length to form. Such stochastic behavior limits the maximum data density. To overcome this issue, researchers have used lithographically fabricated notches to act as domain wall pinning centers [3]. The other method to form pinning centers is based on exchange bias [4]. In our previous study, we proposed the use of non-magnetic metal diffusion or ions implanted locally to control and pin domains in nanowires [5]. In this report, we demonstrate the formation of pinning centers by using exchange interaction between films with perpendicular magnetic anisotropy and in-plane magnetization to create locally tilted magnetization. The perpendicular magnetic anisotropy (PMA) material Ta (1)/ Pt (5)/[Co (0.3)/ Ni (0.4)]$_3$ (all thickness values are in nm) multilayers were deposited on Si (SiO_2) substrate and the in-plane magnetic (IMA) anisotropy material $Co_{10}Ni_{90}$ (2.5 nm) alloy was grown on top of the PMA layer. The thickness of a Pt spacer layer between the PMA layer and IMA layer was varied to tune the angle of magnetization. Figure 1 (a) shows film stack studied in this report. The hysteresis loops of films with various Pt spacer layer thickness in the in-plane direction and out-of-plane direction are shown in (b) and (c) respectively. At Pt layer thickness below 2 nm, the switching behavior of the PMA and IMA layer suggests the presence of exchange interaction between the layers. While a thicker Pt layer of 5 nm causes the switching behavior to be independent of each other and thus increasing the coercivity [6]. Mumax3 simulation was performed to study the domain wall pinning effect and depinning current with various tilt angles. Figure 2 (a) shows the domain wall propagation without pinning. Figure 2 (b) shows domain wall propagation with a pinning center, where the magnetization is tilted at 5 degrees from the perpendicular axis. The result shows that the domain wall is pinned at the edge of the pinning center. Our results further indicate that the magnetization tilt angle can be increased to decrease the barrier energy, which reduces the depinning current as demonstrated in figure 2 (c).

CQ-03. Role of Effective Anisotropy in Temperature Gradient-induced Skyrmion Motion.

X. Wang[1], W. Gan[2], T. Jin[2] and W. Lew[2]
1. School of Science, Lanzhou University of Technology, Lanzhou, China; 2. School of Physical and Mathematical Sciences, Nanyang Technological University, Singapore, Singapore

Skyrmions are promising candidates for information storage applications due to its small size and high thermal stability. While current-induced skyrmion motion has been the focus of many scientific efforts,[1] we show that skyrmion motion induced by thermal gradient is also significant. Several works have already shown that the skyrmion moves towards the hotter region and its speed is proportional to the temperature gradient. However, most existing theories cannot explain the phenomena completely,[2] such as the strong dependence of velocity on skyrmion size. In this work, we propose an intuitive yet comprehensive explanation: the thermal gradient creates a gradient in effective perpendicular magnetic anisotropy, leading to an inhomogeneous energy landscape that creates a driving force. Fig. 1(a) shows that the effective anisotropy field (H_K) and saturation magnetization (M_s) of skyrmion system decrease with the increase of temperature. As effective perpendicular magnetic anisotropy $K_{u,eff}=\mu_0 M_s H_K$, the increase of temperature causes the decrease anisotropy. The energy attributed to the K_u is given by: [3] $E_{Ku}=-K_u(m\bullet z)^2\pi R_{sk}^2 d$ (1) where d is the thickness of skyrmion system, R_{sk} is the radius of skyrmion. These indicate that the increase of temperature leads to the decrease of energy in skyrmion system, which means the total energy of a skyrmion is lower at high temperatures and the skyrmion will drift towards a region of higher temperature to minimize energy. Considering the inhomogeneous energy landscape caused by temperature gradient as a force acting on skyrmion, larger temperature gradient leads to higher average speed of skyrmion motion, which can be verified by Fig.1 (b). Estimating the anisotropy gradient caused by temperature gradient, we demonstrate the anisotropy gradient-induced skyrmion motion, which shows the same trend with temperature gradient-induced, as shown in Fig.1 (b). Furthermore, it was observed that the speed of the skyrmion increases slightly with its size. This phenomenon cannot be explained by the magnon current model developed by previous studies.[2] As we discussed above, positive temperature gradient leads to the decrease of magnetic anisotropy, the domain wall width is expected to increase, leading to a bigger skyrmion during the motion. To verify the effect of skyrmion size, in-plane and out-of-plane magnetic fields were applied. As shown in Fig. 2(a), the size of skyrmion change as a function of the external magnetic field applied in the direction of magnetic moment in the skyrmion center (z-axis), and there is no obvious impact of in-plane field on skyrmion size. The skyrmion velocity indeed changes proportionally to the skyrmion radius, shown in Fig. 2(b). This is consistent with our model, in which a larger skyrmion experiences larger inhomogeneous energy, leading to the increase in skyrmion velocity. In conclusion, we have developed a robust model describing the skyrmion motion in a temperature gradient. Such an understanding is critical for the design of skyrmion devices where pulsed currents are expected to generate temperature gradients.

(b) Average velocity of skyrmion motion as a function of temperature gradient/ magnetic anisotropy gradient, showing the dependence of skyrmion motion.

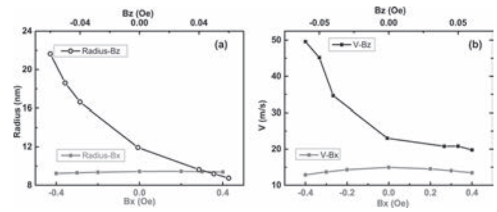

Fig. 2. (a) The change of skyrmion radius with respect to B_x/B_z. (b) The in-plane field (B_x) and out-of-plane field (B_z) as a function of velocity under $dK_u/dx=8\times10^{11}J/m^4$. indicating that the velocity of skyrmion motion corresponds to its size, which is determined by the effective anisotropy energy.

CQ-04. Multilevel Storage Based on Magnetic Skyrmion.

S. Luo[1] and L. You[1]
1. School of Optical and Electronic Information, Huazhong University of Science & Technology, Wuhan, China

Magnetic tunnel junction (MTJ) is the storage element of spin-transfer torque magnetic random access memory (STT-MRAM), consisting of two ferromagnetic (FM) layers separated by a tunneling layer. Generally, with the magnetization direction of two FM layers parallel or antiparallel, the MTJ exhibits two resistances R_p or R_{ap} due to the tunneling magnetoresistance (TMR) effect. The improvement on the TMR as well as the distinction between R_p and R_{ap} offers the possibility to divide the resistance of MTJ into multiple levels, so as to explore multilevel storage technology that is an efficient method to enhance the integration density of STT-MRAM [1,2]. Furthermore, magnetic skyrmion is also considered as the storage unit in new magnetic memory devices, which is an essentially topological spin texture with whirling configuration generated at the FM/heavy metal (HM) bilayer with Dzyaloshinskii–Moriya interaction (DMI) effect. From a practical application point of view, building MTJ stacks to locally address skyrmions is of great promise for future skyrmion based devices [3]. In this work, initialization-free multilevel storage can be implemented based on MTJ structure with an extended free layer (Fig. 1a), and is demonstrated by micromagnetic simulation. We find four resistance states of such a MTJ structure that are distinguished by changing the magnetization configurations with the coexistence of magnetic switching and skyrmion creation/annihilation by applying a current via spin-transfer torque (STT) effect. Comparing with conventional MTJ, the generation of skyrmion in free layer gives rise to another two resistance states except for R_p and R_{ap}, thanks to the non-linear configuration of skyrmion and this topological-phase-like transition. As expected, there exist four states in studied MTJ structures (Fig. 1b-e), according to the magnetization of two FM layers, namely, parallel (P), antiparallel (AP), quasi-parallel (Quasi-P) and quasi-antiparallel (Quasi-AP) states, the latter two denoted as the core of skyrmion is either in parallel or antiparallel with the fixed layer. We calculate the relative resistance R/R_p of the four states dependence on the ratio between the lateral diameter of MTJ stack (d_{MTJ}) and the diameter of skyrmion (d_{sk}). The results indicate that it is optimal to set $d_{MTJ}/d_{sk} \sim 1.2$, where the difference between any two resistance states is larger than 0.2 R_p to distinguish the four states as much as possible. The initialization-free operation of four states are obtained. P can be realized by a negative current with density of J_1 and duration of Δt_1 (Fig. 2a) while AP realized by a positive current of the same density and duration (Fig. 2b). Quasi-AP and Quasi-P can be realized by creating a skyrmion based on P and AP, respectively, with another current pulse of J_2 and Δt_2 (Figs. 2c-d). We find that the required current densities J_1 and J_2, of the order of $\sim 10^8$-10^9 A/cm^2 (Fig. 2e), are relatively large, mainly because of the mismatch between the fixed layer and free layer in dimension and the topological energy barrier for skyrmion creation. The delays Δt_1 and Δt_2, of the order of $\sim 10^1$-10^2 ps (Fig. 2f), are rather small, which is favorable for high-speed spintronics. The results presented in this work provide a completely new strategy for multilevel storage based on magnetic skyrmion that could not only lead to multi-functional applications but also provide novel insight into topological magnetism.

2. Department of Mathematics and Applied Mathematics, University of Crete, Heraklion, Greece; 3. Department of Electric, Electronic and Computer Engineering, University of Catania, Catania, Italy; 4. Department of Electrical and Information Engineering, Politecnico di Bari, Bari, Italy;
5. Department of Mathematical and Computer Sciences, Physical Sciences and Earth Sciences, University of Messina, Messina, Italy

Magnetic skyrmions are localized non-uniform configurations of the magnetization with a unique fundamental feature to be topologically protected, i.e. they are characterized by an integer winding number Q[1]. According to the type of Dzyaloshinskii-Moriya interaction (DMI) and the material properties, different skyrmion patterns can be stabilized, such as Bloch and Néel[1] as well as antiskyrmions[2]. In this work, we will focus on Néel skyrmions, which are the most promising for applications. In fact, on the technological side, the possibility to electrically manipulate skyrmions[3–6] by means of spin-polarized currents, opens the way for many promising applications as information carriers in low-power microelectronic technologies[4,7]. To this aim, the analysis of the current-driven skyrmion motion becomes crucial. In particular, this motion is characterized by an in-plane angle with respect to the direction of the applied current, i.e. the skyrmion Hall angle. In an ideal system, micromagnetic simulations and the theoretical approach based on Thiele's equation[5,8] predict a constant skyrmion Hall angle independent of the value of the applied current. On the contrary, recent experimental observations[6] have shown that the presence of a perpendicular anisotropy linear gradient can strongly affect the spin-Hall effect (SHE)-driven skyrmion motion, and hence the skyrmion Hall angle, which cannot be predicted theoretically by the current form of Thiele's equation[5,8]. Here, we have combined micromagnetic simulations with an analytical model based on Thiele's formalism to investigate, from a fundamental point of view, the SHE-driven skyrmion motion in presence of a new force arising from a perpendicular anisotropy linear gradient. We have observed two key dynamics: (*i*) the presence of only the gradient leads the skyrmion to mainly move in the direction perpendicular to the gradient itself; (*ii*) the simultaneous action of gradient and SHE yields a skyrmion expansion while it moves, consequently leading to an accelerated motion. We consider a ferromagnet in a square geometry with side lengths L_x=L_y=400 nm and a thickness t_{FM}=1 nm (Fig. 1). This is coupled to a heavy metal layer (Pt) in order to achieve a sufficiently large interfacial DMI. Statics and dynamics of the magnetization are modeled by the Landau-Lifshitz equation where we add a Gilbert damping term and a Slonczewski term that models the spin-torque effect deriving from the SHE. We consider a current j_{HM} flowing along the *x*-axis and a spin polarization in the *y*-axis. We study the dynamical behavior of the skyrmion where a constant anisotropy gradient exists along the-direction (Fig. 1). Hence, the anisotropy coefficient K can be written as K=K_u+Gy, where K_u is the perpendicular anisotorpy constant at the center of the sample. In order to study this dynamical behavior, we assume a rigid skyrmion configuration that travels with a constant velocity v=(v_x,v_y). We also apply an out-of-plane field H_{ext}=50 mT. Figs. 2(a) and (b) show the effect of only the perpendicular anisotropy linear gradient G on the skyrmion motion. Both velocity components increase with the gradient. However, the skyrmion is characterized by a larger positive v_x and a very small negative v_y. The latter is due to a torque linked to the damping term. Heuristically, the skyrmion motion induced by the anisotropy gradient can be understood as follows. The presence of the anisotropy gradient gives rise to two different values of the effective field for the upper and lower in-plane magnetization of the skyrmion domain wall, where the magnetization is mainly oriented along the *y*-direction, thus generating two different conservative torques acting on the skyrmion (see inset in Fig. 2(a)). These torques do not balance each other leading to a resulting torque along the *x*-direction which induces the skyrmion motion. The larger is the skyrmion and/or the larger is the gradient, the faster is the motion. Moreover, the key result concerns the effect of the *y*-component of the velocity. The presence of the negative v_y leads the skyrmion to move towards a region with lower K_u, thus inducing its expansion[7,9]. For what explained above, a larger skyrmion undergoes a larger gradient, and hence, the torque from the gradient increases while the skyrmion moves along the negative *y*-direction. This induces an accelerated motion of the skyrmion. In order to describe correctly such a motion within the analytical framework, the Thiele's equation has to take into account a variable skyrmion diameter. This key analytical advance becomes more important when the skyrmion motion is driven by the SHE in presence of G, due to a larger expansion of the skyrmion. Figs. 2(c) and (d) show the velocity components as a function of the local K_u value linked to the linear gradient, for j_{HM}=10 MA/cm^2 and G=0.5 TJ/m^4. Analytics and micromagnetics agree well in predicting an increase of the velocity with the decrease of the K_u, and, therefore, in describining the accelarated motion of the skyrmion.

CQ-06. Spectroscopic Evaluation of Non-Adiabatic Spin Transfer Torque Using Coupled Oscillation of Magnetic Vortices.

T. Horaguchi[1], T. Tanazawa[1] and Y. Nozaki[1,2]
1. Department of Physics, Keio University, Yokohama, Japan; 2. Center for Spintronics Research Network, Keio University, Yokohama, Japan

We demonstrated a reliable evaluation of a non-adiabatic spin-transfer torque coefficient β by an electrical detection of coupled oscillation of magnetic vortices in NiFe gourd-shaped thin film. The value of β was evaluated to be which was 9.3 times larger than the Gilbert damping constant α. It is noted that our method is not affected by a spin polarization of driving current and can exclude the contribution of magnetic torque owing to the magnetic field produced by the current. Spin polarized current in a ferromagnetic metal can transfer a spin angular momentum to the local magnetization via s-d exchange interaction. The consequent torque on magnetization is called as spin-transfer torque (STT). It has been suggested that there are two processes in the transfer mechanism; i.e. adiabatic and non-adiabatic processes. Non-adiabatic contribution which is generally scaled by β is important to understand the STT related phenomena. For example, it determines a velocity of domain wall [1] and an amplification ratio of spin waves [2]. The non-adiabatic STT is considered to depend on both the value of α and a spatial gradient of magnetization [3]. However, the previously reported values of β are widely scattered because it is difficult to exclude the magnetic torque owing to the magnetic field produced by the current. Thus, we need more reliable method to measure β precisely. In this study, the value of β is evaluated by analyzing spectra of translational mode in coupled magnetic vortices which is causes by not only spin transfer torque but also the Oersted field torque. In the coupled oscillation of vortices, the eigenfrequencies of translational modes owing to STT and Oersted field torque are totally different. In general, a coupled oscillation has two classes of oscillation, i.e. a center-of-mass and relative motions. Moreover, when a magnetic vortex is confined in an ellipsoidal disk of ferromagnet, a restoring force acting on the vortex core depends on the oscillation direction. As a consequence, there are four resonant modes with different eigen frequencies in the coupled oscillation. Hata et al. analytically calculated that not only the relative orientation of core magnetization (p_1=p_2 or -p_2) but also the applied directions of electrical current (u_x or u_y) and Oersted field (h_x or h_y) determined which mode was excited in the coupled magnetic vortices [4]. The spectrum of coupled oscillation is, therefore, suitable to evaluate a non-adiabatic STT coefficient β which is generally difficult to be distinguished from the Oersted field contribution. Figure 1 shows our experimental setup where a self-homodyne technique is used to measure a spectrum of coupled oscillation of magnetic vortices in a NiFe gourd-shaped thin film. The self-homodyne measurement of the STT-induced translational mode in a magnetic vortex is a powerful tool to evaluate the value of β. The rectified voltage V_{det} is in proportion to the complex amplitude of coupled oscillation via anisotropic magnetoresistance (AMR) effect. An alternating current produced by a radio-frequency signal synthesizer was applied to the NiFe gourd-shaped thin film. A direct current (dc) rectified voltage between electrodes was measured via dc port of bias-tee while the external alternating current was applied to the longitudinal direction of the gourd-shaped thin film. At that time, the Oersted field according to the Ampere's law was simultaneously generated. Figure 2 shows a rectified voltage as a function of frequency of alternating current applied to the gourd-shaped thin film. As indicated by arrows in Fig. 2(a) and 2(b), we observed two different spectra consisting of 1 and 2 resonant peaks which are associated with the translational modes for p_1=p_2 and p_1=-p_2, respectively. From the analytical calculation, we found that the rectified voltage spectra consist of the sum of Lorentzian and anti-Lorentzian (dispersion) functions, $A_L f_L(f)$ and $A_{AL} f_{AL}(f)$, and the value of β can be evaluated from the relative amplitude of A_L/A_{AL}. The evaluated value of β is 0.14±0.02 (9.3α) which is comparable to the previous β evaluated from a direct tracing of single vortex core motions. The ratio between β and α is also consistent with the previous study [5]. The similarity in β suggests that the spatial gradient of core magnetization is significant to determine the magnitude of β.

Magnetic domain-wall (DW) motion has been attracted a great attention due to its promising application toward the next-generation magnetic memory/logic devices [1,2]. For a better performance of these DW-based devices, achievement of fast DW speed is of necessity. For this purpose, various studies have been conducted using various materials and structure engineering [3-5]. Here, we report the ferromagnetic-layer-thickness dependence of the DW speed in ultra-thin non-magnet/ferromagnet/non-magnet multilayer films. For this study, 5.0-nm Ta/2.5-nm Pt/-nm Co/1.5-nm TiO_2/2.0-nm Pt films were fabricated on a Si/100-nm SiO_2 substrate using dc and ac magnetron sputtering, where the Co layer thickness t_{Co} varied from 0.65 to 1.00 nm with a 0.05-nm increment. The TiO_2 layer was formed by Ti-layer deposition, followed by oxidation under 3.3-Torr O_2 pressure for 1 h. All films exhibited strong perpendicular magnetic anisotropy and clear DW motion under the application of a magnetic field. The DW speed v_{DW} was then measured by use of magneto-optical Kerr effect microscope equipped with an electromagnet. Figure 1 shows the creep-scaling plots of v_{DW} as a function of $H^{-1/4}$ for films with different t_{Co}'s, as denoted in the plot. All curves showed typical creep-scaling behavior with linear dependence in the present scaled axes. The plot also shows the existence of an overall tendency between t_{Co} and v_{DW}; thinner t_{Co} exhibits faster v_{DW}. It is worthwhile to note that v_{DW} varies even more than 10^5 times depending on v_{DW}, as indicated by the vertical arrow. To investigate the origin of this significant variation of the DW speed with respect to t_{Co}, variation of creep scaling constant α with respect to t_{Co} was investigated, which was determined by the slope of creep curves (Figure 1). Interestingly, as shown by Figure 2, α exhibited clear linear dependence on t_{Co}. This linear dependence was then finally demonstrated by the creep theory, which will be discussed in the presentation. We expect that our present observation may provide a guide for an optimal design rule of the ferromagnetic layer thickness for better performance of DW-based spintronics devices.

In modern communications, information is carried by electromagnetic waves whose frequency is limited to ≈0.1 terahertz (THz), the frequency of oscillating circuits based on high-speed transistors [1]. On the other hand, semiconductor lasers generate coherent light with a frequency >30 THz [2]. The terahertz gap refers to the fact that no relevant technology exists in the frequency range between these two limits (0.1–30 THz). Therefore, it is of critical importance to find relevant physical phenomena that fill in the terahertz gap. In this respect, antiferromagnets whose resonance frequencies are in the THz range [3,4] are of interest [5,6]. It has been reported that coherent THz magnons or spin waves are generated in antiferromagnets, driven by a laser [7,8] or an electrical current [9,10]. However, THz spin-wave excitations by a dc magnetic field are in principle not possible for antiferromagnets as their magnetic moments are compensated on an atomic scale. In this presentation, we theoretically show that the generation of coherent THz spin waves can be achieved by field-driven domain wall (DW) motion in ferrimagnet/heavy metal bilayers in which the interfacial Dzyaloshinskii-Moriya interaction (DMI) is present. The DMI is shown to facilitate THz spin-wave emission in a wide range of the net angular momentum by increasing the Walker breakdown field. Moreover, we show that spin-orbit torque combined with the DMI also drives fast ferrimagnetic domain wall motion by emitting terahertz spin waves. Figure 1 shows domain wall velocity V_{DW} with external field H_z. The numerically obtained values (symbols) of V_{DW} are in good agreement with theoretical solutions (solid lines) except for the case of angular momentum compensation temperature T_A. Because net angular momentum is vanished at T_A, Walker breakdown does not occur resulting in linear increase in V_{DW} with H_z. In the high H_z regime at T_A, however, nonlinearity of V_{DW} appears, and it is analogous with relativistic kinematics. The maximum spin wave group velocity $v_{g,max}$ (dashed line) acts as the speed of light and the domain wall width shrinks as V_{DW} approaches $v_{g,max}$ via Lorentz contraction. Moreover, domain wall emits terahertz range spin wave to dissipate the raised domain wall energy. Red line in Fig. 1 represents the 'relativistically' modified solution. For the cases showing nonlinearity at T_A, we observe spin-wave emission from the DW (Fig. 2). We confirm that the emitted spin-wave frequency is in the THz range. To elaborate the nonlinearity and associated THz spin-wave emission, we derive the spin-wave dispersion for ferrimagnets on top of a uniform ground state as $\omega_{\pm}=\{\pm\delta_s+[\delta_s^2+4\rho(Ak^2+K-h)]^{1/2}\}/2\rho$, where the upper (lower) sign corresponds to the right-handed (left-handed) circular mode. δ_s is the net angular momentum, ρ parametrizes the inertia of the dynamics, A is the exchange energy constant, k is the wave vector, K is the easy-axis anisotropy energy constant, and h represents the Zeeman energy. We note that the DMI does not contribute to spin-wave dispersion as it is effective only for the y component of magnetization, which is negligible for perpendicularly magnetized ferrimagnets. From the dispersion, we obtain the maximum spin-wave group velocity $v_{g,max}=A/ds$, where d is the lattice constant, $s=(s_1+s_2)/2$, and s_i is the spin density for each site i. In conclusion, we have shown field-driven THz spin-wave emission for ferrimagnetic DWs, which is not possible for ferromagnetic or antiferromagnetic DWs. Our finding suggests that ferrimagnetic DWs are potentially useful for high-speed and high-frequency spintronics devices.

CQ-09. Domain wall configurations in amorphous ferromagnetic nanowires with cylindrical symmetry.

C. Rotarescu[1], H. Chiriac[1], N. Lupu[1] and *T.A. Ovari*[1]
1. National Institute of Research and Development for Technical Physics, Iasi, Romania

Long amorphous glass-coated magnetic nanowires with metallic nucleus diameters down to 90 nm have been recently prepared by an enhanced glass-coated melt spinning method [1]. These nanowires with cylindrical symmetry are composite materials, obtained in a single-step fabrication process, in which a ferromagnetic material (the actual nanowire) is embedded in a glass coating. Their main characteristic is a magnetically bistable behavior, i.e. a single step reversal of the axial magnetization when the applied field reaches a threshold value called switching field, and which appears irrespective of the sign and magnitude of the alloy's magnetostriction constant, λ, i.e. in both nearly zero magnetostrictive samples, e.g., $(Co_{0.94}Fe_{0.06})_{72.5}Si_{12.5}B_{15}$ with $\lambda \approx -1 \times 10^{-7}$, considered as $\lambda \approx 0$, and highly magnetostrictive ones, e.g., $Fe_{77.5}Si_{7.5}B_{15}$ with $\lambda = +25 \times 10^{-6}$, considered as $\lambda >> 0$. Here we report on the magnetization process and domain wall configurations in such bistable amorphous nanowires with cylindrical symmetry by taking into account the nonlinear distribution of their intrinsic magnetoelastic anisotropy, K_{me}. We investigated the axial magnetization process through a novel, finite element-based micromagnetic model, in order to describe the magnetization process and associated hysteresis loops in such rapidly solidified ultrathin samples. In this study, we have employed the parallel computing implementation of the MAGPAR finite element micromagnetics package [2]. Figure 1 shows the calculated loops in case of a zero-magnetostrictive sample ($\lambda \approx 0 \Rightarrow K_{me} \approx 0$), as well as for a highly magnetostrictive one ($\lambda >> 0 \Rightarrow K_{me} \neq 0$) in two cases: (i) for a standard anisotropy distribution given by $K_{me}(r) = K_{max} \times \cos[\pi(r/R)]$, in which K_{max} is the maximum anisotropy, r the radial coordinate and R the nanowire radius, and (ii) for a radially shifted anisotropy distribution, $K_{me}(r) = K_{max} \times \cos\{\pi[(r-r_0)/R]\}$, respectively. The radial shift $r_0 = 0.3R$ was included in order to get the shape of the distribution as close as possible to the one expected to emerge from the distribution of internal stresses found in this type of nanowires [3]. These results have been compared to experimentally measured inductive hysteresis loops, showing that the radially shifted anisotropy distribution offers a far more precise description of the magnetic behavior than the standard anisotropy distribution. The proposed model allows one to visualize the configurations of the magnetic moments, which are difficult to see experimentally. Figure 2 shows the distributions of magnetic moments at remanence for the case $K_{me} \approx 0$. One observes that the magnetization at the nanowire end displays an open vortex-like structure. Such a structure minimizes the magnetostatic energy at the nanowire ends and decreases the shape anisotropy. If the external field is increased or further rotated, these structures suffer depinning from the end of the nanowire and subsequently propagate as vortex domain walls. These vortex walls appear spontaneously at room temperature due to demagnetization. Their actual propagation at magnetization switching allows one to consider these ultrathin cylindrical amorphous nanowires as potential nanoconduits for the displacement of domain walls with vortex configurations. This is a key result, given the large domain wall propagation velocities that have been experimentally found in this novel type of nanowires, i.e. well over 1200 m/s [4]. Therefore, it is expected to have a significant impact on the applications of these cylindrical ferromagnetic nanowires, opening up extremely promising opportunities for their use in magnetic logic applications. Utilizing a spin-polarized current to manipulate the magnetization has become the subject of intensive study leading to the development of novel spintronic devices [1–3]. The future domain wall (DW) based spintronic devices rely on the ability to accurately manipulate the position of domain wall which can be controlled by injecting the spin current. In addition, there is a new possibility to represent the data bits by DWs themselves [4]. Therefore, it is necessary for device design to understand underlying interplay between the spin-polarized current and the local magnetization giving rise to the spin-transfer torque (STT) acting on DW. In often-used micromagnetic model, spin torques are generally represented by the coefficients μ and β describing the adiabatic and non-adiabatic torques [5-6]. The adiabatic and non-adiabatic torques are empirical constants which are assumed to be spatial independent and their magnitudes are still a matter of discussion. Recently, these spin torque coefficients can be calculated directly from the spin accumulation [7–8] and the results demonstrated that μ and β are nonuniform throughout the structure due to the fact that they strongly depend on the gradient of magnetisation. Although there are several studies of spin transfer torque but the effect of thermal fluctuation on magnetisation dynamic has not been comprehensively investigated. In previous studies [5-6], the effect of thermal fluctuation is represented by the random fluctuating field taken into account the micromagnetic model. It can be used to represent the thermal fluctuation but the magnitudes of spin torque coefficients are still assumed which may lead to the missing some of relevant physics. In this work, the spin accumulation is suggested to describe the effect of spin transfer torque directly as well as the atomistic model will be used to investigate the magnetisation dynamic which is able to deal with the interface properties instead of using the standard micromagnetic model. We will also investigate the effect of spin transfer torque and thermal fluctuation on DW motion by using atomistic modeling coupled with the spin accumulation model. To investigate the thermally domain wall motion driven by injecting spin current, the generalized spin accumulation model coupled with atomistic model is employed. The magnetization dynamic can be considered by performing the atomistic model via the Landau-Lifshitz-Gilbert (LLG) equation using a transfer matrix approach proposed by P.Chureemart *et.al.* [9] and thermal field is introduced into the LLG equation as the additional field. The bilayer structure with a pinned layer providing a spin-polarized current and a free layer are created with dimensions of 60 nmx 30nm x 1.5nm in order to calculate the spin accumulation and spin torque the system is discretized into macrocells at 1.15 nm x1.15 nmx1.15 nm in size. We first investigate the effect of uniaxial anisotropy on domain wall motion by introducing the current density of 5×10^{11} A/m^2 for athermal case. The anisotropy constant is varied from 6 K_U to 80 K_U where K_U is the uniaxial anisotropy constant based on cobalt, $K_U = 4.644 \times 10^{-24}$ J/atom. As shown in Fig. 1(a), it is found that DW can move easily for higher anisotropy as expected. Next observation is to study the effect of current density, the system with high anisotropy constant of 40K_U is chosen. Increasing current density tends to shift DW easily due to high spin polarized current as demonstrated in Fig. 1(b). In addition, we also observe that the equilibrium time becomes shorter for the case of high current density. Finally, we now consider the effect of thermal fluctuations taken into account the atomistic model on DW translation. The temperature dependence of DW displacement and initial DW velocity of the system with current density of $j_e = 10^{12}$ A/m^2 are investigated as shown in figure 2 (a) and (b) respectively. It interestingly shows that the thermal fluctuation can assist DW motion. The initial DW velocity increases with increasing temperature. At 300K, the DW velocity is up to 900 m/s which is consistent with previous experimental studies. The atomistic model coupled with spin accumulation model is proposed to be a new route to use for DW-based devices design.

CQ-11. Magnetic skyrmion motion in the presence of defect.

I. Hong[1] and K. Lee[1,2]
1. KU-KIST graduate school of converging science and technology, Korea University, Seoul, The Republic of Korea; 2. Department of materials science and engineering, Korea University, Seoul, The Republic of Korea

In the magnetic system, defect can be occurred by impurity or faulty at the process. Study of defect carried out in various ways with magnetic texture, such as domain walls, vortices, and magnetic skyrmions[1]. Among these texture, skyrmion has emerged as a major interest for the reason of topological protection and high speed with low current. In the thin films, magnetic skyrmion stuructures are stabilized by the competition of magnetic energy terms like exchange interaction, Dzyaloshinskii-Moriya interaction(DMI), anisotropy. In the last work, we studied about domain wall motion at the step of DMI[2], which induced a different energy landscape for a domain wall. In the same way, one can expect that the step of DMI or anisotropy change the energy landscape of magnetic skyrmions. We performed the two dimensional micromagnetics simulation with the following parameters: exchange stiffness constant $A=1.3\times10^{-6}$ erg/cm, uniaxial anisotropy constant with z easy axis $K=7\times10^{6}$ erg/cm^3, DMI constant $D=2.5$ erg/cm^2. Skyrmion can be moved by the spin-transfer-torque(STT), which induced by the spin-polarized current. STT is described by the two torques; adiabatic term, $(j\ \nabla)m$, and non-adiabatic term, $\beta m\times(j\ \nabla)m$. First, we studied about point defect of DMI constant and anisotropy. We find that, in both cases, skyrmions scattered with defects and moved to y direction while scattering with defects (see Figure. 1). Both –y and +y direction motion appear while skyrmion pass through the defects. On the other hand, in the plannar defect, large y motion can be arise, but back motion has not generated. We find that the defect causes a skyrmion motion transverse to the external driving force. The transverse for a point defect is consistent with the previously reported skyrmion Hall effect[1]. On the other hand, the transverse motion for a planar defect is found to have a much larger deflection of magnetic skyrmion in addition to the skyrmion Hall effect.

Magnetic skyrmionium [1,2] is novel topological protected state without skyrmion Hall effect (SkHE) [3] in ferromagnets. This state represents a skyrmion surrounded by circular domain wall with opposite topological charge (Q), this structure is elastically coupled due to magnetostatic repulsion. Since the direction of deviation from longitudinal motion due to SkHE depends on a sign of Q. Therefore the topological inhibition of Magnus effect is observed in this composite structure. Skyrmionium moves directly along the nanotrack under the action small current density [4]. These advantage make skyrmionuim useful for application in racetrack memory. Firstly, we need to control the processes of nucleation and annihilation of skyrmoinium, for its application in real racetrack memory devices. In previous works the spin-transfer torque effect was used for this goal [4]. Spin current polarized along z was locally injected perpendicularly to disk plane. However, the experimental implementation of this method is rather problematic, because of the complexity of creating a nanocontact of an annular shape. We propose a novel method of skyrmionium nucleation using the spin-orbit torque (SOT) effect [5,6]. For nucleation of the domain with required shape, for example annular, we offer locally change the magnitude of SOT effect. It can be realized in system ferromagnetic/heavy metal (FM/HM) by addition of HM with opposite Spin hall angle on the second interface (HM_1/FM/HM_2) [7]. Based on the system Pt/Co/Ta investigated in the article [7] we studied trilayer structure with consist of continuous films Pt/Co and nanostructured capping layer Ta (Fig. 1a). Capping layer has nanoring shape with diameter 100 nm and width 25 nm. This nanostructured layer allows enhance local spin current density which will be injected perpendicularly Co film. Taking in account geometry, conductive parameters and local Spin Hall effect engineering the spin current density distribution map was calculated (Fig. 1b). Simulation of the process of the skyrmionium nucleation was carried out for a nanotrack with a size of 1000×400×0.6 nm^3 and the magnetic parameters were chosen according to data in article [7]. Initially ferromagnetic film was saturated along z. Then external magnetic field B_x=0.6 T and 20 ps impulse spin current with distribution accordingly Fig. 1b were applied. Under the action of current and magnetic field the m_z component of the magnetization decreases (Fig 1c), which corresponds to the incline of the magnetization under the influence of a plane magnetic field and the nucleation and growth of a domain under the SOT effect. Since the distribution of the spin current is non-uniform, the density is higher in the region under the nanoring, the nucleated domain also has an annular shape (Fig. 1d). Drag force acting from spin current on domain wall shifts the domain. Therefore the external action is removed (j_s=0 A/m^2 and B_x=0 T) to prevent further growth and displacement of the domain. The self-organization of the magnetization configuration occurs after disabling the external influence. In thin FM layers with high perpendicular magnetic anisotropy (PMA) and positive Dzyaloshinskii-Moriya interaction (DMI), Neel's domain walls with left-handed chirality are stabilized [8]. The stabilized skyrmionium had an asymmetric shape and a large size for these magnetic parameters (Fig. 1d). Therefore, the transition to the equilibrium state takes some time, with a decreasing the size of the skyrmionium, the value of m_z in the considered region increases (Fig. 1c). The complete process of nucleation and stabilization of the skyrmionium for these magnetic parameters is 700 ps. Also we studied static and dynamic properties of skyrmionium in comparison with free skyrmion. The stability regions and the dependences of radii for skyrmion and skyrmiounium on magnetic parameters are presented on Fig. 2a,b. Under the action of perpendicular spin current j_s polarized along y simple skyrmion moves with non-zero velocities V_x and V_y (Fig. 2c). In the case of skyrmion full compensation of Magnus force leads to rectilinear motion along the nanotrack. We found that skyrmionium has higher dissipation efficiency, in comparison with free skyrmion, consequently greater drag force acts on skyrmionium and it moves faster. Support by RFBR (grants 17-52-50060, 15-02-05302, 17-52-45135, 18-02-00205), the state task (3.5178.2017) and the Grant program of the Russian President (MK-2643.2017.2, MK-5021.2018.2) are acknowledged.

Magnetic skyrmions are nanoscale particle-like topological configurations, which have been found in certain magnetic bulks, films and nanowire. The skyrmion is stabilized by delicate competitions among the ferromagnetic exchange coupling, perpendicular magnetic anisotropy (PMA) and Dzyaloshinskii-Moriya interaction (DMI) in magnetic systems.[1-2] In this work, we report the dynamics of a skyrmion in a narrow ferromagnetic nanotrack channel with voltage-controlled perpendicular magnetic anisotropy(VCMA), which can be used to build the skyrmion diode and ratchet memory and avoid from the skymion hall effect.[3] The pinning and depinning of the magnetic skyrmion in the nanotrack through the VCMA gate are investigated. This work will be useful for the design and development of the skyrmion transport channel, which is a building block for any future skyrmion-based information devices. The simulation model is an ultrathin ferromagnetic nanotrack, 1000 nm * 80 nm * 0.4 nm, as shown in Fig. 1a.[4] The model is discretized into tetragonal volume elements with the size of 2 nm * 2 nm * 0.4 nm. The micromagnetic simulations are performed with the Object Oriented MicroMagnetic Framework (OOMMF). The dynamic of magnetization is described by Landau-Lifshitz-Gilbert LLG (LLG) equation. The parameters for the micromagnetic simulation the saturation magnetization M_S = 580 kA/m, the damping coefficient α = 0.3, the DMI constant D = 3 mJ/m^2, and the exchange constant A = 15 pJ/m. For the simulation of the motion of skyrmion, two types of VCMA profile are considered, period wedge-shape and sinusoidal functions, as shown in Figs. 1c and d respectively. The function for the period wedge-shape profile is given as: Ku(x) = $K_{u0} + K_{uv} - K_{u0wx}$ (1) Ku(x) = $K_{u0} + K_{uv} - K_{u0}2(1 + \sin(2\pi x = w - \phi))$ (2) where w is the period length w, ϕ is the phase, and x is the longitudinal coordinate. The period wedge-shape is given in the Eq. 1 and the sinusoidal function is given in the Eq. 2. The linear anisotropy profile and the sinusoidal function profile are given in the Figs. 1b and c. The motion of the magnetic skyrmion in the nanotrack with VCMA driven by the current pulse also be simulated. The initial position the skyrmion is x = 86 nm which is the middle of a voltage gate. Fig. 2 shows the motion of the skyrmion in the nanotrack with a periodical wedge-shaped profile with Kuv = 0.750 MJ/m^3 with the period length w = 50 nm. The current density of the pulse is 20MA = cm^2. The pulse is applied at t = 0.5 ns. For one period of the current pulse, te is the time interval applying the current and tr is the relax time without applying current. tr = 5 ns in the simulations. When te = 1 ns, the skyrmion cannot pass the voltage gate and moves in a circle trajectory as shown in Figs. 3a and b. For te = 2 ns, the trajectory of the skyrmion is shown in Fig. 2c. The time-dependence of the position in the x direction and the current density are shown in Fig. 2d. At t = 14.5 ns, the skyrmion is located at x = 187 nm. After applying the pulse, x = 241 nm at t = 16.5 ns. Then the applied current is off. The skyrmion further relax to x = 236 nm before the next pulse. The displacement of skyrmion is 50 nm after a pulse is applied. For te = 3 ns, Figs. 2e and f, one current pulse results in a displacement of 100 nm. In this work, the skyrmion motion in a ferromagnetic nanotrack with single or multiple VCMA gates is studied. This work shows the trajectory and location of the skyrmion can be controlled by periodically located VCMA gates as well as the driving current pulse. The unidirectional motion of the skyrmion realized by the VCMA effect can be used to build the skyrmion-based one-way information channel and the skyrmion diode. Our results are useful for the design and development of the skyrmion-based spintronic devices.

The magnetic skyrmion is an exotic and versatile topological object in condensed matter physics, which promises novel applications in electronic and spintronic devices [1-2]. Recently, a rich phase diagram of an anisotropic frustrated magnet and properties of frustrated skyrmions with arbitrary vorticity and helicity were investigated [3]. Other remarkable physical properties of skyrmions in the frustrated magnetic system have also been studied theoretically [4-6]. Here, we explore the skyrmion dynamics in a frustrated magnet based on the J_1-J_2-J_3 classical Heisenberg model explicitly by including the dipole-dipole interaction [7]. The skyrmion energy acquires a helicity dependence due to the dipole-dipole interaction, resulting in the current-induced translational motion with a fixed helicity. The lowest-energy states are the degenerate Bloch-type states, which can be used for building the binary memory. By increasing the driving current, the helicity locking-unlocking transition occurs, where the translational motion changes to the rotational motion. Furthermore, we demonstrate that two skyrmions can spontaneously form a bound state. The separation of the bound state forced by a driving current is also studied. In addition, we show the annihilation of a pair of skyrmion and antiskyrmion. Our results reveal the distinctive frustrated skyrmions may enable new applications.

The helicity is flipped by a strong 80-ps-long current pulse and becomes $\eta = \pi/2$. Such a flip does not occur by applying a small current pulse with the same duration. (b) A similar flip occurs also for an antiskyrmion. (c)-(f) Snapshots of the skyrmion during the helicity flip process. (g)-(j) Snapshots of the antiskyrmion during the helicity flip process.

CQ-15. Bidirectional propagation of tilting domain wall due to the interfacial Dzyaloshinskii-Moriya interaction in perpendicularly magnetized T-junction.

J. Kwon[1], H. Hwang[1], J. Hong[1] and C. You[1]
1. Department of Emerging Materials Science, Daegu Gyeongbuk Institute of Science and Technology, Daegu, The Republic of Korea

The use of field-driven magnetic domain wall (DW) in one-dimensional wire is one of the crucial development element for the spin-based logic or memristor devices.[1,2] The presence of interfacial Dzyaloshinskii-Moriya interaction (iDMI) in the inversion symmetry breaking structure induces an asymmetrical DW configuration with respect to the direction of in-plane field.[3,4] The dynamics of field-driven DW motion in perpendicular magnetic anisotropy (PMA) influenced by DW tilt due to iDMI effect, edge defects, and roughness in the T-shaped structure. The dependence of DW configuration and location in a T-shaped junction structure has been investigated with visualizing the DWs configuration and position by utilizing Kerr microscopy technique. Thin film stacks $Si/SiO_2/Ta/Pt/[Co/Pt]_{x4}$ with Ta capping were used for T-shape device fabrication. Images from Kerr microscopy reveal that the iDMI effective field contributes a right-hand tilt of the DW configuration along its propagation direction in Fig. 1(b)-1. Due to the influence of the iDMI and the edge defects in the input line, a DW enables to change its tilt angle responding to the initial types of DW (up-down or down-up DW) respect to its propagation direction. At the junction, due to the initial tilting orientation, the expansion of DW having a crescent profile extends towards B2 output such as elongated DW profile, as shown in Fig. 1(b)-2. A DW configuration in the two-dimensional T-shaped structure changes from right or left-hand tilting DW to dendritic-domain wall at the junction. Then, DW restores the tilting DW configuration due to the iDMI and propagates through branches, B1 and B2. The elongation direction of DW towards branches at the junction can play a significant role that one of DWs in the branches approaches first to the destination pad, as shown in Fig. 1(b)-6. Accordingly, the DMI constant has been estimated by measuring circular DW expansion on the film utilizing Kerr microscopy technique.[5] In addition to, micromagnetic simulation result provides a clue to understand for dynamics of the DW configuration in the structure.

CR-01. Mechanism of spin re-orientation phase transition in $SmCrO_3$.

M. Tripathi[1], T. Chatterji[2], R.J. Choudhary[1], D.M. Phase[1] and H.E. Fischer[2]
1. Thin film magnetization, UGC DAE Consortium for Scientific research, Indore, India; 2. Institut Laue-Langevin, Grenoble, France

Understanding the mechanism of Spin reorientation phase transition (SRPT) plays an important role in designing of ultrafast switching equipment as well as in learning the fundamental aspects of complex magnetic exchange interactions [1,2]. The phenomenon of SRPT in $SmCrO_3$ has been considered as a process comprising continuous rotation of magnetic moments of chromium ions, the belief which is incompetent to explain the intrinsically associated thermal hysteresis and magnetic glassy state below SRPT [3-5]. The presence of highly neutron absorbing natural Sm atoms has prevented to record neutron diffraction patterns and consequently getting a microscopic insight of SRPT so far. In the present work, we have utilized high energy 'hot neutrons' with λ= 0.4997 Å, a value which is much higher than corresponding resonance energy width responsible for high absorption of neutrons, and succeeded to probe the evolution of microscopic spin configuration with temperature. Unambiguously three distinct phases were observed : Γ_4 or G_x A_y F_z configuration where uncompensated magnetic moments lie along c-cyrstallographic axis just below Neel temperature (T_N = 191 K); Γ_1 or A_x G_y C_z fully compensated spin structure below T< 10 K ; and non-equilibrium configuration with co-existing Γ_4 and Γ_1 phases in the vicinity of SRPT (10 K < T < 40 K). The transfer of magnetic scattering intensities associated with $(011)_m$ and $(101)_m$ Bragg's planes is observed in the vicinity of SRPT indicating the reorientation of magnetic moments from b-c to a-c crystallographic plane. In addition, the intensities related to $(010)_m$ and $(100)_m$ planes significantly increase below 40 K. The emergence of $(010)_m$ and $(100)_m$ planes correspond to the ordering of Sm moments [6,7]. In Γ_4(G_x, A_y, F_z) antiferromagnetic structure, the magnetic moments on neighboring atomic sites point exactly opposite to each other along x || a and y || b directions whereas, the z || c components are parallel, giving rise to weak ferromagnetism along c axis. Very small canting with respect to z || c axis results in a small (0.18-0.39 μ_B) uncompensated moment along -c axis. Γ_1 is a collinear antiferromagnetic structure not allowing any uncompensated moment. The temperarute driven magnetic phase diagram along with evolution of magnetic moments with temperature is constructed in Fig.1. The phase co-existence in the vicinity of SRPT reveals the discontinuous nature of transition and thus we divulge that $SmCrO_3$ possess a discontinuous first order SRPT and uncompensated antiferromagnetic ground state in contrast to the earlier predictions [3,4,8]. In addition, we qualitatively estimated the free energy in the vicinity of SRPT in the functional form of Sm^{3+}- Cr^{3+} antisymmetric-anisotropic exchange interactions and canting angles of moments, a value equivalent to the magneto-crystalline anisotropy, revealing the mechanism of SRPT is governed by completion between exchange interactions and anisotropy energy [8]. To summarize by the present studies, we determined the magnetic structure of $SmCrO_3$ for the first time, evidencing the uncompensated canted antiferromagnetic phase below Néel temperature, collinear antiferromagnetic ground state and the co-existence of both phases in the SRPT regime. Moreover, this is the first time in our knowledge to present the neutron diffraction of Sm- containing polycrystallites using high energy neutrons and we insist that this approach would be in general helpful for any Sm-containing insulating material where Sm moment is significantly high.

$Ln_{2-2x}A_{1+2x}Mn_2O_7$ (*Ln* and *A* are lanthanide and alkaline-earth metals, respectively) is a member of the Ruddlesden-Popper family ($Ln_{n+1}Mn_nO_{3n+1}$ with *n* is the dimension), which have attracted considerable interest due to their rich electrical-magnetic phase diagram. Previous reports have pointed that with $n = 1$, such as $La_{2-x}Sr_xMnO_4$, it has a layered perovskite structure and is a two-dimensional anti-ferromagnetic [1]. Meanwhile, with $n = 2$, it has a double-layered perovskite structure and is considered to be a two dimensional ferromagnetic (FM). Its structure is a stack of FM metal sheets composed of MnO_2 bilayers separated by a $(Ln,A)_2O_2$ rock-salt layer, thus forming a natural array of FM-insulator-FM junctions. Thus, the materials usually exhibit strongly anisotropic and complex physical properties [2, 3]. Though the anisotropy and the dimensionality of $Ln_{2-2x}A_{1+2x}Mn_2O_7$ are well known to play key roles in the magnetoresistance effect, but detailed analyses related to the ferromagnetic-paramagnetic (FM-PM) critical region have not yet been carried out. In this report, we present a detailed analysis on the critical behaviors in a single crystal of $La_{1.2}Sr_{1.8}Mn_2O_7$ via isothermal magnetization measured at different temperatures in the magnetic phase transition. Our results reveal that the material exhibits a single FM-PM phase transition corresponding to a second-order phase transition, takes place at $T_C = 85$ K. An analysis of the Landau-Lifshitz coefficients from the Arrott plots ($H/M = a(T) + b(T)M^2$) showed that $a(T)$ changed from the positive to the negative values at different temperatures in the field ranges of $H =$ 0-10 kOe, 10-30 kOe, and 30-50 kOe, indicating that the critical behavior could not be described with a single model under different applied fields. Using the Kouvel-Fisher and the critical isotherm analysis methods [4], we determined the values of the critical exponents for $La_{1.2}Sr_{1.8}Mn_2O_7$ around its FM-PM phase transition over different ranges of the magnetic field (Fig. 1). The critical exponent β value is found to be 0.51, 0.417, and 0.371 under field ranges of $H =$ 0-10, 10-30, and 30-50 kOe, respectively. Meanwhile, the value of the critical exponent γ is quite stable (γ = 0.973-1.074). It almost in-depends on the choice of field fitting range. This means that the critical exponent β depends strongly on the choice of the field's range, shifting from the value approaching that of the mean field model (β = 0.5) [5] to the value approaching that of the 3D-Heisenbeg model (β = 0.365) [5]. Additionally, with the obtained critical exponents, almost $M(H, T)$ data measured in the vicinity of T_C obeys the scaling equation $M(H, \varepsilon) = \varepsilon^\beta f_\pm(H/\varepsilon^{\beta+\gamma})$, where f_+ for $T > T_C$ and f_- for $T < T_C$ are regular analytic functions, and $\varepsilon = (T - T_C)/T_C$ is the reduced temperature [5]. Fig. 2 shows the $M/|\varepsilon|^\beta$ versus $H/|\varepsilon|^{\beta+\gamma}$ curves in a log-log scale for $La_{1.2}Sr_{1.8}Mn_2O_7$ single crystal. The natures of these phenomena are discussed thoroughly by means of the crystal structure and magnetic anisotropy of the material.

Although $LaMnO_3$ is an insulating antiferromagnetic material, $La_{1-x}A_xMnO_3$ (A is an alkali earth and/or alkali element) exhibits some the electrical and the magnetic phase transitions, such as the ferromagnetic-paramagnetic (FM-PM) and the metal-insulating phase transitions, the magnetoresistance and the magnetocaloric effects [1, 2, 3]. However, detailed analyses related to the FM-PM critical region in a compound exhibiting the presence of the Griffiths phase have not yet been carried out. In this work, we have investigated the critical properties in the vicinity of the FM-PM phase transition in a polycrystalline sample of La0.75Ca0.2Ag0.05MnO3, which was prepared by a solid-state reaction method. The Rietveld refinement technique has been used to analyze the structure at room temperature, indicating all X-ray diffraction peaks belong to an orthorhombic structure (space group *Pnma*) with a = 4.486 Å, b = 7.767 Å, and c = 5.493 Å. Temperature dependence of the inverse of the susceptibility $\chi^{-1}(T)$ proves an existence of the Griffiths phase well above Curie temperature (Tc = 230 K) [4]. Detailed analyses of the isothermal magnetization $M(H, T)$ data reveal the sample exhibiting a second-order phase transition (SOPT), and its the temperature dependences of the saturation magnetization and the initial susceptibility obey the asymptotic relations. Using the Kouvel-Fisher and the critical isotherm analysis methods [5], the critical parameters (β, γ, δ, and Tc) for sample in two representative regions of low (below 15 kOe) and high (above 15 kOe) magnetic fields in the case of the no-subtracting and subtracting the demagnetization field (H_d) have been estimated. Experimental results suggest that the values of the critical exponents in the low magnetic field region are quite close to those expected for the 3D-Heisenberg model (β = 0.365 and γ = 1.336) [6]. Meanwhile, in the high magnetic field region, an unusual critical behavior has been observed, both β and γ values are found to be about 0.5. Using these critical exponent values, almost $M(H, T)$ data measured at different temperatures around FM-PM phase transition are collapsed onto two universal curves of $M/|\varepsilon|^{\beta}$ versus $H/|\varepsilon|^{(\beta+\gamma)}$ corresponding to the regular functions for $T > T_C$ and $T < T_C$, respectively. The natures of these phenomena are discussed thoroughly by means of a contribution of the Griffiths phase [4] and a coexistence of the short-range and the long-range magnetic interactions in material.

CR-04. Observation of Griffiths like phase above room temperature in antiferromagnetic double perovskite Pr_2CoFeO_6.

A. Pal[1], V. Gangwar[1] and S. Chatterjee[1]
1. Physics, Indian Institute of Technology BHU, Varanasi, India

: Rare earth and transition metal oxides with rock-salt ordered doubleperovskite structure ($A_2B^{/}B^{//}O6$, A being rare earth and $B^{'}$& $B^{''}$ are transition metal ions) have been extensively studied for last few decades due to their technologically attractive and wide spectrum of physical properties. In these double perovskite systems B-site ordering and anti-site disorder play the crucial role in deciding its magnetic ground state. Depending on the magnetic interactions between B-site ions, double perovskite systems are reported to show ferromagnetism, exchange bias, spin-glass, magneto-resistance and magneto-capacitance etc. We report a spectrum of unusual magnetic properties including near room temperature antiferromagnetism (AFM) with existence of Griffiths like phase above neel temperature in double perovskite Pr2CoFeO6. In most of the previous studies in double perovskites, people have studied with $B^{/}$ and $B^{//}$ having oxidation states +2 and +4 respectively which give rise to ferromagnetic ordering following Goodenough-Kanamori (GK) rule[1]. In our sample, the nominal valency of both the B-site cations (Co and Fe) is +3 which is expected to produce antiferromagnetic ordering according to GK rule. In the temperature dependent magnetization study, we observed a AFM transition near room temperature at 270K, which is supported by observation of sharp and frequency independent peaks in ac susceptibility data, Fig-1. Inset of figure-1, showing isothermal magnetization as a function of magnetic field at temperatures 250K and 265K. The linear non-saturating behaviour of the magnetization curves clearly suggesting antiferromagnetic ordering. The dominant AFM behaviour is associated to the AFM exchange interactions occurring in Co^{3+}/Co^{3+}, Fe^{3+}/Fe^{3+} and Co^{3+}/Fe^{3+}. Most interestingly, a Griffiths like phase is observed above neel temperature (T_N 270K). Griffiths phase is usually observed in ferromagnetic systems but a paradigm shift occurred since few groups recently have reported existence of Griffiths phase in antiferromagnetic system [2]. In figure-2, a down turn behaviour is observed below a temperature T_G 370K in field dependent "temperature (T) variation of inverse susceptibility $1/\chi$" study,- which is the signature pattern of typical Griffiths phase. In typical Griffiths phase region, the temperature variation of inverse susceptibility follows a characteristic dependence given by χ^{-1} α $(T-T_N)^{1-\lambda}$, where T_N is ordering temperature and the range of λ lies between 0 to 1 in Griffiths phase regime[3]. Inset of figure 2, showing the fitted curve for applied magnetic field 250 Oe, the value obtained for λ is 0.9 which confirms the existence of Griffiths phase in PCFO.

Frustrated pyrochlore compounds with general formula $A_2B_2O_7$ [1-5], where A is a trivalent rare-earth ion and B is a tetravalent transition-metal ion [1], with space group *Fd-3m*, is constituted by two individual interpenetrating A_2O' and B_2O_6 sublattices, composed by corner-sharing tetrahedra. Pyrochlore oxides have been extensively studied in the past few decades, and various novel magnetic behaviors have been discovered, including metal-insulator transition, spin glass [2], spin ice [3,4], and spin liquid [5]. These behaviors come from the geometrical frustration of pyrochlore lattice, which may lead to the macroscopic magnetic degenerate ground states rather than conventional long-range ordered ground states. We have performed x-ray diffraction, dc and ac magnetic susceptibilities, isothermal magnetization, heat capacity and neutron diffraction measurements of polycrystalline $Nd_2Ru_2O_7$ down to 0.4 K. Synchrotron x-ray studies confirm the phase purity and face-centered-cubic (space group *Fd-3m)* pyrochlore structure with lattice parameter, a = 10.3544 Å (5×10^{-4}). Three anomalies are observed in the dc magnetic susceptibility measurements at 146 K, 21 K and 1.8 K, which are due to the ordering of the Ru^{4+} moments into an antiferromagnetically coupled state, a weak canting of the ferromagnetic spins attributed to both Nd^{3+} and Ru^{4+} ions and a long-range-ordering of Nd^{3+} spins, respectively. A bifurcation of ZFC-FC susceptibility curves are observed at 146 K and 21 K, indicating spin canting which leads to weak ferromagnetism. We clarify the ambiguity regarding 21 K anomaly in $Nd_2Ru_2O_7$ reported in ref. [6,7] and we discussed 21 K anomaly on the pretext of spin canting. We fit $\chi(T)$ for T < 20 K with modified Curie-Weiss behavior $\chi(T) = \chi_0 + C/(T - \theta_{CW})$, where temperature independent term χ_0 represents Van Vleck contribution. The fit yields $\mu_{eff} = 2.37\ \mu_B$/Nd for Ising ground state of $Nd_2Ru_2O_7$ and $\theta_{CW} = +0.11(4)$ K. The positive value of θ_{CW} indicates weak ferromagnetic coupling among Nd spins. The isothermal magnetization data behavior at 2 K indicates significant single-ion anisotropy, expected for a local <111> Ising anisotropic system. The nearest neighbor dipole-dipole interactions D_{nn} is estimated to be ≈ 0.16 K. The nearest neighbor exchange interaction J_{nn} between the <111> Ising moments is estimated to be ≈ -0.77 K, from the dc susceptibility data. The value of J_{nn} indicates that antiferromagnetic exchange interactions dominate over dipolar interactions in $Nd_2Ru_2O_7$. A long-range ordering of Nd^{3+} spins is observed and confirmed at 1.8 K in all the measurements, indicating the ground state of the compound was not the glassy transition at ~ 21 K. Low temperature magnetic entropy is accumulated as *R*ln2 up to 5 K, suggesting Nd^{3+} doublet ground state. Lattice distortions are accompanied along with the transitions as revealed by the neutron and synchrotron x-ray diffraction measurements [8]. The magnetic moment of Nd^{3+} ion at 0.4 K is estimated as 1.54(2) μ_B and the magnetic structure is all-in all-out as determined by the powder neutron diffraction measurements. This is the first report on long range ordering of Nd^{3+} in $Nd_2Ru_2O_7$.

CR-06. Magnetic excitation, partial gap opening and chemical pressure effect in $CeNiGe_2$.

K. Singh[1] and *K. Mukherjee*[1]
1. School of Basic Sciences, Indian Institute of Technology, Mandi, India

The hybridization of 4*f*-electrons with conducting electrons results in fascinating ground state due to the competition between inter-site Ruderman-Kittel-Kasuya-Yosida (RKKY), and intra-site Kondo interaction in Ce-based intermetallics compound [1]. In such systems, parameters like magnetic field, external and/or chemical pressure is used to tune the ground state, leading to intriguing phases, such magnetic instability, non-Fermi liquid behavior, unconventional superconductivity, etc [2-3]. Literature report suggests that beyond the oxide family, it is relatively rare to observe the phenomenon of spin density wave (SDW) and itinerant antiferromagnetism [3, 4]. In some heavy fermionic system, the phenomenon of SDW is reported owing to the presence of a partially gapping of Fermi surface [5, 6]. The heavy fermion antiferromagnetic compound $CeNiGe_2$ is investigated by Jung et al., due to the intriguing physics exhibited by this compound [7]. Recent studies indicate that external pressure and high magnetic field are incapable to repress the long range ordering, resulting in the absence of Quantum critical point (QCP) and that the behavior of this compound is not in accordance to the Doniach model, which is widely used to classify heavy fermion compounds [8, 9]. Kim et al., reported that partial replacement of Ge in place Si leads to magnetic order being suppressed and some sign of Quantum critical point (QCP) is observed [10]. However to the best of our knowledge there are no literature reports about whether QCP or signature of non-fermi liquid behavior is observed due to Ce-site dilution by a nonmagnetic ion. Also, the low temperature ground state of $CeNiGe_2$ which has received considerable attention in the past decade remains undetermined. Here, we report the results of our investigation of magnetization, transport, thermodynamic and non-linear dc susceptibility measurements for the Y-substituted heavy fermion system $CeNiGe_2$. Y-substitution results in sequential suppression of magnetic ordering temperature below 1.8 K and also increases itinerancy among the spins. In $CeNiGe_2$ below ordering temperature, our results point towards the observation of SDW due to the presence of partial gap over a portion of the Fermi surface. Non linear dc susceptibility indicates the presence of multipolar magnetic order due to the coexistence of itinerant and localized moment in this compound. Our results indicate that the quadupolar orders leads to magnetic excitation, which is accountable for the development of the gap. This gap opening is suppressed and also is shifted down in temperature with the increase in Y-substitution. Signature of non Fermi liquid behavior or quantum critical point is absent even after 40% dilution of Ce-site, unlike to that, observed for Si substituted $CeNiGe_2$. Further, investigation of Gruneisen parameter gives an indication of fluctuations among spins which increases in itinerant state as observed for Y-0.4 compound.

Imaging&Characterization Core Lab, King Abdullah University of Science and Technology (KAUST), Jeddah, Saudi Arabia

Magnetic semiconductors are highly sought in spintronics, which allow not only the control of charge carriers like in traditional electronics, but also the control of spin states. However, almost all known magnetic semiconductors are featured with bandgaps larger than 1 eV, which limits their applications in long-wavelength regimes. In this work, we report the discovery of orthorhombic-structured Ti_2O_3 (R-Ti_2O_3) films as a unique narrow-bandgap (~0.1 eV) ferromagnetic oxide semiconductor. In contrast, the well-known corundum-structured Ti_2O_3 (C-Ti_2O_3) polymorph has an antiferromagnetic ground state.[1] Our comprehensive study on epitaxial Ti_2O_3 thin films reveals strong correlations between structure, electrical, and magnetic properties. The new orthorhombic Ti_2O_3 polymorph was found to be n-type with very high electron concentration, while the bulk-type trigonal-structured Ti_2O_3 was p-type.[2] More interestingly, in contrast to the antiferromagnetic ground state of trigonal bulk Ti_2O_3, unexpected ferromagnetism with a transition temperature well above room temperature was observed in the orthorhombic Ti_2O_3, which was confirmed by X-ray magnetic circular dichroism (XMCD) measurements.[3] The room-temperature ferromagnetism observed in orthorhombic-structured Ti_2O_3 demonstrates a new route towards controlling magnetism in epitaxial oxide films through selective stabilization of polymorph phases. Both Ti_2O_3 polymorph thin films were deposited on Al_2O_3 (001) single crystal substrates at different temperatures using pulsed laser deposition, with a corundum Ti_2O_3 target. As shown in Fig. 1, two polymorphs of Ti_2O_3 epitaxial films were characterized by X-ray diffraction and Raman spectroscopy, with well-distinguished polymorph-dependent characteristics. Moreover, X-ray magnetic circular dichroism (XMCD) was performed to investigate the magnetism of both polymorphs. As shown in Fig. 2, a clear ferromagnetic behaviour was observed by Ti L-edge XMCD in R-Ti_2O_3, while C-Ti_2O_3 shows no XMCD signal. Using n_{3d}=1 for Ti^{3+} and taking into account the circular polarization, the value of total magnetic moment 0.16 μ_B/Ti was obtained for R-Ti_2O_3. Although both Ti_2O_3 polymorphs share the similar narrow bandgap of ~0.1 eV, their spin configurations are quite different. Since the ferromagnetic R-Ti_2O_3 polymorph has a bandgap as narrow as 0.1 eV, it might enable the exploration of interaction with polarized infrared light in new types of spintronic devices. Furthermore, the contrast of physical properties in these two polymorph phases of Ti_2O_3 demonstrates a new route to engineering charge and spin ground states in semiconductors, which may inspire the exploration of selective stabilization of polymorph phases in other materials relevant to electronic and spintronic applications.

CR-08. Inverted magnetic hysteresis loop and strong magnetoelectric coupling in mixed ferrimagnetic-multiferroic phases of a double perovskite.

D. Oh[1], M. Kim[1], J. Moon[1], S. Oh[1], Y. Choi[1] and N. Lee[1]
1. Yonsei University, Seoul, The Republic of Korea

Exploring new magnetic materials is essential for finding advantageous functional properties such as magnetoresistance, magnetocaloric effect, spintronic functionality, and multiferroicity. Versatile classes of double perovskite compounds have been recently investigated because of intriguing physical properties arising from the proper combination of several magnetic ions. In this study, we examined magnetic and dielectric properties of single-crystalline double-perovskite Er_2CoMnO_6. In addition to the ferromagnetic order arising at T_C = 67 K from the dominant Co^{2+} and Mn^{4+} superexchange interactions, the long-range order of Er^{3+} moments below T_{Er} = 10 K activates the ferrimagnetic order, characterized by compensated magnetization at T_{Comp} = 3.15 K. The inverted magnetic hysteresis loop observed below T_{Comp} can be described by an extended Stoner–Wohlfarth model that is established from contrasting magnetic anisotropy and moments between Er^{3+} and ferromagnetic Co^{2+}/Mn^{4+} sublattices. From the measurement of dielectric properties, an additional small portion of the multiferroic phase, as found in Lu_2CoMnO_6, is identified at T_C. The coexisting ferrimagnetic and multiferroic phases appear to be strongly correlated in that metamagnetic and dielectric transitions occur simultaneously. Our results based on intricate magnetic correlations and phases in Er_2CoMnO_6 enrich fundamental and applied research on magnetic materials through the scope of distinct magnetic characteristics in double perovskites.

CR-09. Study of Spin Polarized Tunneling in Magnetoresistance and Low Temperature Anomaly in Nanoparticles of $La_{0.5}Ca_{0.5}MnO_3$.

A.K. Saw[1], G. Channagoudra[1], H. Fu[2], *R.L. Hadimani*[3] and V. Dayal[1]
1. Department of Physics, Maharaja Institute of Technology-Mysore, Mandya, India; 2. University of Electronic Science and Technology of China, Chengdu, China; 3. Department of Mechanical and Nuclear Engineering, Virginia Commonwealth University, Richmond, VA, United States

Perovskite oxides are typical correlated electron systems and important functional materials, owning fascinating physical properties and promising potential for applications [1–4]. Half doped manganites with generic formula $R_{0.5}A_{0.5}MnO_3$ (where R, trivalent rare earth and A, divalent alkaline earth element) are topic of significant interest in both theoretical and experimental frontiers. The ground state of half doped manganites show contrasting behavior where the charge ordering (CO), orbital ordering (OO) coupled with antiferromagnetic insulating (AFI) state favored by the localizing effects and ferromagnetic metallic (FMM) state driven by the delocalizing effects. The low-temperature electronic transport in some manganites presents a feature of weak insulating/semiconducting behavior and has been explained using different mechanisms [5-9]. Furthermore, physical properties are also modified to a considerable extent subject to the reduction of particle size. This occurs mainly due to the finite size effect, surface and interface effect in magnetic nanoparticles. In this digest, the low temperature resistivity and magnetoresistance (MR) in polycrystalline half doped $La_{0.5}Ca_{0.5}MnO_3$ of ~25.9 nm size nanoparticle synthesized using citrate route has been investigated in the absence and presence of the magnetic field (H = 0T, 4T and 8T). As shown in Fig 1 (a). X-ray diffraction data along with fitting using Rietveld Fullprof software [10] to the orthorhombic unit cell structure crystallizes in Pnma space group (No. 62).The lower value of χ^2 =1.48 indicated a good agreement between observed and calculated patterns. The average crystallite size calculated to be 25.9 nm using the Scherrer's formula [11] after correcting for instrumental contribution to line broadening. Fig. 1 (b) and (c) depicts images elucidating the surface morphology of the sample obtained using Scanning Electron Microscopy at 1μm and 3 μm respectively taken 15KeV. It can be seen that, the grains are in average spherical shaped nano size possessing fine and clear grain boundaries with a small neck between two adjacent grains. From the temperature dependence of resistivity plot shows metal–insulator (MI) transitions at temperature (T_{MI}) = 89 K at 0T as shown in Fig. 2. With the application of magnetic field, the decrease in resistivity and shifting of T_{MI} towards higher temperatures suggests consolidation of Double Exchange mechanism [12]. The significant decreases in resistivity with field over a wide temperature range, for example, from lowest temperature of measurement to ~250 K indicates that FM interaction starts dominating well above observed T_{MI}. This is further supported by isothermal MR measurement which shows PM like behaivour at 300 K and FM like below 200 K discussed later. Based on the phenomenon of phase coexistence in ferromagnetic metallic and paramagnetic insulating regions in the doped manganites, the temperature variation of the resistivity between 50 K and 300 K are in agreement with combined contributions of empirical [13,14] and Small Polaronic Conduction (SPC) model written as; $\rho_{whole}(T)=(\rho_0+\rho_1 T^2+\rho_2 T^{4.5}).f+(1-f).B.T.\exp(E_a/k_B T)$..... (1), where $f=\{[\exp(T-T^M_c/\text{delta})+1]^{-1}$ is the Boltzmann's distribution function of charge carriers in the metallic state. And the characteristic T_{MI} is denoted as T^M_c and delta as the effective transition width over the interval of T^M_c. At temperature below 40 K, a shallow minimum (T_{min}) appears in resistivity plot. The application of the magnetic field suppresses the effect and gradually decreases T_{min} with increasing magnetic field. However application of even 8T could not diminish the effect and is explained considering intergrain tunneling of the charge carriers between anti-ferromagnetically coupled grains. Inset of Fig. 2 shows the magnetic field (H) dependent magnetoresistance [MR % =ρ(H)-ρ(0)/ρ(0)×100] isotherms. At 5 K and H=0.5 T (<1T), the observed MR is ~ 30 %, which increases with the increasing H. At highest measured H= 8 T, the MR is ~ 65%, 60%, ~30% and ~10% at 5 K, 100 K, 250 K and 300 K respectively. MR plot also suggest PM like behavior (concave shape) at 300 K and FM like below 200 K (Convex shape). At 250 K MR behavior seems to be typical of PM near FM transition temperature as discussed earlier. The lower T_{MI} appears to be due to nanoparticle nature of the sample where surface could be insulating. The evidence of metallic seem in isothermal MR as at 8T field MR is about 30%, which is expected due to spin polarized tunneling between two FM grains. Similar such behavior was suggested by Rawat et al. [15] for $GdPd_2Si$ and Lee et. al.[16] for perovskite manganites. The disappearance of the MR at higher temperature regime in insulating state can be ascribed to the weakening of the DE mechanism because of the paramagnetic (PM) state. The present results are discussed and possible explanations are given based on the allied theory.

CR-10. Non-collinear spin structure at ultrathin magnetic interfaces and its evolution by the oxygen adsorption.

T. Chuang[1], C. Huang[2], C. Lu[1] and D. Wei[1,2]
1. National Synchrotron Radiation Research Center, Hsinchu, Taiwan;
2. National Sun Yat-sen University, Program for Synchrotron Radiation and Neutron Beam Applications, Kaohsiung, Taiwan

The study of non-collinear spin structures has recently attracted much attention, since manipulating these magnetic textures offers a possibility to achieve fast ultrahigh-density data manipulation. The origin of the chirality is caused by the anti-symmetric exchange interaction, i.e. Dzyaloshinskii-Moriya interaction (DMI). Large DMI has been predicted and observed at interfaces between heavy metals and transition metal ferromagnets, resulting in asymmetric spin wave dispersion relation [1-2] and chiral spin structures, such as Skyrmions within external magnetic field at low temperature [3]. Recently, these chiral spin textures have been observed by X-ray magnetic circular dichroism (XMCD) based photoemission electron microscope (XPEEM) at room temperature without external field in the system of MgO covered Co/Pt [4], demonstrating the possibilities of investigating chiral spin structures by XPEEM. In the other hand, a real-space imaging of magnetic stripe domain structures in epitaxial Fe/Ni bilayers grown on Cu(001) [5] and Co/Ni multilayers grown on Pt(111) or Ir(111) [6] has suggested the existence of Néel-type chiral domain walls with a fixed chirality at room temperature by spin-polarized low energy electron microscopy (SPLEEM), which indicates that the underlying mechanism is the DMI [5]. Recently, it has been predicted that the DMI in the Fe/Ir system can be tuned and even controlled by the adsorption of electronegative ions, such as oxygen or nitrogen [7], due to the hybridization of transition metals and the ions, which alters the degree of electronic asymmetry at the interface. However, at this moment there is still no direct experimental proof. Here we report that by using XPEEM with XMCD contrast at BL05B2 end-station at Taiwan Light Source a Néel-type out-of-plane chiral magnetic domain wall structure was observed in epitaxial Fe/Ni/Cu(001) across stripe domains within the spin reorientation transition (SRT) (see Fig. 1 (a)). The information of a fixed right-handed chirality can be obtained from a high-resolution XPEEM image with a line-profile of the intensity of the XMCD contrast (Fig. 1 (b)), which is in line with the result of SPLEEM [5]. Furthermore, by taking the advantage of the synchrotron-based element-selective technique, it is found that the spin structure in Fe films is ferromagnetically coupled to the one in Ni films in this system. In addition, the evolution of the stripe domains by the oxygen adsorption is also presented and discussed (see Fig. 1 (c)-(e)). It is found that the domain periodicity becomes larger and averaged domain width is increased when the thickness of oxygen passivation is increased from 0 to 1 Langmuir. It is an evidence that the DMI-magnitude is decreased when the oxygen atoms are passivated on top of the Fe surface, which has been predicted by calculation [7]. Moreover, the X-ray absorption spectra (XAS) of oxygen *K*-edge and Fe *L*-edge indicate that the oxygen atoms are only passivated on the Fe surface without having Fe-O state. Realizing the control of the DMI in ultrathin metal films is of great importance in the surface/interface physics and it will pave the way towards the design of chiral magnetic properties through interface engineering.

CR-11. Role of Fe-doped effect in two-dimensional MoS_2 magnetic semiconductor.

C. Kao[2], C. Yang[2], H. Kao[2], Y. Tung[2], T. Hsu[2], W. Wu[2] and K. Lin[1]
1. Chemical Engineering and Material Science, Yuan Ze University, Taoyuan City, Taiwan; 2. Physics, Chung Yuan Christian University, Taoyuan City, Taiwan

Two two-dimensional $Mo_{1-x}Fe_xS_2$ (x=0, 0.01) nanosheets were fabricated by the hydrothermal method. High-resolution TEM images show both samples were composited with amount 12 layers. As Figure 1(a) show the Raman peaks were broadening in the iron-doped sample. In the two-dimensional MoS_2, the 1 % Fe^{4+} doping means the irons were separated by eight Mo^{4+} alone *a* or *b* axis in the *a-b* plane. The larger Mo^{4+} ion (r_{ion} = 0.65 Å) were replaced by smaller Fe^{4+} (r_{ion}=0.585 Å), and caused the structural distortion. The imperfect periodicity will cause the soften of the phonon mode and make Raman peaks broadening. Ac conductivity experiments revealed both samples obeyed small polaron hopping model as Fig. 1(b). The activation energies of x=0 are 0.121(3) eV and 0.066(1) eV above and below 200 K. Similar two difference activation energies, 0.140(2) eV and 0.082(1) eV above and below 240 K are also found in x=0.01 sample. The effect of iron-doped may raise the activation energies of small polaron. Figure 2 (a) show the magnetic susceptibility of both samples. The diamagnetism is observed in pure MoS_2 between 20 K and 300 K.[1] In contrast, the x=0.01 sample exhibited paramagnetism from 5 K to 300 K. The χ^{-1}-T plot shows the magnetic correlation started at about 270 K. Figure 2 (b) displayed the magnetic hysteresis experiments. No hysteresis loops were found in both samples. For x=0.01 sample, this is an evidence that the doped iron are not aggregated and formed as a magnetic domain. Furthermore, the Brillouin function plus a linear term can be utilized to describe the collected curves of x=0 and 0.01 samples. Small positive and negative slopes of the linear term were found in x=0 and 0.01, respectively. These results revealed both samples contain two origins of magnetism. For x=0, the paramagnetic behavior is found at low field and low temperature. But the diamagnetism is observed at all temperature region. The temperature independent diamagnetic behavior is associated with Langevin diamagnetism. For x=0.01 sample, the Brillouin term is coming from the doped iron ions. The fitted $<m_z>$ of the x=0.01 sample is about 0.019 $m_B/f.\ u.$, which matched the value of 1 % Fe^{4+} (S=2) ion-doped.

CR-12. Reversible 90-Degree Rotation of Fe Magnetic Moment Using Hydrogen.

W. Lin[1], C. Hsu[1], P. Chang[1], Y. Chen[1] and C. Liu[1]
1. Department of Physics, National Taiwan Normal University, Taipei, Taiwan

$[Pd/Fe]_2$ multilayers were deposited on a flat MgO(001) to study the effect of hydrogen on magnetic interlayer coupling. Complex magnetic hysteresis behavior, including single, double, and triple loops, were measured as a function of the azimuthal angle in a longitudinal and transverse direction. With a combination of a 2-fold magnetic anisotropy energy in the bottom-Fe and a 4-fold MAE in the top-Fe, the complex magnetic hysteresis behavior could be clearly explained. Two well-split hysteresis loops with almost zero Kerr remanence were measured by choosing a suitable Pd thickness and applying the magnetic field perpendicular to the easy axis of the bottom-Fe. The split double loops originated from the 90°-rotation of the top-Fe moment. On exposure to a hydrogen gas atmosphere, the separation of the two minor loops increased, indicating that Pd-hydride formation enhanced the ferromagnetic coupling between the two Fe layers. Based on these observations, we proposed that, by applying a suitable constant magnetic field, the top-Fe moment could undergo reversible 90°-rotation following hydrogen exposure. The results suggest that the Pd space layer used for mediating the magnetic interlayer coupling is sensitive to hydrogen, and therefore, the multilayer system can function as a giant magnetoresistance-type sensor suitable for hydrogen gas.

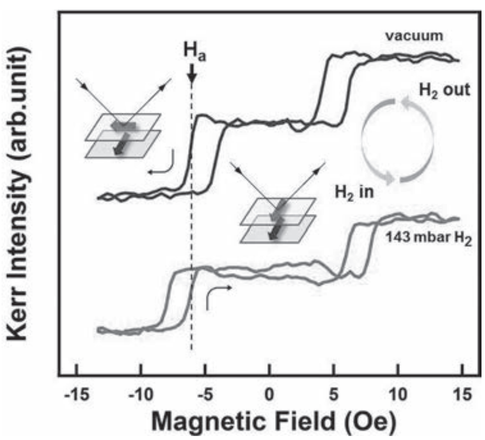

Fig. 1. Reversible 90° rotation of the magnetic moment in the top Fe layer through hydrogen charging. Following H_2 gas absorbtion or desorption, the magnetization minor hysteresis loop shifted toward a larger or smaller coercivity field. When a suitable constant field H_a (as indicated by the dashed line) was applied, the hydrogen charging or discharging reverses the top-Fe layer by 90°.

CR-13. The Role of Graphene Oxide Precursor on Magnetic and Microwave Properties of Nitrogen-doped Graphene.

L. Quan[1], *F. Qin*[1], H. Wang[1] and H. Peng[1]
1. Zhejiang University, Hangzhou, China

Two-dimensional nanomaterials, owing to their excellent physical, chemical and electronic properties, have been extensively explored[1]. Graphene, among others, has attracted tremendous attention since its discovery in 2004[2]. It has outstanding thermal conductivity, electrical conductivity, mechanical properties and high specific surface area with ultrathin thickness, all these properties make graphene a star material. However, pristine graphene is diamagnetic due to the lack of local magnetic moments, which limited its application in many spintronic and magnetic devices. According to the first principle calculations, different kinds of defects (etc. vacancies, adatoms, heteroatoms) can induce different magnetic moments[3]. Nitrogen falls into our best choice as the doping element, in that it is adjacent to carbon in the periodic table and hence has the similar atom size and valence, thus, the introduction of nitrogen will not cause excessive distortion to graphene lattice. Besides, the electronegativity divergence between C atom (2.55) and N atom (3.04) can breach the electroneutrality of graphene material and lead to the change of atomic charge distribution and spin density, which may serve as the resource of graphene magnetism[4]. In this work, a facile thermal annealing method was conducted for two types of GO (GO-1 stands for monolayer; GO-2 stands for multi-layer) to synthesize the nitrogen-doped graphene (NG), through the programmed temperature to achieve a control between doping and reduction process. Several factors that influence the doping and reduction degree have been investigated to reveal the dominant factor that affect the magnetic properties of NG. Table 1 showed that the lower doping is attained with higher reduction degree, which suggests that the doping process is closely related with the oxygen-containing groups in graphene sheets. It is also found that the precursor GO-1 with a slightly lower C/O ratio than GO-2 can be so much more reduced to the extent with C/O ratio obtained more than twice than that of GO-2. This is consistent with the AFM characterization (Fig.1(c,d)): GO-1-NG obtained has more layers than GO-2-NG, which is attributed to less oxygen-containing functional groups left likely leading to a restacking. Also, as indicated in the Raman spectra (Fig.1(a)), I_D/I_G of GO-1 is decreased after reduction, which is opposite to the case of GO-2. Such a striking contrast points to the fact that the graphitic sp^2 hybrid structure was better restored after the reduction and doping process for monolayer than multilayer. Since the doped N does not vary much for these two types of GO, it follows that the increasing number of GO layers has little influence on the doping degree but may suppress the reduction process. With respect to the magnetic properties (Fig.1(b)), both NG samples obtained affords improved magnetization at 2K than their precursor GO, respectively. But the M_s of GO-1-NG reaches 1.31 emu/g, which is far larger than that of GO-2-NG, which indicates that a well restored graphitic structure plays a determinant role here on magnetization of graphene.

I. INTRODUCTION $L1_0$ ordered Fe-Pt films are attractive film-magnets for small-sized medical devices due to their high crystalline anisotropy and high biological safety, and some researchers have been reported the $L1_0$ ordered Fe-Pt thick films (> 1 μm) prepared by sputtering methods [1-2]. For applying the films to the devices, fabrication processes with high deposition rate are effective. Thus, we have employed an electroplating method using high current density (> 0.5 A/cm^2). Although we realized 23 μm-thick Fe-Pt films with high coercivity (approx. 700 kA/m) in the past study [3], partial peelings of the films from Ta substrates, which is attributed to many cracks on the film surface, prevented us from accurate evaluation of the magnetic polarization of the films. Recently, we employed Cu substrates instead of the Ta ones for the electroplating, and clarified that the Cu substrates are hopeful for the electroplated Fe-Pt thick films to reduce the cracks and the partial peelings [4]. In the present study, we electroplated Fe-Pt thick films (> 10 μm) on the Cu substrates and evaluated their magnetic properties. II. EXPERIMENTAL PROCEDDURES We carried out an electroplating to obtain Fe-Pt thick films by using a direct current. The electrolyte of the plating bath contained the following: 10 g/L of $Pt(NO_2)_2(NH_3)_2$, 5-10 g/L of $FeSO_4 \cdot 7H_2O$, 25 g/L of $H_6N_2O_3S$ or NH_4Cl, 30 g/L of $C_6H_8O_7$-H_2O (Citric acid). 5 mm-wide Pt mesh and 500 μm-thick Cu plate were used as the anode and the cathode, respectively. 75 mm^2 (5 mm × 15 mm) Fe-Pt films were electroplated on the Cu plate. The current density of 1 A/cm^2 and the plating time from 10 to 60 min were controlled by using a computer-aided dc current source. The bath temperature was kept at 70°C during the plating. To promote $L1_0$ ordering of the Fe-Pt crystalline phase, we annealed as-plated Fe-Pt films at 700°C for 30 min in a vacuum (< 10^{-2} Pa). The compositions of the as-plated Fe-Pt films and the hysteresis loops of the annealed ones were measured with a SEM-EDX system and a VSM, respectively. III. RESULTS AND DISSCUSSION Figure 1 shows thickness of the $Fe_{50}Pt_{50}$ films plated on the Cu substrates as a function of plating time. Typical hysteresis loop of an annealed thick films is also shown in Fig.1 as an inset. As shown in Fig.1, the thickness increases with increasing plating time, and the deposition rate, which is calculated by the slope of the linier fitting line, is 0.5 μm/min. Owing to high deposition rate, we could obtain 30 μm-thick Fe-Pt films in 60 min. This thickness is much higher than 1 μm of electroplated Fe-Pt films reported by S. Thongmee *et al.* [5] and 23 μm for our previous study [3]. Figure 2 shows coercivity and remanence of the annealed Fe-Pt films as a function of Fe content in the film. As shown in Fig.2, high coercivity values of approximately 1,000 kA/m were obtained at the Fe content of approximately 50 at.%. The coercivity values are much higher than 446 kA/m [1] and 580 kA/m [2] for thick Fe-Pt films prepared by sputtering methods, and are also much higher than 700 kA/m for our previous study, in which Ta substrates were employed [3]. From the result for the coercivity, we found that the Cu substrate is more effective to obtain Fe-Pt films with high coercivity. The remanence slightly increased with increasing the Fe content, and approximately 0.7 T was obtained when the coercivity is almost the same as those for the sputtered films [1-2] (approx. 500 kA/m). Although the remanence value is slightly smaller than 0.9 T [1] and 0.8 T [2], deposition rate of our process (0.5 μm/min) clearly higher than 0.08 μm/min [2]. Therefore, we concluded that the electroplating is one of attractive methods for high speed preparation of the Fe-Pt thick-film magnets with high coercivity.

CS-02. Mossbauer studies and magnetic properties of Fe-doped MnAl(C) alloys.

V. Nguyen[1,2], F. Calvayrac[1] and N. Randrianantoandro[1]
1. Institut des Molécules et Matériaux du Mans – UMR CNRS n°6283, Le Mans Université, Le Mans, France; 2. Advanced Materials Science and Nanotechnology, University of Science and Technology of Hanoi, Vietnam Academy of Science and Technology, Hanoi, Vietnam

The manganese aluminum (MnAl) alloy, which was first reported by Kono [1] and Koch *et al.* [2], is one of the promising rare-earth-free magnets as having interesting intrinsic properties. The τ–phase is normally formed from the high-temperature ε-phase by cooling the ε-phase at an appropriate rate or annealing it at 400-600^{o}C [1, 3]. Through ε to τ transformation, stable phases like γ_2-Mn_5Al_8 and the β-Mn phase can appear (Fig.1). Doping of carbon has been proved to improve the stabilization of the ferromagnetic τ–phase MnAl ($L1_o$) [4-6]. Mossbauer spectrometry is based on the resonant effect of absorption and emission of gamma rays of nuclei of the same isotope in solid. It is a very sensitive technique, being capable of detecting changes in the order of 10^{-11} thanks to its extremely narrow line widths of gamma rays. In particular, Mossbauer spectrometry allows to probe microscopically at the atomic scale, and therefore it is very efficient for studying atomic environment in solid materials. Normally, three kinds of nuclear interactions are recorded by Mossbauer spectrometry: - Isomer shift (δ): It describes a positive or negative shift of the spectra depending on the increase or decrease of s-electron density at the nucleus of the absorber in comparison with the source. It is often used for examining oxidation state, valency states, electron shielding and the electron-drawing power of electronegative groups. - Quadrupole splitting (Q.S.): It is caused by the interaction between the nuclear quadrupole moment with the surrounding electric field gradient (EFG), causing the splitting of the nuclear energy level. Oxidation state, spin state, and site symmetry can be determined by measuring the Q.S. - Magnetic hyperfine field (B_{hf}): This interaction is based on the nuclear Zeeman effect that occurs when a magnetic field exists at the nucleus. This magnetic field may come from within the crystal by exchange interaction or by applying an external magnetic field. In the topic of the metastable MnAl(C) τ-phase, our aim is to probe the local behavior of Mn atoms when its environment is perturbed by the presence of atomic insertion (C atoms), change of temperature or application external magnetic field. In the absence of Mossbauer isotope for manganese, we substituted some Mn atoms in MnAl(C) alloys by ^{57}Fe atoms. Therefore, four nominal compositions with ^{57}Fe enrichment: ε-$Mn_{50.5}Fe_{0.5}Al_{47}C_2$, and its corresponding τ-$Mn_{50.5}Fe_{0.5}Al_{47}C_2$, γ_2-$Mn_{40}Fe_{0.5}Al_{59.5}$, and β-$Mn_{60}Fe_{0.5}Al_{39.5}$ were mechanically synthesized for Mossbauer studies. A non-iron $Mn_{50.7}Al_{47.3}C_2$ was also synthesized for magnetic properties comparison. Fig.2 shows the X-ray diffraction diagrams of the samples. As can be seen, high purities of all the phases were obtained under 10h of milling by tungsten carbide (WC) vials of a planetary ball mill (PULVERISETTE 7 premium line), the balls-to-powder weight ratio is 25:1, followed by an appropriate heat treatment. A trace of Al_2O_3 was found in ε and τ phases, and a small amount of $MnAlC_3$ was found in the β phase, which is due to a small carbon contamination from the WC vials during the milling process. Further results and discussion on the microstructure, Mossbauer spectra analysis, and magnetic properties will be presented at the conference.

CS-03. Magnetic properties and morphologies of synthesized strontium ferrite powders by the molten salt method.

M. Kim[1], K. Lee[1], M. Choi[1] and J. Kim[1]
1. Materials Science and Chemical Engineering, Hanyang University, Ansan, The Republic of Korea

M-type ferrite magnets have been widely used in various applications in electronic devices such as motors, sensors, and etc., because of their relatively good magnetic characteristics and very low manufacturing cost. In addition, compared with $Nd_2Fe_{14}B_1$ magnets, the ferrite magnets possess excellent high temperature properties and corrosion resistance properties [1]. Thus, the ferrite magnets have been widely used under severe operating conditions, such as magnetic core powders for encoders in automobile motors. In recent, these encoders are strongly required to increase the angular resolution for more precise control. This indicates that these M-type ferrite powders should be homogeneously distributed in a composite matrix to reduce the positional errors. In addition, the composite magnet with ferrite powders is required to increase the remanence and coercivity. Therefore, it is critical to develop new M-type ferrite powders with homogeneous shape, dimensions and excellent magnetic properties. To synthesize ferrite powders, various methods, such as solid state reaction, sol-gel and molten salt method have been commonly used. Among them, the molten salt method is known to have an advantage of preventing the aggregation and controlling the shape and dimensions of powders. Thus, in this experiment, strontium hexa-ferrite powders were synthesized by the molten salt method and subsequent two step heat treatment. The morphological changes depending on processing conditions were analyzed using X-ray diffractometer and electron microscopes and then the relationship between their morphologies and magnetic properties measured by a vibrating sample magnetometer and a B-H analyzer were investigated. In this experiment, strontium ferrite powders were synthesized by a molten salt method for controlling the size and shape of synthesized powders. Before calcination, strontium carbonate ($SrCO_3$, 97.0%, DAEJUNG, Korea) with an average size of 1μm, α-hematite (Fe_2O_3, 99.9%, KOJUNDO, Japan) with an average size of 1μm and sodium chloride (NaCl, 99.0%, DUKSAN Pure Chemical, Korea) with the mole ratio of 1:5.7:x (x=0, 10, 20, 30, 40) were mixed by planetary centrifugal mixer at 1500 rpm for 60 min. These mixed raw materials were calcined using an alumina crucible in a box furnace under O_2 atmosphere. During calcination, the flow rate of O_2 gas was maintained at 3 L/min and the heating rate was controlled at 10°C/min. After the calcination process, these synthesized powders were furnace-cooled to the room temperature. In order to control the morphology of powders, the calcination process consisted of two successive annealing steps. At the first step, the first annealing was carried out over the melting temperature of NaCl for the dissolution. This dissolution process should enhance the dispersion of the Fe_2O_3 and the $SrCO_3$ powders to be dispersed in the liquid NaCl matrix, which induces the homogeneous nucleation and suppresses excessive growth of strontium ferrite powders. At the second step, the temperature increased to form the strontium hexa-ferrite phase at the elevated temperature. In this calcination process, it is expected to control the size and shape of strontium ferrite powders by changing the temperature and time. After the calcination process, these synthesized powders were washed 10 times with distilled water using a sonicator to remove the residual NaCl powders and then dried at 60°C for 24 hr. The microstructures of the strontium ferrite powders were analyzed by an X-ray diffractometer (XRD, Rigaku, D/MAX-2500) using CuKα radiation. The magnetization(M_S), remanence value(M_r) and coercivity(H_C) were measured by a vibrating sample magnetometer (VSM, LakeShore 7404) under 15 kOe. The morphology of the strontium ferrite powders was observed by a scanning electron microscope (SEM, Tescan MIRA3) Figure 1 shows the XRD patterns and VSM results of strontium ferrite powders synthesized with different NaCl ratios at the calcination condition of 850°C for 60 min and 1050°C 90 min. As shown in the figure, the peak positions of strontium ferrite powders were well matched with those of JCPDS card (#01-080-1197) although the small amount of residual Fe_2O_3 powders still existed. As shown in the attached table, the magnetic properties of these powders clearly demonstrate the formation of M-type hexa-ferrite. Despite the same annealing condition, the coercivity and remanence were increased with increasing the NaCl ratio. In order to investigate the changes in the magnetic properties of these two ferrite powders, the SEM morphologies were observed and shown in figure 2. As shown in the figure, the size of synthesized powders became smaller and the shape became more uniform as the NaCl ratio increased. In addition, the aspect ratio of hexagonal type powders is shown to be dependent on the NaCl ratio. Thus, it is expected that these ferrite powders with controlled shape and dimensions enhance the magnetic properties of the composite magnets used in magnetic encoders. A more detailed discussion on the effects of various heat treatment conditions on the morphology of ferrite powders will be presented.

Introduction Incorporating shells on magnetic nanoparticles (NPs) has received much interest because a shell offers protections of the active core component against oxidation, corrosion, magnetic lateral interaction among magnetic nanoparticles, and sintering phenomena.[1]Moreover, the core-shell structured NPs has potential applications in high density data storage, the biomedical field, catalysis, etc.[2-3] Recently, one of the attractive shell applications is for surface modification of α"-$Fe_{16}N_2$ NPs, in which they are used for creating a permanent magnetic material with a giant magnetic moment as an alternative to rare-earth-free magnetic material.[4] In this work, we report an effective and simple way for synthesizing well-dispersed spherical core-shell α"-$Fe_{16}N_2/SiO_2$ ferromagnetic NPs from core-shell Fe_3O_4/SiO_2 NPs. The influences of coating process on the formation of α"-$Fe_{16}N_2$ were studied, the magnetic properties of the synthesized α"-$Fe_{16}N_2/SiO_2$ NPs were also investigated. Experimental Core-shell α"-$Fe_{16}N_2/SiO_2$ NPs were synthesized by means of two-step process: (1) to prepare core-shell Fe_3O_4/SiO_2 NPs by Stöber method, (2) low temperature nitridation of α-Fe/SiO_2 obtained from the reduction of Fe_3O_4/SiO_2 NPs. In the first step, Fe_3O_4 NPs were dispersed in 50 ml of hydrochloric acid solution with a concentration of 0.1 mol/L, with ultrasonic stirring for 10 min at room temperature. After that, the above solution was washed with distilled water to remove the residual hydrochloric acid, which were then dissolved in the mixed solution that contains 80 ml ethanol and 20 ml distilled water. A certain amount of ammonia water and teraethoxysilane was successively added to the above mixture in drop and stirring for 6 h at certain temperature. Subsequently the mixture solution was washed several times with ethanol and distilled water successively to remove the suspended solids. Finally, the sample was dried in vacuum drying oven at 60 °C for 6 h. For the second step, the core-shell Fe_3O_4/SiO_2 NPs were reduced with hydrogen gas for 4 h at a temperature of 400 °C, after which the furnace was purged for 5min with argon gas. The temperature of the furnace was then reduced to 170 °C, after which a nitriding treatment was performed in a flow of ammonia gas. Results and Discussion The core-shell Fe_3O_4/SiO_2 samples were characterized via X-ray diffraction and infrared spectroscopic analysis, which demonstrated the Fe_3O_4 NPs were well coated with SiO_2. The XRD patterns of nitriding products obtained at 170 °C with various time are exhibited in figure 1. The proportion of α"-$Fe_{16}N_2$ gradually increases with increasing nitridation time, when the nitridation time was 12 h, high-purity α"-$Fe_{16}N_2$ /SiO_2 was obtained. However, with longer nitriding time, the proportion of α"-$Fe_{16}N_2$ decreases then. When the nitriding time is 12h, the saturation magnetization of α"-$Fe_{16}N_2/SiO_2$ is 138.2 emu/g. Fig. 2 shows the TEM images of the Fe_3O_4 and α"-$Fe_{16}N_2/SiO_2$ NPs respectively, a transparent layer of silica dioxide coated on the surface of α"-$Fe_{16}N_2$ can be clearly seen, indicating core-shell α"-$Fe_{16}N_2/SiO_2$ was successfully prepared.

INTRODUCTION Permanent magnet is an essential functional material in the area of energy saving and clean environment technology. Current extensive research activities on the permanent magnetic materials can be categorized into three domains : First and most of all, maximizing performance, in particular coercivity, of the current Nd-Fe-B-type magnet using less or no heavy rare-earth element (Dy, Tb). Secondly, searching for new rare-earth compound having high magnetocrystalline anisotropy (MCA) and saturation magnetization (Ms). Finally and equally important, finding new 3d transition metal compound alloy with high MCA and Ms. The latter one seemingly comes into spotlight in relation to next generation permanent magnetic material, and much attention has been paid to Fe-Co alloy having high Ms. First-principles calculations have predicted that tetragonal Fe-Co alloy could have high MCA, provided that high degree of order and large tetragonality are secured in the alloy, which are understood not to be as straightforward. In the meantime, it has long been known that $(FeCo)_2B$-type compound had uniaxial MCA with considerably high magnetocrystalline anisotropy energy (MAE). Recently, it was reported that the Re-substituted $(FeCo)_2B$-type compound had good hard magnetic properties such that it caught much attention as new permanent magnetic material being free of rare-earth metals [1]. In the present study, realization of coercivity in the Re-substituted $(FeCo)_2B$-type compound alloy prepared mainly by mechanical milling was investigated. Phase evolution in the $(FeCo)_2B$-type alloy by mechanical milling and annealing was also investigated. EXPERIMENTAL Re-substituted $(FeCo)_2B$-type alloy with composition of $(Fe_{0.675}Co_{0.3}Re_{0.025})_2B$ was melted in an arc-melting furnace and then the melt was suctioned onto a cold mold to prepare flake-form material by suction cast technique. Prepared flakes were mechanically milled and annealed in various conditions. Annealing of some milled alloy samples was performed in a thermomagnetic analyzer (TMA) to accomplish simultaneously annealing and phase analysis. On annealing in the TMA, sample was swiftly heated to the annealing temperature by pushing into hot zone in the oven, which was heated beforehand to the desired temperature, and held there for desired time. No sooner did the sample temperature arrive and stay at the desired temperature than cooling-down toward room temperature started by cutting off the power for heating oven. In the course of cooling the magnetization variation was monitored. Magnetic, microstructural characterization and phase analysis of the material were performed by using VSM, TMA, SEM, TEM, and XRD. RESULTS AND DISCUSSION The Re-substituted $(FeCo)_2B$-type alloy in suction-cast condition consisted of $(FeCo)_2B$-type and (FeCo) B-type phases. Phase constitution in the mechanically milled alloy varied according to the condition of mechanical milling and subsequent annealing. The material milled for short period (3 hrs) consisted of $(FeCo)_2B$-type, (FeCo)B-type, $(FeCo)_3B$-type, and amorphous phases. The (FeCo)B-type and $(FeCo)_3B$-type phases disappeared as milling time increased, and the material milled for longer than 12 hrs consisted of $(FeCo)_2B$-type and amorphous phases. Fig. 1 (a) and (b) show phase analysis results in the Re-substituted $(FeCo)_2B$-type alloy in as-milled (24 hrs) and annealed (890 °C, 15 min) conditions examined by means of XRD and TMA. In XRD patterns of the material in as-milled condition a broad hump appeared in the low angle range and peaks corresponding to the $(FeCo)_2B$-type phase were extensively broadened, indicating that the material consisted of very finely crystallized $(FeCo)_2B$-type phase and amorphous phase. This phase constitution in the material in as-milled condition was also evidenced by the phase analysis results by TMA. Magnetic transitions occurring at around 375 °C and above 600 °C were corresponding to the Curie temperature of the amorphous and $(FeCo)_2B$-type phases, respectively. The sufficiently milled material being consisted of $(FeCo)_2B$-type and amorphous phases could be converted into $(FeCo)_2B$-type single phase material by brief annealing at elevated temperature above 740 °C. As can be seen in Fig. 1(a) and (b), the as-milled material converted into $(FeCo)_2B$-type single phase by brief annealing at 890 °C for 15 min. This finding is interesting in that single phase $(FeCo)_2B$-type material can be obtained by rather easily by combination of suction casting and mechanical milling with respect to standard alloy preparation technique. The Fe_2B-type compound is known to form at high temperature over 1400 °C via peritectic reaction between solid and liquid phases in Fe-B alloy system, which is basically very sluggish metallurgical process. A prolonged annealing of the cast alloy at high temperature is, therefore, required as a matter of course to acquire single phase $(FeCo)_2B$-type alloy in standard alloy preparation route. The alloy in as-milled condition (24 hrs) exhibited low coercivity of 0.2 kOe, and the coercivity was increased up to around 1 kOe by brief annealing (890 °C, 15 min). In this article, phase evolution and coercivity development in the mechanically milled and subsequently annealed Re-substituted $(FeCo)_2B$-type alloy are to be discussed.

Development of novel permanent magnetic materials is very important in modern technology due to ever-increasing demand for the wide applications in consumer electronics, hybrid electric vehicles, wind power generators, and robotics, etc. Rare earth (R) cobalt alloys, such as $SmCo_5$ and Sm_2Co_{17}, with excellent magnetically hard intrinsic properties have attracted much attention for decades. Unlike $SmCo_5$, the developed $PrCo_5$ alloys so far showed low coercivity due to relatively smaller magnetocrystalline anisotropy field, though $PrCo_5$ has the highest the saturation magnetization and therefore theoretical energy product among RCo_5 systems [1-2]. Limited report related to the magnetic and microstructural characterizations for $PrCo_5$ system in ribbon form is available till today. Proper Fe addition into YCo_5 system has been reported to effectively improve the magnetically hard intrinsic properties, especially the saturation magnetization, and appropriate C doping in various permanent magnetic alloys, i.e. $R_2Fe_{14}B$ and $SmCo_7$, is helpful in microstructure refinement and the improvement of magnetic properties [3-5]. It is of interest to find out whether these effects contribute to the improvement of the hard magnetic performance of $PrCo_5$ alloys or not. Accordingly, doping effects of Fe and C on the magnetic properties, crystal structure, and microstructure of $PrCo_5$ alloys are studied. The melt spinning process is adopted to prepare the $PrCo_{5-x-y}Fe_xC_y$ (x=0-0.3; y=0-0.4) ribbons at a wheel speed of 10-40 m/s. All samples were magnetized by a 50 kOe peak pulse field before magnetic measurement. No demagnetization field correction was made in this study. Curie temperature (T_C) of magnetic phase was determined by thermo-gravimetric analysis with an applied magnetic field at a heating rate of 20 ^oC/min. At first, effect of quenching rate on the magnetic properties and microstructure of $PrCo_5$ ribbons has been studied. At lower wheel speed of 10-20 m/s, the coexistence of 2:17 phase with magnetic hard 1:5 phase leads to low coercivity of below 0.5 kOe, while increasing wheel speed to 40 m/s improves the coercivity to 3.3 kOe due to the suppression of 2:17 phase. Most importantly, magnetic properties of melt spun $PrCo_5$ ribbons are significantly enhanced by doping Fe and C. Listed in Table 1, lower permanent magnetic properties of B_r = 6.4 kG, $_iH_c$ = 3.3 kOe, and $(BH)_{max}$ = 5.0 MGOe are obtained for binary $PrCo_5$ ribbon, and improved to B_r = 6.1-6.9 kG, $_iH_c$ = 7.3-13.5 kOe, $(BH)_{max}$ = 7.3-8.9 MGOe by doping C, yet slightly decreased to B_r = 5.1 kG, $_iH_c$ = 4.5 kOe, $(BH)_{max}$ = 4.2 MGOe by doping Fe, respectively. Most interestingly, the optimal magnetic properties of B_r = 5.8 kG, $_iH_c$ = 16.2 kOe, $(BH)_{max}$ = 8.0 MGOe are achieved for C and Fe co-doped $PrCo_{4.6}Fe_{0.3}C_{0.1}$ ribbons, where the coercivity is the highest value in $PrCo_5$ system ever reported. Shown in Fig.1, x-ray diffraction analysis indicates that all studied ribbons consist of hexagonal 1:5 phase and minor 2:17 phase. Fe or C-doping could suppress the 2:17 phase and stabilize 1:5 phase, and therefore enhance coercivity but decrease the remanence of $PrCo_5$ ribbons. The slightly changed lattice constants of the 1:5 phase by doping Fe or C, i.e. enlarged *a* and reduced *c*, reveals the entrance of Fe and C into the crystal structure of 1:5 phase. The *c/a* ratio of 1:5 phase are decreased from 0.825 to 0.800 by doping C, to 0.797 by doping Fe, and to 0.801 by co-doping Fe and C, respectively. The change in *c/a* ratio of 1:5 phase may improve magnetocrystalline anisotropy field to contribute the coercivity enhancement. Besides, the Rietveld refinement finds that about 3 volume percentage of nonmagnetic Pr_2C_3 phase appears for the ribbons co-doped with Fe and C. T_C of 1:5 phase is increased from 609 ^oC to 650 ^oC by doping C, to 646 ^oC by doping Fe, and to 673 ^oC by co-doping Fe and C, respectively. The different degree of the increment of T_C with Fe and C substitution is related to different strength of exchange interaction for neighboring magnetic atoms. Importantly, the increased T_C of 1:5 phase by co-doping Fe and C is beneficial in improving the thermal stability of the magnet. Transmission electron microscopy (TEM) images of $PrCo_{5-x-y}Fe_xC_y$ ribbons are shown in each inset of Fig.1. The large grain size of 100-120 nm is observed for $PrCo_5$ ribbon, and it is refined to 30-70 nm by doping Fe, to 10-30 nm by doping C, and to 5-20 nm by co-doping Fe and C, respectively. The microstructure refinement is helpful in improving $_iH_c$, the squareness of demagnetization curve, and therefore $(BH)_{max}$. Besides, some small precipitates found for the sample co-doped with Fe and C is Pr_2C_3, identified by energy dispersive x-ray spectroscopy, which well agrees with XRD analysis. The nonmagnetic Pr_2C_3 precipitates impede the magnetization reversal and thus enhance coercivity. Summarized with the above results, the increased volume fraction of 1:5 phase, the strengthened H_A, and the refined microstructure, the induction of nonmagnetic Pr_2C_3 precipitates by co-doping Fe and C make $PrCo_{4.6}Fe_{0.3}C_{0.1}$ ribbons exhibit high permanent magnetic performance of $_iH_c$ = 16.2 kOe and $(BH)_{max}$ = 8.0 MGOe. They are promising candidate materials for making bonded magnets.

Introduction Behavior of magnetic properties at finite temperatures is important in applications of hard magnets, and *ab initio* modeling of spins for them has become one of the standard techniques for addressing it today. In construction of such a model, intersite magnetic interaction is evaluated based on first-principles calculation. The spin-wave dispersion derived from the interactions offers information of magnetic collective modes that are related to finite temperature properties in an intuitive way, and the dispersion can be compared directly to that obtained by experiments. Magnetic compounds with the $ThMn_{12}$ structure have regained attention since their potential as the main phase in a hard magnet was reevaluated by a first-principles study [1] and experimental works [2, 3] in these years. Hirayama et al. have recently synthesized $Sm(Fe_{1-x}Co_x)_{12}$ films for $x = 0$, 0.1, 0.2, and shown that $Sm(Fe_{0.8}Co_{0.2})_{12}$ has favorable magnetic properties, including the spontaneous magnetization of 1.78 T at room temperature [4]. We in this paper present spin-wave dispersion in $Sm(FeCo)_{12}$ calculated based on first-principles to address magnetic properties of the system at finite temperatures. Because there is no experiment clarifying its spin-wave dispersion to the best of our knowledge, we compare our values of the spin-wave stiffness with those obtained from the experiment by Hirayama et al. We also discuss anisotropy in the lowest branch around the Gamma point: spin-waves are more easily propagate along a*-axis than along c*-axis especially in $SmFe_{12}$. Methods We use the Korringa–Kohn–Rostoker Green function method for solving the Kohn-Sham equation of density functional theory. The exchange–correlation functional is approximated within the local density approximation. The f-orbitals at the Sm site are treated as a trivalent open core, and the self-interaction correction is applied to the orbitals. We assume the Fe and Co atoms randomly occupy the 8f, 8i and 8j site in the $ThMn_{12}$ structure and their site preference is disregarded. We treat the randomness with the virtual crystal approximation (VCA). The magnetic coupling is calculated by using Liechtenstein's formula [5]. For the calculation of spin-wave dispersion, we refer readers to Ref. 6. We use the experimental lattice constant *a* and *c* given in Ref. 4. For the lack of experimental data to fix the inner freedom of the coordinate, we use the calculated values of the inner parameters for $SmFe_{12}$ given in Ref. 7. Results and Discussion Figure 1 shows the spin-wave dispersion in $SmFe_{12}$ (purple) and $Sm(Fe_{0.8}Co_{0.2})_{12}$ (green). The green lines are aligned comparatively upward because the introduction of Co in $Sm(Fe_{0.8}Co_{0.2})_{12}$ enhances the magnetic exchange interaction and makes the excitation energy for the collective modes higher than in $SmFe_{12}$. The energy difference between $SmFe_{12}$ and $Sm(Fe_{0.8}Co_{0.2})_{12}$ at the Z point = (1 0 0) on the lowest branch is especially noteworthy. In $SmFe_{12}$, the curvatures around the Gamma point is larger along c*-axis than that along a*-axis (see also Fig. 2), and the smallness of the excitation energy of the Z mode is typical of this anisotropy (the shortest path of Γ–Z is along a*-axis, which is shown in Fig. 1). As for the $Sm(Fe_{0.8}Co_{0.2})_{12}$, the curvatures become more isotropic due to the enhancement of the exchange interaction. We also calculated the spin-wave stiffness from the dispersion. Figure 2 shows values of them calculated by $D = (D_a^2 D_c)^{1/3}$ where D_a and D_c is the curvature along the a*- and c*-axis, respectively, so that D gives the coefficient of $T^{2/3}$ in Bloch's law with the expression derived for the isotropic case. Those are in adequate agreement with the value obtained by Hirayama et al [4]. Conclusion We presented calculation of the spin-wave dispersion in $SmFe_{12}$ and $Sm(Fe_{0.8}Co_{0.2})_{12}$, and discussed how the introduction of Co enhances the exchange interaction. Our calculation predicted anisotropy in the curvatures of the lowest branch around the Gamma point in $SmFe_{12}$ and weakening of the anisotropy when Co is introduced into the system. We also calculated the spin-wave stiffness of the systems, which values are in adequate agreement with the experimental values by Hirayama et al [4].

1:12 phase structures are an alternative candidate to the current high temperature magnets $Nd_2Fe_{14}B$. Work by T. Mikyake et al.[1] showed that with minor Ti substitution and nitrogenation, $NdFe_{12}$ could be changed to $NdFe_{11}TiN$ which has comparable magnetic properties to $Nd_2Fe_{14}B$ at room temperature, but a higher curie temperature making it ideal for high temperature applications. To study the formation energy of 1:12 phase structures and how it changes with Titanium percentage, ab initio calculations on the lattice structure must be performed. In order to calculate the minimum energy from first principle one has to calculate first the site probability of the substituted Titanium in the 1:12 structure. We use molecular dynamics with potentials derived from first principle to calculate the site probability for Titanium using GULP[2]. Atom interaction was modelled using Morse potentials[3]. The Titanium substitution was permutated through all possible substitution positions and the lowest energy configuration was derived and from that the site probability calculated. The results of these simulations are shown in figure 1. Figure 1 shows the probability distribution of Ti as function of atom percentage and site preference. For $NdFe_{12-x}Ti_x$ and $SmFe_{12-x}Ti_x$, the preferred position of Titanium in all investigated 1:12 phase structures follows the same probability pattern, and fills in the different atomic positions by group. There are three groups associated with the 1:12 phase the 8i, 8j, and 8f groups. The groups contain atomic sites that are equally likely to be filled at any Titanium substitution when the precise path to that substitution is unknown, see figure 2. For $NdFe_{12-x}Ti_x$ and $Sm_{12-x}Ti_x$; there is no preference for any particular atom within the groups at any Titanium substitution as shown in figure 2 for the Sm based system. There it can be seen that the Ti atom has the same probability energy wise to populate any of the 8 possible 8i sites, lowest energy of -142.6eV, followed by the 8j site of -141.5 eV and the least probable one the 8f site with -140.6 eV. The statistical distribution of the Titanium substitutions by atomic site grouping is shown in figure 1 at various Titanium at. %. The graphs show how Titanium switches preference between atomic group sets as the Titanium percentage in the structure increases. An initial preference for the 8i atoms is followed by a switching preference between the 8j and 8i atomic groups every 2 atoms filled, until all 8i positions are filled. For $SmCo_{12-x}Ti_x$, the system follows a similar probability distribution to the RFe_{12} structures, but due to Cobalt's different electronic structure the cohesive energy difference of the $SmCo_{12}$ structure is greater than the Iron based one with one Titanium substitution. For $SmFe_{12}$ the cohesive energy changes from -157.4eV to -158.9eV, a gain of 1.5eV where for $SmCo_{12}$ the cohesive energy changes from -140.2eV to -142.6eV a gain of 2.4eV. This indicates, due to the larger gain in energy, that the Cobalt system is more stable than the Iron based one. In the future we will explore supercell structures and calculate the total formation energy according to the Born Haber cycle and add additional substitutes such as V, C, etc. to improve the phase stability and formation energy.

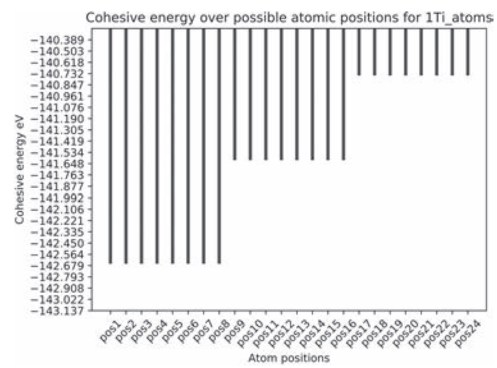

Fig. 2. Cohesive energy of the different atomic positions in SmCo12 with one Titanium substitution. The different energy levels correspond to different atomic site groups, positions 1 to 8 are part of the 8i group, positions 9 to 16 are part of the 8j group, and positions 17 to 24 are part of the 8f group.

CS-09. Magnetic properties of $(Sm,Zr)_5(Fe,Co)_{17-x}Ti_x$ melt-spun ribbons.

T. Saito[1], *T. Horita*[1] and D. Nishio-Hamane[2]
1. Chiba Institute of Technology, Chiba, Japan; 2. Institute for Solid State Physics, The University of Tokyo, Kashiwa, Japan

The Sm_5Fe_{17}-type phase is a new ferromagnetic intermetallic compounds in the binary Sm-Fe system [1-3]. The Sm_5Fe_{17}-type phase has been shown to be a metastable phase that can be prepared by the annealing of amorphous Sm-Fe melt-spun ribbon [4]. Although the Sm_5Fe_{17}-type phase exhibits high coercivity comparable to that of Nd-Fe-B magnets, the reported values of its remanence are relatively low. It is therefore essential to increase the remanence of the Sm_5Fe_{17}-type phase. Several efforts have been made to achieve this objective, but it has been reported that the large compositional modification of the Sm_5Fe_{17}-type phase resulted in its decomposition [5]. In the present study, melt-spun ribbons were prepared containing small amounts of cobalt and zirconium added to Sm_5Fe_{17}-type phase. Small amounts of titanium were also added to the $(Sm,Zr)_5(Fe,Co)_{17}$ phase to improve the magnetic properties. The structures and magnetic properties of these $(Sm,Zr)_5(Fe,Co)_{17-x}Ti_x$ melt-spun ribbons are discussed here. $(Sm_{0.8}Zr_{0.2})_5(Fe_{0.75}Co_{0.25})_{17-x}Ti_x$ (x = 0–2.0) ingots were prepared by induction melting under an argon atmosphere. The molten alloy ingots were then ejected through an orifice with argon onto a copper wheel rotating at a surface velocity of 40 ms^{-1}. The melt-spun ribbons thus obtained were annealed under an argon atmosphere at 773–1273 K for 1 h. The phases in the specimens were investigated by X-ray diffraction (XRD) using Cu Kα radiation. The microstructures of the specimens were examined using a transmission electron microscope (TEM) after ion-beam thinning. The magnetic properties of the specimens were measured at room temperature using a vibrating sample magnetometer (VSM) with a maximum applied field of 25 kOe. The crystalline phases of the $(Sm_{0.8}Zr_{0.2})_5(Fe_{0.75}Co_{0.25})_{17-x}Ti_x$ (x = 0–2.0) melt-spun ribbons were examined in the XRD study. The XRD pattern of the $(Sm_{0.8}Zr_{0.2})_5(Fe_{0.75}Co_{0.25})_{17}$ melt-spun ribbon showed only a fairly broad halo-like peak, which is a characteristic of an amorphous structure. However, the XRD patterns of the $(Sm_{0.8}Zr_{0.2})_5(Fe_{0.75}Co_{0.25})_{17-x}Ti_x$ (x = 0.5–2.0) melt-spun ribbons exhibited small crystalline peaks together with the broad halo-like peak. Thus, the $(Sm_{0.8}Zr_{0.2})_5(Fe_{0.75}Co_{0.25})_{17-x}Ti_x$ (x = 0–2.0) melt-spun ribbons consisted of the amorphous phase either alone or together with small amounts of the crystalline phase. The resultant $(Sm_{0.8}Zr_{0.2})_5(Fe_{0.75}Co_{0.25})_{17-x}Ti_x$ (x = 0–2.0) melt-spun ribbons showed low coercivity values regardless of the Ti content. Heat treatment of these specimens was carried out to increase the coercivity. Figure 1 shows the dependence of the coercivity of the $(Sm_{0.8}Zr_{0.2})_5(Fe_{0.75}Co_{0.25})_{17-x}Ti_x$ (x = 0–2.0) melt-spun ribbons on the annealing temperature. The specimens annealed at 873 K or lower showed a low coercivity value comparable to that of the as-quenched melt-spun ribbons, while the specimens annealed at 973 K and above exhibited high coercivity. The highest coercivity, H_c = 13.3 kOe, was obtained in the $(Sm_{0.8}Zr_{0.2})_5(Fe_{0.75}Co_{0.25})_{15.5}Ti_{1.5}$ specimen after annealing at 1073 K. In order to clarify the origin of the coercivity in the annealed $(Sm_{0.7}Zr_{0.3})_2(Fe_{0.7}Co_{0.3})_{17-x}Ti_x$ (x = 0–2.0) melt-spun ribbons, the structures were examined by XRD and thermomagnetic studies. Figure 2 shows the XRD patterns of the $(Sm_{0.8}Zr_{0.2})_5(Fe_{0.75}Co_{0.25})_{17-x}Ti_x$ (x = 0–2.0) melt-spun ribbons annealed at 1073 K. The $(Sm_{0.8}Zr_{0.2})_5(Fe_{0.75}Co_{0.25})_{17}$ melt-spun ribbon consisted of the Sm_5Fe_{17}-type phase. To our surprise, the specimens with added Ti did not consist of the Sm_5Fe_{17}-type phase but rather the $SmFe_3$-type phase. In other words, the achieved high coercivity in the annealed $(Sm_{0.8}Zr_{0.2})_5(Fe_{0.75}Co_{0.25})_{15.5}Ti_{1.5}$ melt-spun ribbon was not due to the Sm_5Fe_{17}-type phase but to the $SmFe_3$-type phase. This indicates that the addition of Ti to the $(Sm_{0.8}Zr_{0.2})_5(Fe_{0.75}Co_{0.25})_{17}$ melt-spun ribbon impeded the formation of the metastable Sm_5Fe_{17}-type phase and led to the formation of the stable $SmFe_3$-type phase. In conclusion, it was found that the addition of Ti to $(Sm_{0.8}Zr_{0.2})_5(Fe_{0.75}Co_{0.25})_{17}$ melt-spun ribbon changed the metastable Sm_5Fe_{17}-type phase into the stable $SmFe_3$-type phase. The resultant $(Sm_{0.8}Zr_{0.2})_5(Fe_{0.75}Co_{0.25})_{15.5}Ti_{1.5}$ melt-spun ribbon with the $SmFe_3$-type phase exhibited a high coercivity of 13.3 kOe. This work was supported by Grant-in Aid for Scientific Research (KAKENHI) No. 17K06776 from the Japan Society for the Promotion of Science (JSPS). The use of the facilities of the Materials Design and Characterization Laboratory at the Institute for Solid State Physics, The University of Tokyo, is gratefully acknowledged.

CS-10. Coercivity Mechanism of SrO●6Fe_2O_3 Ferrite Magnets.

Y. Matsuura[1]
1. Research Institute for Applied Sciences, Kyoto, Japan

1. Introduction In our previous work[(1), (2)] we found that the alignment dependence of the coercivity (ALDC) of ferrite magnets behaves similar to that of Nd-Fe-B sintered magnets. The coercivity of ferrite magnets decreases as the alignment (α) improves, where α is defined by Br/Js, and Br and Js are the residual and saturation magnetizations. α is also calculated using the alignment distribution function (ADF) ($P(\theta)$), which is obtained by electron back-scattered diffraction (EBSD). θ indicates the angle from the alignment direction. Further, $P(\theta)$ was found to be similar to the Gaussian distribution function (GDF) from EBSD. It was found that the calculated α agreed well with the experimental results.[(2)] From the ALDC in Nd-Fe-B sintered magnets, the coercivity decrease ratio (β) is defined by as follows, $\beta=((H_{cJ} - H_{cJisotropy}) / H_{cJisotropy})$ x 100. where H_{cJ} and $H_{cJisotropy}$ are the coercivities of the aligned and isotropic magnets, respectively. The value for β is also calculated using $P(\theta)$. The coercivity is determined by the magnetic field at zero magnetization. The value of H_{cJ} is determined by the magnetic field at J=0 in the calculation using $P(\theta)$. θ_1 is defined as the angle of the magnetization reversal area (AMRA). The calculated and measured results for β exhibit a large discrepancy, demonstrating the invalidity of the postulation that every grain independently reverses by the magnetic domain wall motion or the 1/cos θ law. Instead, it is suggested that the simultaneous reversal of a number of grains is induced by the magnetic domain wall jump. The measured θ_1, which is defined as the angle of the magnetization reverse area, is obtained using the measured β and, when compared with the calculated θ_1, the measured θ_1 is found to be larger than the calculated θ_1.[(3)] Further, the measured θ_1 is more similar to that of a lower-alignment magnet of calculation than the measured θ_1. Thus, in the magnetization reversal process, the coercivity of the aligned magnets behaves like that of low-aligned magnets: by the pinning and de-pinning of the magnetic domain walls. When a GDF with a standard deviation (σ) is used for calculation of the angular dependence of the coercivity (ANDC), where the GDF has same θ_1 value as that obtained by experiment, it was found that the experimental results of the ANDC are qualitatively explained. It is important to determine whether the ANDC of ferrite magnets can also be explained using same logic used for Nd-Fe-B sintered magnets. 2. Experiment Ferrite magnets with a composition of $Sr_{0.6}Fe_2O_3$ and α=0.5, 0.57, 0.87 and 093 were cut in 7×7×7 mm cubes for magnetic property measurements of the ALDC, and into $^{\Phi}4\times4$ mm cylinders to measure ANDC. The Br and Js values are measured by a permeameter with a 2 T maximum magnetic field. ANDC is measured by a vibrating sample magnetometer with a 1.7 T magnetic field. 3. Results and Discussion Figure 1 shows the calculated values of θ_1, and the θ_1 values of the $Sr_{0.6}Fe_2O_3$ magnets calculated using the measured β value. The calculated values for θ_1 imply that every grain independently follows the 1/cos θ law. However, the measured θ_1 values in the actual magnets are greater than the calculated ones, suggesting that a number of grains reverse simultaneously by pinning and de-pinning of the magnetic domain walls. It was found that $Sr_{0.6}Fe_2O_3$ with α=0.93 has a θ_1 of 41°, similar to the calculated results with the GDF of σ=70°. Using σ=70°, the ANDC is calculated and is then compared with the experiment. Figure 2 shows the calculated and experimental results. The ANDC of $Sr_{0.6}Fe_2O_3$ decreases with increasing magnetic field angle until 40°, after which the coercivity gradually increases until 70°. At a glance, this behavior of the ANDC seems like a coherent rotation of magnetization, but the calculation results using σ=70° and θ_1=41°, obtained from the ALDC, agrees well with the experiment until Φ=40°. These results reinforce our speculation that the coercivity of ferrite magnets is also determined by the pinning and de-pinning of magnetic domain walls.

CS-11. Electronic structure and magnetic property of $Ba_{1-x}Sr_{x}CoFe_{11}O_{19}$ hexaferrites.

N. Tran[1], D. Kim[1], H. Kim[1], S. Lee[1], T. Phan[1] and B. Lee[1]
1. Department of Physics and Oxide Research Center, Hankuk University of Foreign Studies, Yongsi-si, The Republic of Korea

Ferrite materials play an important role in promoting the development of modern electrical and electronic devices. In the oxide form, two ferrite systems are usually interested to be cubic spinel ferrites (*Me*Fe_2O_4, where *Me* is a divalent cation) and hexagonal ferrites (hexaferrites). Though the hexaferrites were discovered since 1950s, there has been an exponentially increasing interest until now [1]. Among the hexaferrites, M-type barium hexaferrite ($BaFe_{12}O_{19}$) has attracted a special interest because this material can be fabricated by simple techniques and has many intriguing properties. For example, with the large coercive force (H_c), high Curie temperature (T_C, above 700 K [2]), corrosion resistance, and high chemical stability, $BaFe_{12}O_{19}$ is usually used to fabricate permanent magnets. One has also found its promising applications in high-density recording media, microwave-related devices, and energy conversion and storage devices [1, 3]. Because the magnetic property of $BaFe_{12}O_{19}$ can easily tuned as expected upon changing fabrication conditions, crystal sizes, and dopants, its application range is remarkably widened. It has been found that the changes in fabrication conditions and dopants would create different intrinsic defects (such as crystal defects, impurities, and grain morphology), which influences the magnitude of H_c and the saturation magnetization (M_s). For the doping case, Ba and Fe in $BaFe_{12}O_{19}$ can be substituted with alkaline-earth (or rare-earth) and 3*d* transition metals, respectively [2-5]. To explain the magnetic property of these compounds, it is necessary to know the crystal and electronic structures. Such works are usually based on X-ray diffraction, X-ray photoelectron spectroscopy, and Mössbauer technique [2, 4]. To the best of our knowledge, there is no work on X-ray absorption spectroscopy (XAS) to find out the relation between the electronic structure and magnetic property of doped $BaFe_{12}O_{19}$. Taking into this problem, we have prepared $Ba_{1-x}Sr_{x}CoFe_{11}O_{19}$ samples. Their crystalline/electronic structures and magnetic property were then studied. $Ba_{1-x}Sr_{x}CoFe_{11}O_{19}$ (x = 0-1) nanoparticles (NPs) were prepared by co-precipitation method, using $Ba(NO_3)_2$, $Sr(NO_3)_2$, $Co(NO_3)_2.6H_2O$, and $Fe(NO_3)_3.9H_2O$ as precursors. These chemicals with stoichiometric ratios were dissolved in 100 mL DI water at 90 °C. After that, 50 mL NaOH solution (1 M) was added to the mixtures and continuously stirred for 2 h. The products after chemical reactions were filtered, washed by ethanol and DI water, and annealed at 900 °C for 3 h in air. Finally, the products were checked the grain morphology by a scanning electron microscope (SEM, JSM-5410LV). Their crystal and electronic structures were studied by an X-ray diffractometer (Rigaku, MiniFlex) and XAS (the 8C nano-XAFS beamline, Pohang Light Source). The magnetic property was studied by a vibrating sample magnetometer. All investigations were carried out at room temperature. Results revealed that fabricated $Ba_{1-x}Sr_{x}CoFe_{11}O_{19}$ NPs with average particle sizes of 100~300 nm crystallized in a hexagonal structure (P6$_3$/mmc space group). When Sr content (x) increases, the shape of crystals modifies very much while the unit-cell parameters decrease due to the replacement of Sr^{2+} (1.18 Å) for Ba^{2+} (1.35 Å). Detailed analyses for the Fe and Co *K*-edge XAS spectra prove oxidation numbers of Fe and Co to be 3+ and 2+, respectively, which are stable versus an x change in $Ba_{1-x}Sr_{x}CoFe_{11}O_{19}$, Fig. 1. Our study has also found a small change of the Fe-O bond length in between 1.89 and 1.91 Å. Though both the hexagonal and electronic structures are almost unchanged by Sr doping (excepting for the lattice parameters), our study on the magnetic property has indicated the x dependence of magnetic parameters, as seen in Fig. 2. While M_s decreases from 46.1 emu/g for x = 0 to 34.2 emu/g for x = 1, H_c tends to increase from 1630 Oe for x = 0 to ~2200 Oe for x = 0.5, but slightly decreases to 2040 Oe as x = 1. We think that such M_s changes are related to in the exchange interactions between Fe^{3+} and/or Co^{2+} ions located at the octahedral, tetrahedral, and bipyramid sites, which are sensitive to the changes related to local structures, such as Fe/Co-O bond lengths and Fe/Co-O-Fe/Co bond angles. Meanwhile, the H_c change is mainly due to different grain sizes, morphology, and shapes. Our work also reviews recent reports on M-hexaferrites, and discuss in detail their magnetic property, particularly $BaFe_{12}O_{19}$-related compounds.

CT-01. Characteristic Analysis and Design of a Novel Ironless Halbach-magnetized Permanent Magnet Linear Synchronous Motor.

L. Zhang[1] and B. Kou[1]
1. Department of Electrical Engineering, Harbin Institute of Technology, Harbin, China

Abstract —This paper proposes an ironless permanent magnet linear synchronous motor (ILPMLSM) with a novel Halbach array. The magnetic flux density distribution of the Halbach array is solved analytically by using the equivalent magnetization current method (EMCM). Expressions of the no-load back-EMF and the electromagnetic thrust are obtained. The design of the coils and permanent magnet are studied respectively, the effects of the parameters of the magnets on the electrical properties of the ILPMLSM are analysed. A prototype motor is manufactured, and some experiments were carried out with it. I. Introduction At the present time, there exist many various applications with linear motor in all parts of the industry. In some special applications, the low torque ripple and high precision position control are needed. In this case, the permanent magnet linear synchronous motor with moving ironless windings seems to be as suitable electrical machine. In this paper, an ironless permanent magnet linear synchronous motor (ILPMLSM) with a novel double side Halbach array is analysed, as shown in Fig. 1. Electromagnetic analysis and design method investigation of the ILPMLSM are the main contribution of this paper. II. Analytical Model of the ILPMLSM Based on the equivalent magnetization current method, the air-gap flux density distribution of the motor is obtained by calculating the vector sum of the field generated by all the magnets in the array. The y-component of air-gap flux density distribution can be obtained. Based on the Lorentz law, the thrust of the ironless permanent magnet linear synchronous motor can be derived. Assuming the ironless windings moving in the x-direction with a velocity v, the expression of the back-EMF of coils with *N* turns can be also derived. III. Design and Optimization of the ILPMLSM The main dimensions of the ILPMLSM are derived. The design of the coils and permanent magnet are studied respectively, the effects of the parameters of the magnets on the electrical properties of the ILPMLSM are analyzed. The fundamental component of the air-gap flux density affects directly the amplitude of the average thrust, and the magnetic flux density is mainly affected by the top width and the top height of the PMs, the bottom width and the bottom height of the PMs, and the air-gap length. The relationships between the fundamental air-gap flux density and the five dimension coefficients are investigated. IV. Prototype and Experiment Based on the previous analysis in this paper, a prototype of the ILPMLSM has been designed and manufactured, as shown in Fig.2. And some experiments are carried out with the prototype to verify the satisfactory design of the ILPMLSM. Fig. 2 shows the prototype and experimental results. V. Conclusion This paper investigates an ironless Halbach-magnetized permanent-magnet linear synchronous motor. The air-gap flux density distribution was obtained by using equivalent magnetization current methods and the analytical model of the ILPMLSM was established. Design method and optimization of the ILPMLSM were investigated. Based on the analysis, a prototype motor was designed, built and tested. Experimental data indicated satisfactory design.

CT-02. Power Factor Improvement of Linear Permanent-Magnet Vernier Motor by Using Dual-Inverter.

D. Xu[1], *W. Zhao*[1] and P. Zhao[1]
1. School of Electrical and Information Engineering, Jiangsu University, Zhenjiang, China

INTRODUCTION Linear permanent-magnet vernier motor (LPMVM) has the merits of high efficiency, high force density and low cost, which is very suitable for long stroke applications [1]. However, it suffers from relatively lower power factor [2]. Recently, open-winding (OW) motor fed by dual-inverter with a floating capacitor was presented by opening the neutral point of three-phase stator windings and then connecting two inverters to two winding ends respectively [3]-[5]. The purpose of this paper is to improve the power factor of the LPMVM by using the dual inverter OW technique. METHOD Fig. 1 shows the block diagram of the proposed control method. The terminal voltage vector of the OW-LPMVM is decomposed into two orthogonal quantities to drive the dual-inverter. The active and reactive powers required by the motor are produced by main inverter (MI) powered the DC power and compensation inverter (CI) powered the floating capacitor respectively, so the power factor of the LPMVM system can be improved. In this work, an acquisition method of orthogonal voltage vectors is proposed based on instantaneous power theory, which can avoid the use of the trigonometric and inverse trigonometric functions. Consequently, the proposed method can be easily implemented without heavy computational load. RESULTS Laboratory prototype of an OW-LPMVM is shown in Fig. 2. Fig. 3 shows the experimental results of the electromagnetic force, the mover velocity, and the floating capacitor voltage of the OW-LPMVM dual-inverter drive system. It can be seen from Fig. 3(a) and Fig. 3 (b) that the LPMVM has a good performance when system enters a steady state with v_{ref} = 0.32 m/s and F_L = 100 N. It can be seen from Fig. 3(c) that the capacitor voltage can be controlled to dynamically keep as a constant value that is the same as the DC-link power voltage. Fig. 4 shows the experimental results of the low-pass filtered pole voltages of dual-inverter and armature current. It can be observed from Fig. 4 that pole voltage u_{a1} of the MI is in phase with armature current i_a while pole voltage u_{a2} of the CI approximately lag i_a by 90 degrees. Therefore, the proposed power factor improvement method exhibits a good effect in improving the equivalent power factor of the LPMVM. More details will be given in the full paper.

CT-03. Detent Force Investigation in Long-stator PM Linear Machines with Non-ideal Mechanical Airgap Condition.

M. Ma[1]
1. School of Electrical Engineering and Automation, Hefei University of Technology, Hefei, China

I. Introduction The end effects of detent force is inherent characteristic of permanent magnet (PM) linear machines, and it is also the significant drawbacks for motion control and high-precision applications. Many foregoing efforts have been proposed to reduce detent force [1]. For the long-stator (Moving-magnet) linear machines, it is widely adopted modular segments, which is easy to assemble and maintain. But the assembled structure will causes non-ideal mechanical airgap condition inevitably, and it brings significant effects on detent force, which is comparatively less observed by researchers. Because of the uneven actual airgap situation, the calculation model and the suppression method of detent force should be discussed and determined. Hence, in this paper the non-ideal mechanical airgap condition in long-stator linear machines is generalized and simplified. And then, the detent force characteristics are studied based on the variable airgap analysis model. Finally the the measures to eliminate the detent force in the non-ideal mechanical airgap condition are analyzed. II. non-ideal mechanical airgap condition analysis The uneven mechanical airgap condition in long-stator linear machines is mainly caused by the deformation of the mover and the assembly errors shown in Fig.1 a). Generally the large normal force exits between PM mover and stator core, so the mover yoke will be deformed. In addition, the multi-segments stator appears in an assembled array, and the air gap length of boundary between two stator segments is hard to control. To sum up, the non-ideal air-gap condition appears. First, the actual air gap situation in long-stator prototype are tested, and the data is listed as shown in Fig. 1 b). The measured point 1 and point 7 are located ends of stator, while point 3 and point5 are located at the junction of segments. The other points are distributed in equally space. It is well known that accurate calculated results can be obtained by finite element method. However, the actual air gap situation for long-stator linear prototype is very complex for the whole stroke, modeling analysis will face the meshing problem of irregular air gap. Hence, based on the actual data the non-ideal mechanical air gap conditions are categorized into two types: linear deviation air gap situation and V shaped airgap situation. III. detent force calculation and suppression Based on the above categories, the detent force characteristics in different non-ideal mechanical air gap condition are analyzed by finite element method. In numerical model, a wedge-shaped air gap develops because of uneven air gap conditions. The wedge-shaped air gap needs to be divided into several combinations of entities, and corresponding mesh lengths are set for different entities different. The sub-regional triangulation technology are adopted to ensure the quality of narrow area of grid. The results show that: 1) the positive and negative amplitude of detent force waveforms are asymmetrical in linear deviation air gap situation. The deviation in one direction occurs, and the positive or negative deviation will produce corresponding changes. 2) The V shaped air gap includes two conditions: V mouth up and V mouth down. In V shape air gap it can be seen that the positive and negative amplitude of detent force are still asymmetrical, but they gradually tend toward uniformity in middle region. For the detent force in non-ideal airgap condition, the suppression method of skewing is effective, and the optimal skewing length are obtained. The experiment of detent force shown in Fig. 2 are carried out to verify the correctness of the analysis results. IV. Conclusion This paper presents detent force characteristics analyses for long-stator PM linear machines with non-ideal mechanical air gap situation. The non-ideal mechanical air gap condition is categorized depending on measured data of actual airgap length. And then corresponding calculated models with sub-regional triangulation technology are established. The skewing method is an efficient way for detent force suppression. The analysis results can provide references to operational analysis and assembly process for long-stator PM linear machines.

CT-04. Algorithm of Linear Induction Motor Control Considering End-effect of Magnetic Levitation Train Propulsion System.

H. Seo[2], J. Jeong[1], G. Choe[3] and J. Lim[4]

1. Dept. of Electrical Engineering, Chungnam National University, Daejeon, The Republic of Korea; 2. EV Team, R&D Center, VCTech, Gunpo, The Republic of Korea; 3. Dept. of Electrical Engineering, Konkuk University, Seoul, The Republic of Korea; 4. Dept. of Magnetic Levitation and Linear Drive, Korea Institute of Machinery & Materials, Daejeon, The Republic of Korea

This paper proposes a propulsion control algorithm considering End-effect of a linear induction motor (LIM) used in a magnetic levitation train. Indirect field oriented control (IFOC) technique is one of the popular control techniques widely applied to LIM drive control. The main idea of IFOC in a LIM is the decoupling of the flux and torque. Therefore, IFOC has a higher dynamic characteristic than the scalar control [1]. The LIM applied to the magnetic levitation trains should control the thrust force and also take into account the normal force for levitation stabilization. When the LIM is driven, normal force is inevitable. The normal force is a function of the speed, the slip frequency and the current of the train. In the rotary type induction motor, the normal force is canceled due to its symmetrical structure. Therefore, IM could operate in a low slip and high efficiency range. However, in the case of LIM, a high attraction force is generated in a low slip region, which cause the instability of the levitation system. Therefore, the propulsion control for magnetic levitation trains must operate in a higher slip region than the slip used in conventional IFOC. In this paper, the slip characteristics of the LIM are analyzed to improve the efficiency and safety of the magnetic levitation train by FEM analysis. A constant slip frequency propulsion control algorithm is proposed for operation in the analyzed slip region. The proposed algorithm can be controlled by separating magnetic flux and thrust from IFOC. The proposed algorithm is verified in 250 kW test bench. The results of FEM analysis according to speed and slip at constant voltage condition are shown on Fig. 1. The dotted lines of Indirect Field Oriented Control(IFOC) and Constant Slip Indirect Field Oriented Control(CSIFOC) are shown on the figure. The slip of the IFOC is low and that leads to operate near the maximum thrust and efficiency. However, the normal force of LIM is also increase, which could not be allowed in maglev application. On the other hand, when CSIFOC is performed considering normal force, the slip is higher than the conventional algorithm. Although the CSIFOC is not operated in maximum thrust slip, the normal force could be greatly reduced. Fig. 2 (a) shows the CSIFOC algorithm considering the end-effect of the linear induction motor. In general IFOC, the d-axis current reference is calculated through the magnetic flux reference value, and the q-axis is calculated based on thrust. However, the CSIFOC for the LIM generates the d-axis and q-axis current references along with the slip frequency and thrust. Fig. 2 (b) shows the waveform of the experimental results based on the general IFOC and the proposed algorithm. Both IFOC and CSIFOC were tested with the same rate pattern of the same load. It is confirmed that CSIVC has larger slip than conventional IFOC and low normal force in all regions. In this paper, a constant slip frequency IFOC algorithm is proposed considering the end effect of LIM used for magnetic levitation trains. The efficiency, thrust and normal force according to the speed and slip through the FEM analysis of the LIM were analyzed and the slip condition suitable for the magnetic levitation train is proposed. In addition, a current reference generation algorithm based on the thrust and slip is proposed in the IFOC considering the end effect to operate under the proposed slip condition. In the full paper, the detailed formulas of the proposed algorithm are developed and will be verified through simulation and experimental results.

CT-05. Experimental Verification of Characteristic Analysis and Performance Verification of Double-Sided Permanent Magnet Linear Synchronous Generator Designed with Three-Dimensional Effects for Ocean Wave Energy Converter.

S. Seo[1], G. Jang[1], M. Koo[1], K. Kim[2], K. Hong[2] and J. Choi[1]
1. Electrical Engineering, Chung-nam National University, Daejeon, The Republic of Korea; 2. Offshore Plant Research Division, Korea Research Institute of Ships & Ocean Engineering, DaeJeon, The Republic of Korea

In this study, a three-dimensional (3D) analysis method and a manufacturing model are used for generating performance analysis and experimental verification on a double-sided permanent magnet linear synchronous generator (PMLSG) with a slotless stator, as shown in Fig. 1(a) [1]. The PMLSG with a slotless stator has a moderately large magnetic air gap; thus, it should be analyzed considering the end effects, such as fringing and leakage flux. Due to these effects, the PMLSG requires a 3D analysis method and a variety of other approaches, including the numerical and analytical methods that have been used in previous studies, for electromagnetic field analysis [2-4]. The 3D finite element (FE) analysis is a highly reliable numerical method; however, the design parameters increase the analysis time, as shown in Fig. 1(b). Conversely, there are methods to reduce the analysis time along with increased reliability, such as the 3D analytical approach. For the 3D analytical approach, the PMLSG can be simplified and represented on an xy-plane and a yz-plane, as shown in Fig. 1(c). As the fringing and leakage flux emerge in the z direction, its end effects should be considered to improve the accuracy. Further, the flux density results of the open circuit and armature reaction fields are generated by permanent magnets (PMs) in a mover and by currents in stator windings. Articles designed in this manner have already been published in reference paper [1]. However, reference paper [1] addressed the results up to the counter-electromotive force at no load. Therefore, in this paper, we will cover the details of the process subsequent to those outlined in the reference paper [1]. For the PM linear generator to be applied to the ocean wave energy converter, highly efficient energy conversion is important; however, maximum power generation is more important considering the wave motion to change in real-time. Therefore, we propose the characteristic map of the generating performance, that is, the characteristic results of power, losses, efficiency, force, and power take-off (PTO) damping coefficient. The conditions for optimum performance and the range of maximum power generation can be obtained from these results. Further, when regular wave energy is generated, the heaving motion of the buoy is changed by the PTO damping coefficient from the PM linear generator, and the input velocity of the PM linear generator is affected by this phenomenon. Therefore, the condition selection for maximum power in regular wave energy is very important for the ocean wave energy converter. Therefore, this paper deals with the generating characteristics of the PM linear generator, with the heaving motion of the buoy coupled with the generator according to the ocean wave variation. Finally, we deal with the generating results of the PM linear generator for the ocean wave energy converter according to the irregular input wave. Fig. 2 shows the experimental results of two cases with the no-load and load tests (load resistance condition, 2 Ω). Here, the two cases represent the difference in the irregular velocity. The irregular velocity is simulated using irregular wave energy and heaving buoy motion equation. In the detailed manuscript, firstly, we will present a simple summary process of the 3D analysis method and various experimental results of the manufactured model; and all the analytical procedures are specially designed to contribute to related research and industrial applications. ACKNOWLEDGMENTS This work was supported by the Basic Research Laboratory (BRL) of the National Research Foundation (NRF-2017R1A4A1015744) funded by the Korean government.

Single-sided linear induction motors (SLIMs) have merits such as high initial thrust, simple structure, flexible mechanism, absence of dust emission, and low noise [1]. Thus, SLIMs are broadly adopted as a traction component in many industrial applications, especially in magnetic levitation (maglev) transportation systems or urban train systems [2]. The 200km/h-class semi-high-speed maglev train currently being developed in Korea uses SLIMs to propel it. SLIMs are widely used for the propulsion of maglev trains, as they are lightweight and inexpensive to produce. However, their driving characteristics are inferior to those of linear synchronous motors (LSMs) because of their low power factor and the presence of slip. Therefore, to increase the operation efficiency of maglev trains using SLIMs, it is important to analyze the characteristics of speed and slip and identify the optimal operating points. This study analyzes the thrust, normal force, and efficiency characteristics of semi-high-speed maglev train LIMs in detail, using two-dimensional (2D) finite element method (FEM). The maximum thrust and efficiency range were determined using this analysis. An efficiency map was derived based on the operating conditions in the constant-thrust region. Furthermore, the thrust based on the constant power region was analyzed to demonstrate the overall operating capabilities of the LIM. The thrust, normal force, and efficiency were analyzed in detail according to the overall driving speed and slip condition, and it was presented as a contour map. Based on the characteristics map of LIM derived, we proposed a new thrust control algorithm by reflecting the optimum slip frequency in the control algorithm. Among the characteristics of the analyzed LIM, a new propulsion algorithm was proposed to minimize the energy consumption, and the feasibility was verified by simulation and experiment. Finally, the consumption energy of the new algorithm was calculated to confirm that the energy was reduced compared to the existing algorithm. A diagram of the semi-high-speed maglev train and the associated LIM is shown in Fig. 1 (a). Fig. 1 (b) is a plot of the thrust, normal force, and efficiency with respect to slip at the rated speed of 90 km/h. Fig. 1 (c) is an efficiency map created by FEM analysis of slip for various speeds. In this analysis, the variation of efficiency with respect to slip can be observed for speeds of up to the maximum speed of 200 km/h. The map shows very high efficiency values for slip values between 0.1 and 0.3, and the trend indicates that efficiency increases as speed increases at lower speeds. At the points where efficiency increases, the thrust and the normal force values can be referenced for high-efficiency operation of the maglev train. Fig. 2 (a) is a block diagram of the optimal slip indirect vector control (OSIVC) algorithm. The basic configuration is consistent with the constant slip frequency control, but the part of inputting the slip frequency command depending on the optimal slip modeling according to speed is different. Fig. 2 (b) compares the power consumption of thrust control algorithm. The highest power consumption is shown when using regular IVC. When SCFIVC and IVC are compared, the final amount of power can be reduced by 12%, and it was finally found that 2% is reduced more when using OSIVC. This energy difference is caused by the fact that it was operated with the best slip for the motor and driven with the highest slip frequency. The constant slip frequency control in the acceleration/deceleration regions yields maximum efficiency points different from the constant-speed region, so the energy consumption is greater than in the constant-speed region. These characteristics are valuable to semi-highspeed Maglev trains, as they experience a considerable amount of acceleration and deceleration during their operation. Fig. 2 (c) is a manufacturing model for performance evaluation, and we will present the results on a full paper.

CT-07. Design and Reduction of Thrust Ripple in Transverse Flux Permanent Magnet Linear Machine.

M. Zhao[1,2], K. Liu[3], H. Yang[1], N. Feng[1], D. Hou[1], P. Zhang[1] and M. Xu[1]
1. Ludong University, Yantai, China; 2. Harbin Institute of Technology, Harbin, China; 3. Southeast University, Nanjing, China

This paper proposed a tubular transverse flux permanent magnet linear machine with the quasi-distributed stator segments, due to the problem of larger thrust force ripple in the machine, which has some merits higher force density and better controllable characteristic etc. Firstly, the structure and operating principle of tubular transverse flux permanent magnet linear machine was presented. Secondly, the influence of the quasi-distributed stator segments on the motor performance is analyzed in detail. Special attention is paid to the Back-EMF, cogging force and electromagnetic force etc. The paper investigates the influence of different arrangements in transverse flux permanent magnet linear machine, including theoretical analysis and numerical calculation. The results show that the thrust ripple can be decreased by the quasi-distributed stator segments in transverse flux permanent magnet linear machine. I.Introduction With the concept of shipboard electrical ejection system being put forward, the studies of high thrust permanent magnet linear motor are carried out by international scholars, which are focused on moving-magnetic type permanent magnet linear motor at present [1]. However, as a new type of high thrust density linear motor, the permanent magnet linear motor (PMLM) is still on the stage of exploring study [2-5]. The structure parameters of machine were optimized by 3-D magnetic grid method and response surface method, in order to improve the thrust density of the machine. A novel bidirectional cross-linking transverse flux tubular PMLM was investigated, which has solved the lower utilization rate of secondary permanent magnet in transverse flux PMLM. However, the motor has some disadvantages, such as complicated structure, higher requirements of processing technology and troublesome in winding placement. In a word, this type of motor has a good application prospect in the field of linear direct drive system. II.ICONSTRUCTION AND PRINCIPLE OF TUBULAR TRANSVERSE FLUX PERMANENT MAGNET LINEAR MACHINE The novel stator segment axial distribution arrangement transverse flux PMLM has been investigated in this paper. Fig. 1 shows the physical model of tubular transverse flux PMLM with four core segments on the stator and six pairs of poles on the mover. II.TRANSVERSE FLUX PERMANENT MAGNET LINEAR MACHINE WITH QUASI-DISTRIBUTED STATOR SEGMENTS In general, the stator core stacks of transverse flux linear machine are axially arranged in a distance of a double pole pitch. However, this paper proposed a novel stator stacks distribution, called as class distribution, as shown in Fig.2. One thing to note here is that the class distribution arrangement comes from traditional motor distributed winding while it is different from the definition of distributed winding at the same time. The theoretical derivation process will be presented with more detail in full paper. III.Conclusions A novel tubular transverse flux PMLM with the quasi-distributed stator segments is proposed in this paper. It investigates the influence of different distribution mode on the machine performance including back-EMF, cogging force and electromagnetic force. (1) The 5th and 7th harmonic of back-EMF can be eliminated when the distance of laminations group y1 are $9\tau/5$ and $27\tau/14$ respectively for the given pole pitch of τ and the stator segment number q of 4. Furthermore, it proves the validity of theoretical derivation by using numerical calculation. (2) The amplitude of cogging force is decreasing with the decrease of distances of stator laminations group by using numerical calculation of cogging force. (3) The amplitude of 6th ripple force can be obviously reduction when the distance of stator laminations group is $23\tau/12$ by using numerical calculation of electromagnetic force.

CT-08. Design and Implementation of Amorphous Magnetic Material-Based Common Magnetic-Bus for the Replacement of Common DC-Bus.

M. Islam[1], K. Muttaqi[1], D. Sutanto[1] and J. Zhu[2]
1. Faculty of Engineering and Information Sciences, University of Wollongong, Wollongong, NSW, Australia; 2. Faculty of Engineering and Information Technologies, University of Technology, Sydney, NSW, Australia

In recent years, smart microgrid technologies are gaining considerable interest, where a common dc-bus is generally used to interconnect multiple power sources, e.g. solar photovoltaic (PV) modules [1]– [3]. In a dc-bus based solar microgrid system, multiple PV modules deliver power the dc-bus through maximum power point tracker (MPPT) and dc/dc converters. The MPPT ensures the operation of solar PV modules at maximum power point (MPP) but provides output voltage that is not constant. The dc/dc converter is used to control the output voltage at the dc-bus level. The operating point of all MPPTs may not be the same as the radiation or temperature levels on PV modules are not always the same. Therefore, the generation of common dc-link voltage from different PV modules limit the range of MPPT operation, i.e. some MPPT fails to extract the maximum power. In this paper, a high-frequency (about 10 kHz) common magnetic-bus as a replacement for common dc-bus has been proposed to overcome the restriction of MPPT and complication of the PV inverter operation. The design process of the high-frequency magnetic-link leads to multi-physics problems with some critical decision making tasks and thereby affects the power converter efficiency and cost. Optimal design of high-frequency magnetic-links with advanced soft magnetic materials having high saturation flux density and low specific core loss, is requested to improve the power conversion efficiency. For large capacity high-frequency transformers, it is desirable to have a high saturation flux density to avoid large volume and low core loss to achieve high efficiency. Because of these superior characteristics, e.g. the saturation flux density, specific core loss, cost, and availability of various size strips (wide) the Fe-based amorphous magnetic alloy 2605S3A has been used in high power applications [4]–[8]. Moreover, the price for iron-based Metglas magnetic material has decreased significantly in recent years. The high-frequency magnetic-links are usually excited with square wave voltage which significantly increases the core losses compared with that obtained under sinusoidal voltage excitation. The vendors, e.g. Metglas Metals, provide only the core loss data under sinusoidal voltage excitations. Using the given data (measured under sinusoidal voltage excitation), it is really difficult to obtain an optimal design of high-frequency magnetic-links [9]. In order to obtain an optimal design, the magnetic material 2605S3A is characterise under square-wave voltage excitation. In the ANSOFT Maxwell 3D environment, a magnetic core is modelled using the optimal parameters obtained from optimization and square-wave voltage high-frequency characteristics of amorphous alloy 2605S3A. The ANSOFT Maxwell 3D gives the electromagnetic field distributions for a specific model with given magnetic material, boundaries, and source conditions, applying Maxwell's equations over a finite region of space. To verify the feasibility of the proposed concept a high-frequency magnetic-bus is developed. Based on the optimization results, amorphous alloy 2605S3A sheet (2.5 cm wide and 20 μm thick) was collected from Metglas Metals Inc., USA. For the electrical insulation and mechanical bonding, the Metglas sheet was glued with Araldite 2011 on the surface of each layer. During the wrapping of Metglas stripes of 2605S3A, equal and opposite forces were applied to make a uniform distribution of Araldite. Fig. 1 shows a photograph of the magnetic-bus with inner and outer frames. After wrapping, the frames were removed before the Araldite dried up, e.g. within 2 hours. To minimize the proximity effect, Litz wires are used for windings with single layer placement. Fig. 2 shows a photograph of developed four windings high-frequency magnetic-bus. The high-frequency inverter generates square-wave voltage which is used to energize the primary coil of high-frequency magnetic-bus. The core losses of amorphous alloy 2605S3A in terms of flux density and frequency with square-wave voltage excitation were measured. All secondary windings show similar total loss characteristics. Such a similarity of characteristics is also necessary to ensure balance three dc-supplies for the modular multilevel inverter, which helps to eliminate the extra control circuit to mitigate the imbalancing problem. These design and implementation techniques would have great potential for the development of new medium or high-voltage inverters for solar PV systems and smart micro-grid applications, especially in replacing common dc-buses by magnetic-buses. The detail developmental process of high-frequency magnetic-bus using amorphous magnetic alloys will be explicitly described in full paper.

CT-09. Research on Detent Force for Tubular Permanent Magnet Linear Motor with Skewed Core End.

G. Zhao[1], Y. Wang[1], B. Bai[1] and X. Gao[1]
1. Shenyang University of Technology, Shenyang, China

I. INTRODUCTION Detent force is a major concern in the linear motor, which is brought by the discontinuity of the core end. The detent force can reduce the positioning accuracy in servo system, so many people have done many work to weaken it [1][2]. The method for reducing the cogging force by auxiliary slots is mentioned in [3], in which the analytic relationship between the auxiliary slot number and the cogging force is derived and the selection of the auxiliary slot number is also discussed. The end effect detent force of permanent magnet linear motor (PMLM) is analyzed based on the lateral force method [4]. The analytical expressions describing the position and the width of auxiliary poles are derived. In this paper, a method of skewed primary core end for the tubular PMLM is proposed and the prototype is designed and manufactured. The analytical relation between the skewed primary core end length and the detent force is derived, from which the best skewed end length can be obtained. Subsequently, the detent force is analyzed by finite element method (FEM) and the detent force of the tubular PMLM with the skewed primary core end has been significantly reduced compared to the direct core end one. II. Analysis of tubular PMLM with skewed ends As shown in Fig.1, a common tubular PMLM that its primary core end (called motor 1 below) is direct is designed and the motor have 12 slots 11 poles. Several factors influencing the detent force such as the primary core length, pole arc coefficient and the tooth width have been optimized by FEM. But the peak detent force still exceeds 20N. The design and analysis details will be given in full paper. Based on the motor above, a tubular PMLM scheme with skewed primary core end (called motor 2 below) is proposed as shown in Fig.2. The two motors have the same secondary core in order to compare the influence of skewed core end. For the motor 2, phase difference will be generated between the skewed primary core end and the permanent magnet poles. So if the appropriate length of skewed primary core end is chosen, end force can be reduced significantly because of the phase difference. The analytical equation of the detent force can be deduced according to analyzing the model of motor 2, shown in equation (1), Where F_{slot}, F_{end} is the cogging force and the end force, respectively. d, δ, Φ_m, μ_0, τ is the length of skewed primary core end, the length of the air gap, the maximum magnetic flux, the vacuum permeability, the pole pitch, respectively. S is a half of a magnetic pole area; D is the shaft radius of tubular PMLM; C is an equivalent length that is equal to the product of slot number and slot pitch; α is the equivalent angle between tooth and the permanent magnet if the tubular TMLM is regarded as a rotational motor; Z is the slot number; p is pole pair. The derivation process will be given in full paper. From the equation, the detent force is composed of three parts, the third part is cogging force and it is a constant when the number of slots and poles are certain, but the first and second parts change as the d varies. When different d is chosen, the detent force is also different. When $d=\tau$, the detent force is the minimum. In order to verify the validity of the analytical equation, the 3D model of the tubular PMLM with the skewed primary core end is established in the finite element software Ansys Maxwell, as shown in Fig.3. Fig.4 shows the calculation results for the detent force of the tubular PMLM with different length of skewed primary core end. The peak detent force is extracted and shown in Fig.5. According to Fig.4 and Fig.5, both the fluctuation of detent force waveform and the peak detent force are minimum when the length of skewed core end is one pole pitch. Compared to the direct primary core end motor, the peak detent force of the skewed primary core end motor is reduced from 22.7N to 11.4N, which is reduced by about 50%, when the length of skewed primary core end is one pole pitch. According to Fig.5 the detent force variation versus d is not linear, so not each length of the skewed primary core end is effective to reduce the detent force. The two kinds of prototypes are manufactured for proving the validity, as is shown in Fig.6. The testing results accord with the analytical and calculation results. More testing detail will be given in full paper. III. CONCLUSIONS The method of reducing detent force of the tubular PMLM is proposed through skewing the primary core end. The analytical equation for the detent force of tubular PMLM with skewed primary core end is derived. The validity of the analytical method is verified by the finite element method and the prototype test. The detent force can be reduced effectively through skewing the primary core end, especially the peak detent force is minimum when the length of skewed primary core end is one pole pitch.

CT-10. Thermal Design of a Toroidally Wound Mover Linear Switched Reluctance Machine using 3D Equivalent Thermal Network.

D. Zhang[1], X. Du[1], D. Wang[1] and C. Peng[1]
1. Shandong University, Jinan, China

Abstract-- Thermal analysis is an important issue in machine design which allows to have a knowledge of the machine temperature rise. This paper presents the thermal modeling, analysis and experiments of a linear switched reluctance machine (LSRM) with toroidally wound mover and segmental structure. Firstly, a 3-D heat flow model with the homogenized region for the presented LSRM is established using the thermal equivalent circuit. Then the 3-D thermal model for the presented LSRM is build by FEA which can give the detailed temperature profile of the entire machine. At last, the actual experiment on a prototype is carried out, validating the accuracy and feasibility of the thermal equivalent model above. I.Introduction Linear Switched Reluctance Machine(LSRM) features a double salient structure as its rotary counterpart which has neither magnets nor copper in the secondary, thus resulting in a simple and robust structure, and ultimately exhibiting low cost and high reliability [1]-[2]. Thermal problem has a major impact on the operation performance of the motor because there is always a design objective which requires the windings to supply as much current as possible to achieve high thrust density [3]. So the temperature rise of the machine should be simultaneously observed in the operation as it cannot exceed the maximum value. The accurate method to predict the temperature rise is Finite Element Analysis (FEA) [4]-[5]. However, it is usually very time consuming and cannot give policy to quickly identify the sensitivity of the machine parameters to the temperature rise. This paper put forward the thermal analysis, modeling and experimental validation of a LSRM. A 3-D thermal resistance network model is established to analyze the thermal field. The numerical 3-D heat flow model are developed by FEA and the results are compared to that obtained of thermal resistance network model. Finally, the experiment on a prototype machine is given to validate the analysis and results above. II.Configuration of the LSRM and thermal network Linear switched reluctance machine(LSRM) adopts double salient pole structure, which has 3-phase windings with a 3-pole mover and 2-pole stator. This LSRM has an annular phase winding wound around the mover yoke. The stator consists of series of individual segments embedded in an aluminium base. A.Thermal resistance The thermal field refers to the thermal of all the points in a space at a time. That mains $T=f(x,y,z,t)$ (1) $Q=k_x(\partial T/\partial x)i+ k_y(\partial T/\partial y)j+ k_z(\partial T/\partial z)k$ (2) where T is thermal in K, k_x, k_y and k_z are thermal conductivities in W/m●K. Consider the one-dimensional situation, we assume that the heat can only come in or out in the x direction. The thermal of the cubic region on the plane at $x=0$ is T_{0x} and on the plane at $x=l_x$ is T_{lx}. The steady-state conditions with temperature variation in the x-coordinate is $d^2T(x)/dx^2=-p/k_x$ (3) $Q_x=k_xS_x/l_x\times(T_{lx}-T_{0x}+1/2\times p/k_x\times l_x^2)$ (4) where p is power dissipation density. S_x is the surface area in the x-direction. It is easy to define the thermal resistance of the region in the x-direction as $R_x=l_x/(2k_xS_x)$ (5) B.Thermal equivalent network Assuming that the heat flow is transmitted in all directions equally, the thermal network can form a three-dimensional model. The configuration of the equivalent thermal circuit is shown in Fig. 1. As the linear motor structure is symmetrical, no heat flow will cross the central plane of the motor by thermal symmetry. Due to the symmetry, only a quarter of the move part need to considered. Since the air gap is only 0.5mm, the influence of the stator and aluminum base on the heat dissipation must be considered. The entire areas are divided into 15 parts, where part 5, 7 are coil windings, part 1, 2, 3, 4, 6 and 8 are mover yoke, part 9, 10 are mover teeth, part 11, 12 are stator and part 13, 14 and 15 are aluminium segment, and the temperature of each part is T_1 to T_{15}. For the presented LSRM, the iron loss of silicon steel sheet can be ignored. The dominant heat source of the presented LSRM is generated by the windings, i.e. copper loss $P=I^2R$ (6) where I is rated phase current and R is the resistance of phase winding. III.FEA result and experiment verification To verify the thermal model presented above, the 3-D heat flow model of the LSRM is established by FEA. In the FEA thermal simulation, the ambient temperature is 25°C, and the heat convection factor is 10 W/m²●K. The thermal distribution of the LSRM is shown in Fig. 2. In the 3-D thermal model, the highest temperature is 125.1°C which appears in center of phase B winding(T_5). Mover tooth(T_{10}) and aluminium base(T_{13}) temperature are 108.3°C and 98°C. Which is consistent with the results of the thermal network. To further validate the results of the thermal analysis above, the practical thermal experiment of the prototype is done. The measured temperature of the winding(T_5) is close to that of FEA and thermal equivalent circuit, which is 114.7°C. IV.Conclusions This paper develops a 3-D thermal circuit model of a linear switched reluctance machine with segmental structure stator and toroidal winding. The thermal field and temperature rise of the specific component of the machine is obtained. Then the numerical FEA heat flow models of the machine are established, and the results are compared to that obtained of thermal resistance network model. Finally, the experiment on a prototype machine is done to validate the analysis and results above.

CT-11. A New Decoupled RotLin Motor with Fuzzy Sliding Mode Control.

Y. Zou[1] and E. Cheng[1]
1. Electrical Engineering, The Hong Kong Polytechnic University, Hong Kong, Hong Kong

I. INTRODUCTION Rotary-linear (RotLin) machines are usually employed in industrial devices such as boring machines, grinders and mechanical carving machines [1]. In the past, the primitive investigation on a brushless direct current (BLDC) rotary-linear motor presented the design approach and proposed the coupled output issue for this kind of motor [2]. Also, an inductive rotary-linear motor is studied in [3], elaborating the design procedure and analyzing the end effect of the motor. A voice coil motor combining a linear motor and a rotary motor is studied to improve the acceleration and precision of the movements [4]. A permanent magnet synchronized rotary-linear motor is also investigated, with a prototype shown in the literature [5]. However, the interaction between the linear part and the rotational part deteriorates the performance of these motors, including the accuracy of its position control. In this study, a decoupled RLSRM is designed and manufactured to improve the performance of the motor for practical applications. The motor possesses a decoupled magnetic structure in the linear part and the rotary part, avoided the mentioned coupling effect. It can realize the linear and the rotational movements simultaneously, with experimental results illustrated a spiral motion by using the motor. A sliding mode control (SMC) combined with a fuzzy logic controller (FLC) is designed for the motor against its nonlinear magnetic curves of soft materials. Experiments prove the effectiveness of the controller for the RLSRM considering the nonlinearity, outweighing the traditional proportional-integral-derivative (PID) control. II. STRUCTURE OF THE MOTOR This motor can be considered as a two-stator motor that merges a linear switched reluctance motor (LSRM) and a rotating switched reluctance motor (SRM). The outside stator is responsible for linear movements and the inner stator generates the torque of the mover, as shown in Fig 1.(a). The mover is a solid part stacked by steel sheets. By designing the structure, the size of the motor can be reduced. As the mover is very simple, its manufacturing and assembling will be easy. Consequently, the manufacturing cost of the motor can be also reduced. Meanwhile, short flux paths for the outside stator and the inner stator can avoid the coupling effect from the two stators. Some flux barriers are added for the mover. Therefore, the magnetic decoupling structure has been devised by the simple structure. The linear movements and the rotation can be controlled and realized simultaneously with no coupling effect. Figure 1(b) shows the structure of the mover. This mover has poles and slots deployed alternatively and their lengths are listed in Table I. The section view of the motor including the mover, the outside stator and the inner stator is shown in Fig.1 (c). The flux lines of the motor are plotted in Fig.1 (d). The flux lines pass closed along the stators and the mover with short magnetic circuit paths, which shows the magnetically decoupled structure of the motor. Main specifications are listed in Table I. III. CONTROL OF THE MOTOR The control block of the system is shown in Fig.2. For the linear motion, a proportional- derivative controller gets the control outputs from the FLC block, and outputs force commands for the force distibution funciton (FDF) of the motor. After the FDF converts the force to the reference current for a driver, the drive will supply the regulated power for the motor according to the reference current. Similarly, The SMC is designed for the rotating part. After obtaining the outputs from the FLC block, the SMC outputs torque references for the torque sharing function (TSF) that supplies references for the driver of the motor. The sliding surface of the SMC can be expressed by $s=de/dt+\lambda e,\ \lambda>0$. (1) e is the error of the input and the output and its changing rate is de. The phase plane is (e, de). The first-order equation to represent the sliding mode $(s,ds)=0$. We can obtain $e=-e\lambda$. The solution of this equation is $e(t)=e(t)*e$^-$\lambda(t)$. (2) According to Lyapunov's principle, the following equation needs to be guaranteed if the solution can reach the sliding surface. $s*ds<0,\ V=0.5*s^2(e,t),\ dV<0$. (3) And the control law of the controller can be obtained $u(t)=(\alpha|e|+\beta(de/dt))*sgn(S)$. (4) α and β are constants that can be adjusted by the FLC block. $sgn(S)$ is the signal function. IV. EXPERIMENTAL RESULTS The whole experimental set up consists of a computer, a dSPACE DS1104 card, a power supplier, a driver and the motor, as shown in Fig.3. The static torque and force outputs are measured and given in Fig.4. The control scheme, as well as the controllers, is built using the software package MATLAB/Simulink. After programming and debugging the control scheme into the dSPACE card, the card will output commands for drivers of the motor, getting the feedbacks of position and rotational angle from two encoders and constructing a closed loop control. The mover can move in linear and rotating directions simultaneously and it can realize a spiral movement. The experiments are carried out when the mover rotates at a constant speed of 500 rpm and the reference to the linear movement scope is 20 mm under 0.5 Hz. In Fig.5 (a), the linear movement response is plotted, and position error is given in Fig.5 (b). From Fig.5 (c), the error of the controlled speed is around 1 rpm.

CT-12. Design of VCM actuator with optical zoom for smartphone cameras.

Y. Chang[1], C. Hu[1], C. Hsieh[1] and *C. Liu*[1]
1. National Chung Cheng University, Chiayi County, Taiwan

In recent years, compact and multifunction smartphones have changed the way people live and replaced many electronic products because of their powerful camera features. Smartphones are pretty convenient to be brought to everywhere and smartphones could capture and upload pictures to social networking sites at any time. In addition, the performances of smartphone cameras are as good as digital cameras. Therefore, smartphone cameras have almost replaced digital cameras nowadays. Comparing to the four major functions of the digital cameras: auto-focusing (AF), optical image stabilization (OIS), digital zoom and optical zoom, smartphone cameras has been equipped maturely in terms of AF, OIS, and digital zoom functions, but in the aspect of optical zoom, the optical zoom is restricted by the appearances and dimensions of smart phones. Therefore, the function of optical zooming is really rare in smartphone cameras so far. However, the evolution of cellphones grows intensely, so the manufactures need to provide a better optical performance and make a new gimmick to attract consumers. As a result, it could be predicted that the optical zoom function will be the next focus attention on smartphone cameras. Consequently, this paper proposes a novel smartphone camera with optical zoom. Zoom is a method to get a closer view of far-away objects without moving legs when people are taking a picture. Although the optical zoom has already widely used on digital cameras, most smartphones have only digital zoom because of size limit. The digital zoom is a simple image processing to enlarge the center image, and it causes image quality decreasing [1]. By contrast, the optical zoom enlarges the image through changing the distances of lenses without image quality decreasing [2]. For the purpose of AF, OIS, and optical zoom, many kinds of actuators have been developed for smartphone cameras in the literature. These devices include piezoelectric motors [3], stepping motors [4], ionic polymer metal composites, and voice coil motors (VCMs) [5.6], etc. Because VCMs have the advantage of high-performance dynamic characteristics, simple structure, and low cost, VCMs are the most common actuators in smartphone AF and OIS cameras. However, stepping motors could provide a longer stroke for zoom with small size, so only stepping motors are applied in commercial optical zoom smartphone cameras so far. In this paper, we propose a novel VCM actuator with optical zoom for smartphone cameras. The proposed VCM actuator has a long zoom stroke through specific optical structure layout. Moreover, it has a simpler structure when compared to stepping motor smartphone cameras. Figure 1(a) and 1(b) illustrate the 3D CAD model and laboratory-built prototype of the proposed VCM actuator, respectively. As shown, there are two lens groups, two prisms and two independent VCMs. The light goes through the first lens group, is reflected by these two prisms for changing direction, and then goes through the second lens group to image plane. When two individual currents are passed through to two independent VCMs, the optical zoom actuator could change the distances of these two lens groups to achieve optical zoom function. In addition, the proposed VCM actuator has shorter length and could generate uniform Lorentz force F_{VCM} with shorter magnets. The dynamic performance of the proposed VCM actuator is then verified experimentally using a laboratory-built prototype. Figure 2(a) presents the simulation and experimental results of F_{VCM} with the displacement under the same input current of 30 mA. As shown, the curve "simulation of real module" indicates that the simulation results are obtained using an actual prototype module in which its manufacturing and assembly tolerances are considered. It can be observed that simulation and experimental results are consistent form displacement -3 mm to 3 mm (stroke of 6 mm). Figure 2(b) illustrates the performance verification of the response time with the positive stroke. The dynamic performance of the proposed VCM actuator is is then verified experimentally using a laboratory-built prototype. As shown in Fig. 2(b), the experimental results have shown that the proposed VCM actuator has a good positioning accuracy of 0.01 mm and fast response time of 40 ms with the advantage of long-stroke and simpler structure.

CT-13. Design and Analysis of a Tubular Hybrid-Excited Flux-Modulated PM Motor with Improved Power Factor.

H. Zhou[1], J. Zhang[1], W. Tao[1] and G. Liu[1]
1. School of Electrical and Information Engineering, Jiangsu University, Zhenjiang, China

I. Introduction Tubular permanent magnet motors have been applied to many direct drive applications such as electromagnetic suspension due to their zero net radial force and volumetrically efficient [1]. Vernier permanent-magnet motors have attracted much more attention recently for their low speed and high thrust force features [2]. However, the power factor of vernier permanent-magnet motors is usually lower than that of conventional PM motors [3]. To solve the problem, a new tubular hybrid-excited flux-modulated PM motor with improved power factor is proposed in this paper. II. Proposed motor Fig. 1 shows the structure of the proposed motor. It consists of one stator and one mover. PM excitations are both employed on the stator and the mover. Halbach arrays are used in the stator to solve the problem of the flux leakage. A consequent pole is adopted in the mover, which can reduce the number of PMs required. The armature windings and DC field windings are housed in the stator slots and mover slots, respectively. The main air-gap fluxes are generated by the PMs. The air-gap magnetic field can be modulated by each stator split-poles and mover teeth. Therefore, the proposed motor can offer much higher force capability than the existing ones at low speed. The auxiliary DC field excitation is used to strengthen or weaken the air gap magnetic field, and then the power factor of the proposed motor is improved. Therefore, with incorporation the merits of the flux-modulated structure and the auxiliary DC field excitation, the performances of the proposed motor are flexible and controllable. III. Results The electromagnetic performances of the proposed motor are analyzed by using the finite-element method. Fig. 2 shows the no-load air-gap flux density under operating conditions of flux strengthening (I_{dc}=+5 A), no additional flux control (I_{dc}=0), and flux weakening (I_{dc}=-5 A), respectively. The magnetic field can be regulated from 1.02 T to 1.75 T. Fig. 3 shows the back-EMF waveforms under different states mentioned above. It can be seen that the back-EMF reaches 69 V at I_{dc}=+5 A, which increases by 21.1% compared without DC field excitation (only PM excitations). Fig. 4 shows the steady thrust force when the phase current is 5 A. It can be noted that the average thrust force increases from 701 N to 794 N while I_{dc} increases from 0 to 5 A. Moreover, the power factor increases by 29.5% from 0.454 to 0.588 in the same circumstances. Therefore, the proposed motor can achieve high thrust force and also improve power factor. More detailed content will be discussed in the full paper.

I. Introduction Compared with traditional machines that realize two-dimensional motion usually by using several motors and mechanical devices, two-degree of freedom motors performance outweigh these traditional ones in speed control or positioning tracking. For example, in the paper [1], linear-rotary motors have been investigated to realize linear and rotating motion. It is convenient for automatic machines such as curving machines, print circuit board machines and laser welding machines to get high position responses. Spherical motors are also investigated for two-degree of freedom movement [2,3]. Therefore, direct drive two degrees of freedom motors are helpful both in developing compact structure and outstanding performance in industrial applications. In this study, a direct drive two-freedom of degree spherical motor is proposed. This motor inherits the advantages of DC motors and variable reluctance motors. An elaborated design method for this motor is given and discussed and FEA is used to accurately calculate main parameters for the motor. II. Structure and principles of the motor This motor mainly consists of three parts as shown in Fig.1 (a). The first part is a silicon steel sheets stacked rotor fixed on a shaft supported by two bearings. The two bearings fixed on a crust embrace four moving units, constructing the mover as the second part. The third part is the stator comprised of two circles that sandwich the mover in the direction perpendicular to the shaft. The mover and the stator can be considered as a stepping motor. Interestingly, the mover and the stator can be also treated as an entire part which provides a constant magnetic field consisting two pairs of magnetic poles for the rotor. The rotor rotates along the direction shown in Fig.1(a). The rotor is operated as a DC motor. In the vertical direction, the mover can move along the stator possessing curved teeth, as shown in Fig.1(b). The mover and the stator are curbed and guided by two cone bearings. This motor combines a variable reluctance moving units to adjust the direction of the shaft and a DC motor based rotor rotating at a high speed along the shaft. The motor can be controlled in two modes that are variable reluctance mode and DC mode. Based on the principles, the stator, the movers and the rotor can be simplified as Fig.1 (c). For the variable reluctance mode, the flux lines are closed in a short path shown in phase B of Fig.1 (c). For DC mode, flux lines are shown in lower part of Fig.1 (c). The prototype of the motor is shown in Fig.1 (d). This prototype mainly consists of two stators, four movers and a rotor. The mutual influence between the coils from the mover and the rotor under the two modes can be analyzed by Fig.1 (e) and (f). The premise is that the air gaps in short flux path are identical and there is no saturation in the path. According to the simplified mode Fig.1 (e), it can be seen that source of the flux lines are identical and connected in parallel. Therefore, all flux lines will pass through the long magnetic paths. Assuming that the whole magnetic circuit has no saturation part, when the motor works in short flux path and simplified magnetic circuit is given in Fig.1 (f), the fluxes can be calculated as: $\Phi 1+\Phi 2+\Phi 3=0$,(1) $2Fm+\Phi 2*Rmg-\Phi 1*Rmg=0$,(2) $Fm+\Phi 3*Rrg-Fr-\Phi 1*Rmg=0$,(3) $Fr-\Phi 3*Rrg+Fm+\Phi 2*Rmg=0$.(4) Here, $\Phi 1$,$\Phi 2$ and $\Phi 3$ are flux linkages of the three paths. *Fm* is the magnetic potential force from coils of the stator. *Fr* is the magnetic potential force from the coil of the rotor. *Rmg* and Rrg are magnetic reluctances of the stator and the rotor, respectively. III. Drive topology The magnetic flux distribution of the motor is partly shown in Fig.2 (a). The two modes mentioned can be realized by a parallel-series topology. A simple topology of the electric driver, taking one mover (coil 1 and coil 2) as an example, can realize the connection by using the switch 3 shown in Fig.2 (b). A half bridge topology is mainly controlled by two switches (S1 and S2) that are usually high frequent MOSFETs and two diodes (D1 and D2). S1 and S2 are used to conduct the coils to the power supply of the motor and D1and D2 are freewheeling diodes when S1 and S2 turn off. As shown in Fig.2 (c), when S1 and S2 turn on, if S3 turns to the upper points, the two coils will be connected in series, and the current passing through the two coils will be in series. Flux lines will pass through the mover and the stator along the short path. If S3 turns to the low points, the two coils will be connected in parallel and the current will pass through the two coils parallelly. Flux lines will pass through the rotor, the mover and the stator along the long path as shown in Fig.2 (d). IV. Torque output The inductance profiles of the coils are shown in Fig.2 (e). And torque outputs with the variety of current excitation levels in coils on the movers and the rotor are given in Fig2 (f). Current1 and current2 are current values of the coils on the mover and the rotor, respectively. When the current1 is at 1000 ampere-turns, the torque output from the rotor will be on the rise with the increase of the current of the coils on the rotor. The torque outputs from the rotor with the excitations (current1=current2=1000ampere turns) are larger than the condition (current1=2000, current2 =500), which suggests that the current in the coils of the rotor makes more contributions to the rotating torque and this torque can exceed 6 Nm.

CT-15. Proposal and Design of Primary-PM Transverse-Flux Linear Motor with Enhanced Secondary-PM Structure for High Power Density.

J. Luo[1], B. Kou[1], X. Yang[1], L. Zhang[1] and H. Zhang[1]
1. Electrical Engineering, Harbin Institute of Technology, Harbin, China

I. INTRODUCTION Linear motor has shown its essentiality in industrial applications such as semiconductor manufacturing, high-grade CNC machine tools, rail transportation systems. Nowadays, the urgent demands for high power density linear direct drive system has been proposed. The traditional linear motors are subjected to serious competition between electric loading and magnetic loading. Further improvement of its power density seems uneasy to realize. The transverse-flux motors (TFM) have the peculiarity of decouple of electromagnetic loadings[1]-[3]. The TFMs are considered to be potential candidate for high power density systems. However, there are several common drawbacks need to be addressed before its practical applications. Leakage flux has led to poor utilization of permanent magnets. Owing to the structure peculiarity, TFMs experience more disadvantages from leakage flux. It was reported that the leakage flux would produce negative force in the operating process, led to poor power factor[4]. Up to now, several approaches have been brought forward to inhibit the leakage flux. One possible way is to use high permeability material to enclose the leakage flux, preventing it from interlinking the armature[5]. Another way is to use magnet shield technology. The magnets are placed in the leakage flux path in a direction against the leakage flux[6]. But they all increase the complexity of the motors, making it hard to manufacture and increasing the prime cost. II. BASIC STRUCTURE AND OPERATING PRINCIPLE The proposed primary-PM transverse-flux linear motor is shown in Fig.1. The primary side is comprised of laminated primary core, armature windings intertwined on each primary tooth, and primary magnets. The primary teeth are notched along the direction of motion. There are two types of steel sheets used to construct the primary core as shown in the figure. The upper steel sheet has notched tooth on the second and fourth teeth while the lower steel sheet on the first and third teeth. The two kinds of steel sheets are laminated along the longitudinal direction by turns and retuse slots are formed on the primary teeth. The primary magnets are inserted into these slots with the same polarity. The secondary core is also composed of high permeability materials. And the secondary magnets are embedded into notched slots on the secondary core with the same direction of magnetization as the primary magnets. The long secondary side short primary structure is employed in this paper. Hence, the secondary side is the stator while the primary side is the mover. A minimum element model is employed to explain the operation mechanism as shown in Fig. 1. The flux paths are depicted in Fig. 2. The airgap region faced by the primary is divided into four subregions. Since all the magnets have the same magnetized direction, each magnet will complete its circuit loop by the subregion without magnets located. As the secondary magnet aligns different primary magnet, the magnetic flux will reverse its direction interlinking the coil. III. PARAMETER OPTIMIZATION AND PERFORMANCE EVALUATION In this part, the leading parameters will be analyzed by 3-D finite element method. Based on the optimized dimensions, the static and dynamic performance are investigated, including the magnetic field distribution, the back-EMF waveform, the armature reaction field distribution, thrust force and detent force. The thrust force density is addressed by comparing to the transverse-flux flux-reversal linear motor (TF-FRLM) in [7]. The results show that the proposed motor can achieve a 1.6-times force density than the TF-FRLM and also with lower detent force. IV. CONCLUSION Several conclusions will be drawn in this section. The full paper will be accomplished about 4-5 pages. A prototype motor is also under design at present. The merits of the proposed motor are list as fallows: 1)The leakage flux paths are suppressed from interlinking the armature coils, increasing the power density. 2)Both the primary and secondary cores can be made of steel sheets, which simplifies the manufacturing process and saves the prime cost. 3)The back EMF is highly sinusoidal waveform by star connection, and the proposed motor can be easily driven by conventional controllers. 4)Compared to the traditional linear motors, the proposed motor use fewer magnets to achieve the same power level.

CT-16. Improvement of the self-propelled rotary actuator in consideration of shape and rolling direction of steel sheets.

N. Soda[1], T. Kawano[1] and M. Enokizono[2]
1. College of Engineering, Ibaraki University, Hitachi, Japan; 2. Vector Magnetic Characteristic Technical Laboratory, Usa, Japan

It is very important for prevention of accidents to detect cracks and defects inside of steam generator tubes in the industrial plants as typified by nuclear power plants. In order to detect the defects inside of tube with complicated structure, it is necessary to develop an electromagnetic actuator self-propelled inside of tube [1-5]. The easiest method of applying an exciting magnetic field to the electromagnetic actuator from the outside of tube is how to wind copper wire around tube and form a solenoid coil on the surface of tube. However, in this case, an exciting magnetic field is induced in parallel to the axis direction of tube by the coil. Therefore, as shown in Fig. 1(a), we had fabricated the self-propelled rotary actuator whose rotational axis is parallel to the exciting magnetic field [6-8]. In this actuator, the stator has pole pieces which are made of grain-oriented electrical steel sheet (35G155), and the rotor has permanent magnets (Ne-Fe-B) which are fixed on cylinder made from acrylic. Moreover, as a feature of this actuator, the shape of steel sheet of this stator was not a rectangle but a triangle, as shown in Fig. 1(a). It was thought that a triangle steel sheet generates larger starting torque than a rectangle steel sheet, because magnetic flux distribution at the base of triangle steel sheet under an exciting magnetic field is asymmetrical to the rotational direction of the rotor [7-8]. However, by setting the rolling direction of a grain-oriented electrical steel sheet in the different direction from the exciting magnetic field direction, magnetic flux distribution at the end of the steel sheet becomes asymmetric even if the shape of stator is a rectangle. Accordingly, we clarified that the starting torque of the actuator is improved by setting the rolling direction of rectangle steel sheet appropriately [9]. In this paper, we attempt to improve the starting torque of the actuator by setting the rolling direction of triangle steel sheet. In order to calculate the actuator in consideration of the rolling direction of the steel sheet, we carry out finite element analysis which introduced the complex E&S model [9]. Fig. 1(b) shows the analysis model of actuator's stator with triangle steel sheet and the definition of inclination angle ϕ of rolling direction in the steel sheet. Inclination angle ϕ = 90 deg. means the rolling direction of steel sheet is parallel to the direction of exciting magnetic field H_o. In addition, we analyze the rectangle steel sheet model shown with the dashed line in Fig. 1(b), for comparison. As a result of experiment, when the exciting magnetic field H_o is not applied, the permanent magnet is stationary at the right angle corner of the triangle steel sheet, and is stationary in the middle of the rectangle steel sheet [8]. The magnitude of starting torque of the actuator is dependent on the magnitude of x-component (i.e., the rotational direction of the rotor) of magnetic flux density within the stationary position when the exciting magnetic field H_o is applied. Therefore, we calculate the average of B_x (i.e., x-component of magnetic flux density) within the region of stationary position. The exciting magnetic field H_o is a sign waveform of the peak amplitude 500 Oe, and the frequency is 50 Hz. Fig. 2(a) shows the relationship between the average of B_x within the region of stationary position and the inclination angle ϕ of the rolling direction in the triangle and rectangle steel sheet. In every inclination angle ϕ, the average of B_x of the triangle steel sheet is large than that of the rectangular steel sheet. In both the triangle and the rectangle steel sheet, the average of B_x becomes the maximum when ϕ = 60 deg. At the inclination angle ϕ = 60 deg., the average of B_x of the triangle steel sheet is more than 1.5 times that of the rectangle steel sheet. Therefore, we consider the starting torque of the actuator which used the triangle steel sheet of ϕ = 60 deg. is about 1.5 times as large as that which used the rectangle steel sheet. Next, we evaluate the total iron loss of the steel sheet in actuator's stators. We can calculate directly the iron loss from results obtained by finite element analysis which introduced the complex E&S model. Fig. 2(b) shows the relationship between the total iron loss of the stator core and the inclination angle ϕ. The total iron loss in the rectangle steel sheet becomes large with decrease in the inclination angle ϕ, and takes the minimum value in ϕ = 90 deg. The total iron loss in the triangle steel sheet changes little in inclination angle ϕ from 60 deg. to 90 deg., it increases in inclination angle ϕ less than 60 deg. The difference in the total iron loss between the triangle and the rectangle steel sheet occurs because both shape and rolling direction of steel sheet affect iron loss distribution. As a result, in order to improve the starting torque of the actuator and decrease the total iron loss of that, we consider that the shape of steel sheet in the stator core is a triangle and the optimum inclination angle ϕ of the rolling direction of steel sheet from the rotational axis is 60 deg.

CU-01. Design and Analysis of a Novel Modular Linear Double Stator Biased Flux Machine.

Y. Mao[1] and *S. Niu*[1]
1. Electrical Engineering, The Hong Kong Polytechnic University, Hong Kong, Hong Kong

I. Introduction Wave energy is a kind of renewable energy. It has advantages like other renewable energy such as clean, inexhaustible and widespread. In addition, it exhibits higher power density than other renewable resources [1]. Linear motors have good adaptability to wave motion, because they can produce a direct thrust force without the need of a gearbox that converts the oscillation into rotation which can reduce system cost and complexity [2]. The modular linear double stator biased flux (LDSBF) machine is a novel linear machine which exhibits high torque density in low speed applications. It is promising to generalize the use of LDSBF machine in wave power generation for it can effectively capture the low frequency and high force wave energy. To further improve the power density of linear PM machine, the modular linear double stator biased flux (LDSBF) machine is proposed in this paper. The double stator biased flux machine is researched and developed on the basis of conventional linear biased flux PM (LBFPM) machine [3]. In general, they are both stator PM machines that employ concentrated windings. The flux polarity in an independent coil is whether bipolar or unipolar. II. Configuration and Operating Principle of the Modular LDSBF Machine Fig. 1 shows the configuration of the proposed modular linear double stator biased flux machine. It mainly consists of an inner stator, an outer stator and a rotor sandwiched between the stators. The outer stator has salient structure and coils are wound on the teeth. PMs are set in the inner stator. This linear machine is constituted of several modular units. Each modular consists a π-shaped lamination core, a magnet and two sets of concentrated coil. Adjacent modular are separated by flux-barrier made of nonmagnetic material. The working principle of this machine is due to the flux bias effect. When the mover's position changed, the flux path in each slot also changed. These procedures will keep going and repeating. Motivation of the mover will lead to variation of direction and intensity of flux-linkage in the winding, thus inducing the back electromotive force. Theoretically, the mutual inductance between coils in the outer stator is zero. Since the mutual inductance is insignificant, the proposed linear machine can be regarded as set of several independent single phase machines. Each unit of single phase machine consists one PM piece and two stator teeth with coils wound on it. So it is reasonably to make modular design of the linear double stator bias flux machine. To build a modular LDSBF machine, flux barriers are introduced in the yoke. Modular design can further cut down flux leakage and improve efficiency in usage of magnets. In addition, manufacture cost can be reduced because each unit is easily assembled by a π-shaped lamination core, a magnet and two sets of concentrated coils. III. Slot/Rotor Combination Analysis The stator/ rotor pole combinations 24/20, 24/22, 24/26 and 24/28 are analyzed and compared by finite element method (FEM) in this study. To analyze electromagnetic performance open circuit flux of each coil is measured which is shown in Fig. 2. Partition the coils that have similar flux distribution into one group, it can be seen from Fig. 2 (a), (c), (d) that each group have 4 coils and the phase difference between each group is 120 degree. While in Fig. 2 (b), each group have 2 coils and the phase difference is 60 degree. The coil arrangement method should follow the principle of evenly maximizing the fluxes per phase winding. So for the former type, each group of coils belongs to different phase. And the group of coils that have opposite value (symmetrical parts along the y=0 in the figure) will be connected in reverse series. After arrange the coils according to this approach, waveform of the total flux linkage of three phase is shown in Fig.3 It can be seen from Fig. 3 that coil flux distribution of 24/22 is bipolar while it is unipolar for 24/20, 24/26 and 24/28 combinations. In addition, the three phase flux linkage of 24/22 combinations is more sinusoidal. The reason is mainly caused by the individual coil flux and the connection pattern. For the former type of linear machines, phase fluxes are unipolar with DC component, and all of the harmonics are kept. While in 24/22 combination, the DC component and the even older harmonics of fluxes are eliminated, so the phase flux waveform is more symmetrical. So the 24/22 combination is the best choice. The LDSBF machine is also optimized and compared with its counterpart LBFPM machine. The FEM result presented in Fig. 4 shows that LDSBF machine has better performance than LBFPM machine.

CU-02. Experimental investigation of a new type of oscillation based linear capsule actuator.

L. Wu[1], K. Lu[1] and Y. Xia[1]
1. Department of Energy Technology, Aalborg University, Aalborg, Denmark

Abstract This paper studies new vibration-based linear actuation mechanism for potential active in-vivo capsule applications. The new actuator is very simple in structure, consisting of coil and magnets only. This simple structure contributes to the design of a sealed linear locomotion system, avoiding to damage the intestinal tissue caused by the paddle or leg sticking outside the capsule. In addition, the new capsule actuator utilizes pulsed force source to create controllable oscillation for realizing linear movement. The feasibility of the new actuator structure and driving confirmed experimentally in the laboratory on a prototype and analysis results by using 3D Finite Element Model are provided. 1. Introduction The current capsule endoscopy can only passively travel inside the GI tract, which is propelled by natural peristalsis to travel through the entire GI tract, and it cannot be controlled and stopped at a precise position for diagnosis due to the peristalsis frequency is not controllable. Therefore, a locomotion system needs to be added to improve the current capsule endoscopy, namely, an active capsule endoscopy. The actuator is the key component to achieve an active capsule endoscopy. The main disadvantage of the current capsule is its poor manipulation ability, which can be demonstrated by some peculiarities, such as the movement speed, position as well as orientation of the capsule are out of control. The present capsule, in the existing literature, can achieve an active movement inside the human body by means of a micro DC motor or shape memory alloy (SMA) wire. For example, in [1], SMA can realize inchworm-like actuation achieving forth and backwards movements. But it needs to consume high power in the range of 450-1700wM and increase consequently the temperature by 12°C in 3 minutes, which may damage the intestinal tissue. In [2], a micro-DC motor is employed to drive paddled/legged-type capsule; but this mechanism generates large velocity in a range of several times the desired velocity of 15 cm/min, which may not allow enough time for picturing folds inside the GI tract. The sharp paddles or legs of the paddled/legged-based capsule may also damage the body tissue. Compared with the conventional capsule actuators, the main advantage of a moving coil-magnetic type linear actuator is its simplicity in structure [3]. The other advantages are recognized to be consisting of relatively few components, quick response time, and a long lifetime [4]. Furthermore, this linear actuator can be design as a sealed locomotion system. Therefore, there will be no paddle or leg sticking outside the capsule that may damage the intestinal. 2. The Proposed New Structure The new actuator proposed in this paper consists of three PMs and one small solenoidal coil. Two of the PMs are attached to the two ends of the capsule while the third PM is attached to the small coil in the middle as shown in Fig. 1. When a pulsed current shown as e.g. in Fig. 2(b), is supplied to the small coil, it will produce an electromagnetic force between the small coil and the magnets. The small coil and PM3 will then move towards PM1 due to the attractive (/repelling) force between PM1 (/PM2) and the small coil. Upon suddenly stopping the current supplied to the small coil, the repelling (/attracting) force between PM1 (/PM2) and PM3 will then push the small coil and PM3 to its original position as indicated in Fig. 2(a). This will cause the entire capsule to move forward according to the Momentum Conservation Law. Repeating the pulsed current supply will force the actuator run into a stable vibration state. The vibration frequency and amplitude of this actuator is controllable by controlling the duty ratio and amplitude of the current supplied to the small coil. The linear vibration can be well used to generate controllable linear movement of the capsule, such phenomenon will be demonstrated further in this project. This new linear actuator has strong manipulation ability. It has also the potential to realize more therapeutic functions, such as biopsy tissues, unclogging lumen, coagulating, ablating, and apposing tissue. More details explaining this vibration based linear motion and 3D FEA results will be given in the final paper.

1. Introduction The control element drive mechanism (CEDM) is an electromechanical device to control the reactivity of the nuclear reactor by withdrawing, inserting or holding the control rods. The conventional CEDMs have been installed outside the reactor vessel. However, there have been demands for locating the CEDM inside reactor vessels because it provides significant benefits in respect of safety of the nuclear reactor. Accordingly, an in-vessel CEDM has been developed to meet the harsh environmental condition inside nuclear reactor. The in-vessel CEDM is based on the conventional magnetic jack type external CEDM for commercial reactors in order to take advantage of the proven technologies as much as possible. However, the in-vessel CEDM is differentiated from the conventional CEDM as follows: 1) Mineral-insulated cable was adopted for windings as the enamel-coated wire of the conventional CEDM is not operable in such harsh environment. 2) The in-vessel CEDM has no pressure boundary as the whole assembly is submerged. 3) The latch assembly was designed to meet the driving pitch requirement of 10 mm, which is almost double precision comparing to the conventional CEDM. The fine motion pitch was achieved by changing the double steps per-pitch concept to single step per-pitch concept [1]. 4) Martensitic stainless steel is used for the coil housing to provide magnetic flux path in submerged condition. 5) Diameter of the CEDM assembly was reduced to assign one control rod assembly for each and every fuel assembly. 6) A high-temperature position indicator was designed to monitor the operation inside the reactor. This paper introduces a preliminary test to check the operability of the proposed in-vessel CEDM in dry condition. 2. Prototype Test A prototype of the in-vessel CEDM was manufactured, and it was then installed in a specially designed fixture for dry run test as shown in Figure 1. A prototype of the in-vessel position indicator was also manufactured and installed on the top of the prototype CEDM to monitor the operation. A dummy weight was attached at the bottom of the drive shaft to provide the lifting load of 100kgf. The prototype was run by a control system designed to provide sequential electrical power. The prototype in-vessel CEDM withdrew and inserted the dummy weight at the required speed. Successful operation was monitored by the current traces as shown in Figure 2 together with the position indicator. 3. Concluding Remarks A magnetic jack type in-vessel CEDM was developed for a small modular reactor. A prototype was manufactured to verify its feasibility. A dry run test was performed with the prototype. The prototype in-vessel CEDM was proved to be capable of withdrawing and inserting the required weight at the required speed. The prototype will be tested in high temperature, high pressure and submerged condition in the near future. CU-04. Design and Analysis of Linear Hybrid-Excited Slot Permanent Magnet Machines.

Y. Shen[1] and Q. Lu[1]
1. College of Electrical Engineering, Zhejiang University, Hangzhou, China

I. INTRODUCTION Linear switched reluctance machines (LSRMs) have been extensively researched and applied to long distance direct-drive applications due to their low cost and simple structures [1]-[3]. However, they still suffer from unavoidable high force ripple, acoustic noise and vibration due to the unipolar excitation, as well as relatively low force density [4]. In order to solve these problems, this paper proposes a novel linear hybrid-excited slot permanent magnet machine (LHESPMM). It is modified from a three-phase unipolar excited LSRM by adding non-overlapping DC field windings and PMs in the primary and exciting the armature windings with sinusoidal bipolar currents [5], [6]. Since the PMs are inserted in the primary slots and magnetized in parallel with the motion direction, the PM flux is only located in the primary at open circuit, which makes the cogging force negligible. It is also low PM consumption and especially beneficial to long stroke, and has good flux regulation capability and higher force density with a dual parallel excitation sources of DC current and PMs. Moreover, the excitation with sinusoidal bipolar currents makes it possible to operate in four quadrants and can be supplied with a bidirectional three-phase inverter rather than the asymmetric bridge converter. Therefore, the force ripple, vibration and acoustic noise can be reduced. II. OPTIMIZATION AND PERFORMANCE Fig. 1(a) shows the topology of the proposed 12-slots LHESPMM. Its primary accommodates PMs, DC field and armature windings, while the secondary is only made of slotted lamination. The DC field windings are identically wound on each primary tooth. Moreover, the PMs are magnetized in the opposite direction against the DC-excited flux and then inserted into the primary slots approaching the air gap. In addition, the armature windings are excited with sinusoidal bipolar currents. Fig. 1(b) shows the key geometric parameters of this machine. With the simplified models, the operating principle can be explained. At open circuit, as shown in Fig. 1(c), the PMs are short-circuited by adjacent primary teeth, so that there is very small sinusoidal bipolar variation of the flux-linkage in the coil, which changes 360 electrical degrees with a moving distance of pole pitch. If the PMs are removed and the tooth is excited by a DC coil, the flux links both the primary and secondary, as shown in Fig. 1(d). When both DC coil and PMs are present, as shown in Fig. 1(e), the fluxes from both the DC coil and PMs link both the primary and secondary because of the magnetic pull, which makes induced EMF in the armature windings. For slot/pole combinations, LHESPMM is similar to conventional PMLM, e.g., 12-slots/10-poles (12s/10p), 12s/11p, 12s/13p, 12s/14p, etc. Fig. 1(f) shows the fundamental coil back-EMF phasors of LHESPMM. It can be deduced that the coils for every phase consist of coil back-EMFs in phase or 180° phase shifted, which is indicated with the symbol “’”. The proposed 12s-10/11/13/14p LHESPMMs are globally optimized by 2D finite-element analysis (FEA), where genetic algorithm (GA) is used for maximum average force. The key geometric parameters, including split ratio, primary tooth width, PM height, back iron height, the width and height of secondary tooth, and the auxiliary tooth width have been optimized. When optimizing, the current density is fixed to 7.0 A/mm^2, the coil filling factor is fixed to 0.83, and the number of turns per DC coil is equal to that of armature coil. The other fixed parameters are as follows: slot pitch is 20mm, the machine height is 43.8mm, the active length is 50mm and the air gap length is 0.8mm. The average force and force ripple are shown in Fig. 2(a), where 12s/13p and 12s/14p exhibit higher average force than that of 12s/10p and 12s/11p. Moreover, the machine with odd number secondary poles, e.g., 12s/11p and 12s/13p, exhibit relatively lower force ripple. Therefore, 12s/13p is an optimal choice in order to obtain high force density and relatively low force ripple. The cogging force of the 12s/13p LHESPMM is negligible when DC current is small, as shown in Fig. 2(b). Fig. 2(c) and 2(d) show the phase flux-linkage and back-EMF with different DC currents. Apparently, the flux-linkage and back-EMF in three phases are bipolar and sinusoidal, which can reduce the force ripple. When DC current is 9A, the amplitudes of flux-linkage and back-EMF are smaller than those of 6A, due to the saturation of the primary. Fig. 2(e) shows the force-current characteristic of this machine. It can be deduced that a good flux regulation capability and higher force density can be achieved with DC field windings. Finally, a 12s/13p prototype machine is manufactured to validate the 2D FE predicted results, as shown in Fig. 2(f) and 2(g). III. CONCLUSION This paper proposes a novel 12s/13p LHESPMM. After global optimization with GA, the average force is improved to 88.7N and the force ripple is reduced to 3.2% with the rated phase and DC currents of 3A. This machine exhibits negligible cogging force, a good flux regulation capability and high force density. Finally, the results are validated by a prototype machine.

CU-05. Investigation of Novel Linear Multi-tooth Variable Flux Reluctance Machines.

Y. Shen[1] and Q. Lu[1]
1. College of Electrical Engineering, Zhejiang University, Hangzhou, China

I. INTRODUCTION Due to the high price of rare-earth permanent magnet (PM), non-PM linear switched reluctance machines (LSRMs) attract more and more attention and have been used in direct-drive applications with the merits of their low cost and robust structures [1], [2]. However, since the excitation is unipolar and non-sinusoidal, LSRMs still suffer from high force ripple and relatively low force density. In order to reduce the force ripple meanwhile enhancing the force density, novel linear variable flux reluctance machine (LVFRMs) are developed from LSRMs by splitting the windings into non-overlapping armature and DC field windings [3]. LVFRMs exhibits sinusoidal phase flux linkage and back-EMF, where higher force density and lower force ripple can be achieved compared to LSRMs [4], [5]. However, the force density of LVFRMs is still limited by high copper losses due to both the armature and field windings. Multi-tooth is one of the topology innovations to further improve the thrust force capability, which can also be introduced in LVFRMs [6]. This paper aims to propose a novel three phase multi-tooth LVFRM to further improve the force density. A fair comparison between multi-tooth and single-tooth LVFRMs is implemented under the same copper loss. Moreover, the electromagnetic performance of 4-tooth LVFRMs with different slot/pole combinations is compared. Finally, the merits and drawbacks of multi-tooth LVFRM are drawn. II. ANALYSIS AND COMPARISON Doubly salient structure is adopted in single-tooth LVFRM, where both DC field and armature windings are identically wound on each primary tooth while the secondary is slotted lamination [5]. When splitting each primary tooth into *n* small teeth, multi-tooth LVFRM can be obtained, as shown in Fig. 1(a). The choice of slot/pole combination in multi-tooth LVFRMs is also flexible, where odd number secondary poles also can be employed. Fig. 1(b) and 1(c) show the topologies and winding configurations of single-tooth 6-slots/7-poles (6s/7p) and 4-tooth 6s/25p LVFRMs, respectively. As it can be seen, with $Ns=nNp+1$, these two machines exhibit the same winding configuration. The coil connections of the armature winding are determined by fundamental coil back-EMF phasors, as shown in Fig. 1(d). It can be deduced that the coils for every phase consist of coil back-EMFs in phase or 180° phase shifted that indicated with the symbol "’". The outer geometric parameters of multi-tooth LVFRM are as follows: slot pitch is 20mm, the machine height is 43.8mm, the active length is 50mm and the air gap length is 0.8mm. Due to the constraints of the rated total copper loss and the slot area, the average force varies with the ratio of excitation and armature copper losses. When these two copper losses are equal, i.e., Pf=Pa, the average force will be maximum. In this paper, the total copper loss is fixed to 30W. Fig. 2(a) shows the variation of average force with the number of small teeth when slot/pole combination is determined by $Ns=nNp+1$. It can be seen that 4-tooth LVFRM exhibits the highest average force. Hence, 4-tooth LVFRM will be adopted to compare with single-tooth one. Fig. 2(b) shows the air-gap flux density of 6s/7p and 6s/25p LVFRMs at open circuit (Pf=15W). The flux modulation effect of each primary small teeth can be seen based on the peak number of flux density. Moreover, more sinusoidal back-EMF can be obtained in 6s/25p LVFRM, as shown in Fig. 2(c). Fig. 2(d) shows the cogging force of 6s/7p and 6s/25p LVFRMs. It can be seen that the cogging force will increase with the influence of end effect. Moreover, multi-tooth structure will aggravate the end-effect. At rated copper loss of 30W, the average force of 6s/25p LVFRM is 18.4N and 6s/7p is 14.2N, which increases nearly 30%. However, the force ripple in 4-tooth LVFRM also increases, as shown in Fig. 2(e). Fig. 2(f) shows the variation of average force with total copper loss (Pf=Pa). It can be seen that multi-tooth LVFRM saturates more quickly at high electric load. For 4-tooth LVFRM, the slot/pole combination can be 6s/22p, 6s/23p, 6s/25p and 6s/26p. Fig. 2(g) and 2(h) show the back-EMF at v=0.24m/s and average force at 30W, respectively. It can be deduced that odd number secondary poles exhibit more sinusoidal back-EMF and higher average force than even ones. Finally, a 3D model of 6s/25p LVFRM is built to validate the 2D predicted results and further analyze the end effect. III. CONCLUSION This paper makes a fair comparison between single- and multi-tooth LVFRMs. At rated copper loss, the average force of 6s/25p (4-tooth) LVFRM is 18.4N, which increases nearly 30% compared with single-tooth one. Moreover, odd number secondary poles also exhibit more sinusoidal back-EMF and higher average force in multi-tooth LVFRMs. In terms of thrust force performance, multi-tooth LVFRMs can be adopted at low electric load.

CU-06. A Study of Non-symmetric Double-sided Linear Induction Motor for Hyperloop All-in-one system(Propulsion, Levitation, Guidance).

W. Ji[1], G. Jeong[2], H. Kim[2] and H. Lee[1]
1. Railway Vehicle System Engineering, Korea National University of Transportation, Incheon, The Republic of Korea; 2. Hanyang University, Seoul, The Republic of Korea

1. Introduction Currently demand on environment-friendly ultrahigh speed long distance transportation is increasing, so that Hyperloop is getting attention globally. Hyperloop is a new innovative transportation that a levitated subsonic speed train travels through vacuum cylindrical tube. Hyperloop needs functions of propulsion, levitation and guidance for its service and also many device is necessary for those functions. In high speed maglev train, generally, linear synchronous motor is applied for propulsion and permanent magnet is used for passive levitation, and Electromagnet or permanent magnet is used for guidance. In tube, constrained space, many device makes entire system complicated and size of vehicle, tube is increased. Therefore, costs of maintanace, manufacture, construction are increased and control of each devices is very difficult. This study proposes Non-symmetric Double-sided Linear Induction Motor (NSDLIM) as propulsion, levitation, guidance All-in-one system for Hyperloop. Requirements of NSDLIM was investigated considering special structure and operating environment and basic model was designed. Then force of propulsion, levitation, guide depending on are analyzed by using finite element method (FEM). By adjusting parameters such as materials, shape, slip frequency, validation and possibility of NSDLIM was examined. 2. NSDLIM for Hyperloop All-in-one System Every system of high speed maglev that has been studied and developed requires two or more devices for propulsion, levitation and guidance. MLX in Japan applys a linear synvhronous motor for propulsion, and uses 8-coil on both sides of the guideway and superconducting electromagnets on both sides of the vehicle for levitation and guidance. Trans Rapid in Germany is propelled by a linear synchronous motor and using attractive force by electromagnets and magnetic substances to levitate and guide. Conventional maglev train systems has many devices and large vehicle, guideway so it is hard to be applied to hyperloop As shown in Fig. 1, NSDLIM, the subject of this study, has a primary coil on both sides of the bottom of the tube and vertical secondary reaction plate attached to under the vehicle. NSDLIM is designed based on linear induction motor (LIM) and utilizes three charateristics of a linear induction motor. Thrust force by the propulsion principle of a conventional linear induction motor, levitation force by transverse end effect, guide force by normal force are generated in NSDLIM. Therefore, just one All-in-one system can conduct 3 functions so has advantages small sized vehicle and tube, low cost of maintanance and construction, simple control etc. 3. Design of NSDLIM Hyperloop has unusual structure and operating environment such as vacuum cylindrical tube guideway, so that requirements are different from conventional highspeed maglev train. As shown in Table. 2, very hign speed, acceleration and power are required and length is limited. Basic model of the NSDLIM was designed by using magnetic equivalent circuit and considering analyzing time, it is 1/2 sized. The primary material of the NSDLIM is 35SPN230 and pole pitch is 450mm by considering winding because of thick wire due to high current, winding method is double layer short pitch distributed winding by considering thrust and levitation force ripple. And seconday reaction plate material is aluminum and airgap is 20mm, thickness of plate is 30mm. 4. Analysis of NSDLIM NSDLIM was analyzed by using FEM. Because of its structural characteristics, thrust and guide force by 2D FEM, levitation force by 3D FEM are analyzed. By investigating effects of parameters on force of propulsion, levitation and guide, parameters such as conductivity of secondary plate, teeth width, slot width, airgap, direction of magnetic field, slip, input current, slot per phase per pole were adjusted to improve 3 forces. Fig. 2,3 shows thrust force – slip and levitation force – slip with vertical displacement and input current is 7kA and frequency is 386Hz. Displacement 0mm means that primary and secondary are center arranged. As the displacement increases, the thrust force deceases and levitation force increases. As shown, thrust force is high despite its required force is 27.5kN, but levitation force is low. Fig 3 shows thrust and levitation force of model of different slot per phase per pole. It is seen that thrust force decreases but levitation force increases. So by adjusting parameters NSDLIM model that meet forces requirements could be derived. 5. Conclusion This paper is study of non-symmetric double-sided linear induction motor for Hyperloop All-in-one system. There is 2 or more devices for propulsion, levitation and guidance in hyperloop system. Therefore, entire system is compligated and size of tube and vehicle increase so cost increases and control is difficult. To replace conventional system with NSDLIM, validation and possibility of NSDLIM was examined. Design, analyze, of NSDLIM was conducted and model that meets required thrust force was derived and by adjusting parameters force of propulsion, levitation and guide was improved. The possibility of NSDLIM was verified and through detail design and consider other parameters such as ladder type of secondary plate, NSDLIM could be realized as All-in-one system for Hyperloop.

CU-07. Design and analysis of a novel rotary-linear motor with voice coil structure.

F. Xing[1] and B. Kwon[1]
1. Hanyang University, Ansan, The Republic of Korea

I. INTRODUCTION With the greatly development of the industry, such as the field of integrated circuit and high-precision robot arm, they always require multidimensional complex movements and posture adjustments. Therefore, the multi-degree-of-freedom motion platform is among the most important research topics to advance precision machining. As one of them, the rotary-linear motors have the advantages of two degree-of-freedom motions and simple structures, which can facilitate high performance [1], [2]. However, the conventional rotary-linear motor has the disadvantages of low acceleration, big size, no-smooth force, slow actuation and so on. Therefore, a novel type of rotary linear motor overcoming these disadvantages with high controllability is an increasing necessity. In this paper, a rotary-linear motor combined the SPM motor and the voice coil motor [3] structure (RL-SVCM) is proposed here to achieve rotary and linear motion independently and fully decoupling control with smooth linear force. Furthermore, the voice coil structure of the mover allows the motor to provide a high acceleration and quick response. Especially, the novel unique structure in the linear motion part can make the linear force approaching constant value, which proves a big convenience for the control of the voice coil motor. This motor features a small size, which makes the motor especially suitable for PCB drilling, pick-and place systems, tooling machine, precision operated robot arm and so on. II. MODELING AND FEM ANALYSIS RESULTS Fig. 1 shows the novel structure of the RL-SVCM in 3D, which based on the double stators and one rotor (mover) structure, as well as the sectional views can be found in it. From Fig. 1, it can be found that the outside stator is prepared for the rotating working part of the RL-SVCM, which is a SPM motor with four pole pairs. The outside stator is designed with the concentrated winding in 12 slots, and two different colors of the magnets on the outside of the rotor/mover representing the different magnet direction work for the SPM motor rotating part. Also in Fig. 1 the inside stator is prepared for the linear working part of the RL-SVCM, which is a voice coil motor. The inside stator is designed with the voice coil and the magnet matching with the linear motion is with the single magnet direction shown in green color equipped in the inside of the rotor/mover. Surround the rotor/mover part, the outside is one straight air gap used for the rotating motion part, and the three segments air gap in the inside of the rotor/mover are working for the linear motion part. Meanwhile, the magnetic circuit of the rotary motion and linear motion are shown in the two sectional views of the Fig. 1. The FEM analysis results are shown in the Fig. 2. Fig. 2(a) shows the torque distribution under the max current point of the rotary motion, and Fig. 2(b) shows the linear mover force and force ripple under different currents. The table 1 shows the torque, torque ripple of the rotary motion; the forces, force ripples of the linear motion; and also the detail of the RL-SVCM. III. CONCLUSION This paper proposed a novel rotary-linear motor combined the SPM motor and the voice coil motor structure. The detail structure of the electrical motor is presented here. Also the FEM analysis results are shown in the paper. From the analysis result, the most important advantage of this paper is the smooth constant force in the linear motion and quick response, which is great convenient for the control of it. And also the high acceleration, small size are the advantage of the two degree-of-freedom motions rotary-linear motor. About the detail analysis of the motor will be shown in the full paper.

I. INTRODUCTION Recently, there has been an increasing demand for technological development in the field of renewable energy. This is because of the abnormal climate change on Earth due to greenhouse gas emissions caused by the continuous use of fossil fuels. Among these technologies, cogeneration systems using free-piston Stirling engines (FPSEs) are one of the most effective alternatives to cope with the climate change. The FPSEs can be used with various power sources such as gas, liquid, solid fuel, and thermal energy from both nuclear and solar energies. The FPSEs can also be used for recycling waste heat [1], [2]. The FPSEs consist of linear generators ; this structure has the advantage of less mechanical friction loss because there is no mechanism restricting the motion of the piston. Additionally, linear generators are better than rotating machines in terms of efficiency and maintenance because they have the advantage of generating a linear thrust in a short stroke range [3], [4]. In this study, the optimum design and load characteristics of a linear generator for an FPSE system were discussed. To design a suitable generator for an FPSE system, a single-phase linear permanent magnet generator (SPLPMG) was designed considering the operation speed and stroke characteristics of the engine. Further, no-load and load characteristics were analyzed by the finite element method (FEM) considering the manufacturing process and design parameters of the SPLPMG. In addition, to evaluate the performance of the linear generator, a test rig composed of a crankshaft, whose rotation was converted into a linear motion, was evaluated. The prototype SPLPMG was driven by a servo motor or a gasoline engine to evaluate the operation speed and load resistance characteristics. Finally, the optimum design and characteristics measurement results of the SPLPMG were compared. II. OPTIMAL DESIGN AND EXPERIMENTAL Fig. 1(a) shows the position of SPLPMG in the internal structure of an FPSE system. Fig. 1(b) shows the detailed shape of the SPLPMG. The generator has a stator composed of 12 pieces of iron core, and the inner core is made of radial lamination. It is a generator with an outer stator structure and has two airgaps. The mover in the generator converts the mechanical energy into electric energy by reciprocating the short stroke interval, ±20 mm. Since the stroke length of the generator was very short, it was designed as the SPLPMG rather than a three-phase generator. Moreover, considering the stacking factor due to both the stator manufacturing process and the radial stacking of the inner core, the no-load and load analysis of the SPLPMG was performed according to the frequency. The measurement system was constructed to verify the characteristics of the designed linear generator. Because the designed linear generator was reciprocating, it was more difficult to evaluate than the rotary generator. In this study, a test rig composed of a crankshaft that converts rotational motion into linear motion was fabricated, and the load of the linear generator was tested. To minimize the mechanical loss due to the reciprocating movement of the linear generator, the noncontact air bearing was used instead of the mechanical linear bearing while evaluating the performance of the linear generator. The load evaluation was carried out by serially connecting the resonant capacitor and the load resistor, in accordance with the resonant frequency of the SPLPMG. The linear generator evaluation system is shown in Fig. 2(a). As a result of the load evaluation, it was confirmed that the generator output is 3046 W when the generator operated at a frequency of 27 Hz, the resonant capacitor is 300 uF, and the load resistance is 10 Ω. Fig. 2(b) shows the FEM and measurement results according to the operating frequency and the load resistance of the linear generator. III. RESULTS In this study, the design, analysis, and evaluation methods of a 3 kW-class SPLPMG for an FPSE system were presented. To evaluate the no-load and load characteristics of the optimized generator, a characteristic evaluation system equipped with a motion conversion mechanism was installed, so that the ±20 mm stroke displacement could be linearly operated. As a result, it was confirmed that the generator output was 3046 W when the resonant capacitor was 300 uF, and the load resistance was 10 Ω at a generator driving frequency of 27 Hz. Further, considering the operating frequency deviation between them, the FEM and load test results were confirmed to be almost similar.

Abstract : The bigger cogging force and higher cost are the two main problems for optimizing the design and application of the permanent magnet linear motor (PMLM). This paper proposes a new method of adopting two types of permanent magnet materials applied in a PMLM to decrease the cogging force and cost. Three PM material configurations are considered in this paper, namely (i)NdFeB only poles, (ii)alternate NdFeB and Ferrite poles, and (iii) NdFeB poles with Ferrite edges. Firstly, the PMLM using NdFeB only is designed, then through replacing the adjacent NdFeB pole with a Ferrite pole, or placing Ferrite at the edges of the NdFeB magnets the performances are investigated. It is found that the PMLM with two different permanent magnet materials can achieve a similar magnetic force as the NdFeB only design, and moreover the cogging force can be reduced to under 5% of the rated magnetic force. It is shown that a PMLM with sectional lower magnetic energy magnets can improve performance and lower the overall mass of the rare-earth elements (hence improving the cost). Keywords: PMLM, permanent magnet materials, ferrite, cost I Introduction Permanent magnet electric machines are widely used in industrial manufacture, railway transportation etc. due to the advantages of simple structure, reliable operation, high performance and small size. There are two main design challenges, being reducing the cogging force and lowering the cost cost. Many methods are proposed in [1], [2], [3], [4] to reduce the cogging force. The cost of the permanent magnet motors is still a sensitive issue and a barrier to mass proliferation is some markets, because of the heavy use of the rare earth permanent magnet materials, such as NdFeB, SmCo, etc. In 2017, motor's main manufacturing materials, such as copper, silicon steel and Rubidium metal are experiencing a price increase in different levels, most alarmingly the price of the rubidium which increased by up to 81%. In light of this it is necessary to research on the higher performance and smaller volume motors to decrease the use of Nd-Fe-B permanent magnetic materials, or find other materials to replace the higher cost permanent magnet (PM). In this paper, a method of using the low price permanent magnet materials of Ferrite to replace sections of the NdFeB is proposed. Although the coercivity force and magnetic energy is only 10% of the NdFeB, performance/cost benefits are found when they are used in combination. Starting with a designed PMLM with NdFeB PMs only, shown in Fig.1a, two methods are applied to reduce the cost of the PMLM. In the first method, the alternate poles (in this case being the South pole) are replaced by the Ferrite, with the width and height of these Ferrite PMs optimized to tailor the magnetic flux. Through the optimization, the aforesaid PMLM achieves the same average force as the NeFeB only design, and because of the replacement of the NdFeB, the whole cost of the PMLM will decrease considerably. In this staggered arrangement, shown in Fig.1 (c), the size of the adjacent Ferrite PMs are different, which affects the magnetic flux in the air gap - this principle is similar to change the magnet shape to optimize the cogging force of the PM motors[5]–[7]. Another method is replacing sectional edges of the NdFeB with Ferrite, as shown in Fig.1(b) and through changing the ratio of the Ferrite and NdFeB in one pole pitch, the cogging force is reduced, and the cost of the PMLM is also reduced. II Optimizing of the PMLM with NdFeB and Ferrite edges Two methods are adopted in this paper, as shown in Fig.1 (b) and Fig.1 (c). The optimization the configuration shown in Fig.1(b) will be described in this section. III Optimization results of the PMLM with alternate Ferrite pole The PMLM with the NdFeB only of Fig.1(a) is optimized, and the mean force is 345N, the cogging force being about 2.5%. With the same envelope of the original machine of Fig.1a, another PMLM with Ferrite only, and using alternate NdFeB and Ferrite magnets as shown in Fig1c are built, and the force is compared in Fig.2. Through the optimization the PMLM with NdFeB only and with the alternate Ferrite pole can have a same force level with the PMLM with NdFeB only, as shown in Fig.2, and the cogging force can also be reduced. IV Experiment A PMLM only with the NdFeB is manufactured, and the cogging force is measured, which can be used to verify the modelling for this newly proposed PMLM. V Conclusion In this paper, in order to reduce the manufactured cost and improve the force quality of the permanent magnet electric machines, a PMLM with two types of PM materials is proposed. Through the simulation, it is found that the force of this new PMLM with two magnet types is of the same level of the PMLM with NdFeB magnets only. This structure can reduce the use of the NdFeB, the cost of the PMLM unit, and reduce the force ripple. The final paper will describe and quantify these benefits further.

I. INTRODUCTION The maglev permanent magnet linear motor has the advantages of no mechanical friction and high stiffness, and it is widely researched by many scholars for the great application in high speed, large acceleration and high precision linear positioning movement[1],[2], Compared with the linear motor supported by the air flotation system or mechanical structure, the maglev linear is more suitable for working in dust-free vacuum environment, which makes it a promising research field[3]. The maglev linear motor has three degrees of motion freedom, which are respectively realized by the horizontal thrust force in the *x*-aixs, the normal force in the *z*-aixs and the torque around the *y*-aixs. The horizontal thrust and normal force can be controlled by the conventional *dq* composition method, but both *q*-axis current and *d*-axis current will generate additional torque to rotate the motor mover. In the control process this additional torque can be seen as disturbance. One of the key issues to realize the optimal control of the maglev linear motor control system is to decrease or eliminate this additional torque. To achieve this, a new linear motor structure has been proposed in this paper. First, the analytical model of the maglev linear motor is constructed. The above additional torque can be analyzed, based on which the new-structure maglev linear motor is proposed. Finally, the optimal design for the proposed linear motor is done in this paper. II. MODELING AND TORQUE ANALYSIS First, the coordinate system of the maglev linear and the coordinate transformation system of position and vector are constructed. Second, the electromagnetic force and torque on three degrees of freedom have been numerically analyzed. Finally, the finite element method has been used to validate the analytical analysis. Fig.1 shows the structure of the maglev linear motor model. It consists of the stator, mover and the gap between them. τ is the pole pitch. The stator has ABC three-phase windings and non-conductive plate. The distance between the two winding centers is τ. The three-phase windings are arranged in the *x*-direction with the electrical degree gap of 240. The width of the windings is 4τ. Moreover, the mover consists of permanent magnet and conductive plate. III. DESIGN OF A NEW MAGLEV LINEAR MOTOR Based on the analysis of the additional torque in the above section, two motor units can be combined to cancel out the additional torque. To make sure that two additional torques are in the opposite direction and the horizontal and levitation forces for the two motor units are in the same direction, the phase angle difference between them should be $1/2\tau$. Fig. 2 shows the arrangement of the windings. Moreover, the size of the main and auxiliary permanent magnets of a Halbach permanent magnet array can influence the distribution of the magnetic flux density in the air gap, and therefore the structural optimization of the permanent magnets needs to be performed according to the required performance index. Furthermore, the thickness of the permanent magnets can also affect the motor force coefficient, which will be analyzed in the next section. IV. VALIDATION AND ANALYSIS Fig. 3 shows the electromagnetic force and torque of two motor units as a function of the *x* position. It can be seen that the horizontal force and levitation force of the two motor units always maintain a nearly constant output with the change of the position of the mover, while the torque changes with the change of the mover position. Fig.4a shows that the horizontal force and levitation force produced by the levitation linear motor are the sum of the respective horizontal force and the levitation force produced by the two units. From Fig.4b it can be seen that the additional torques acting on the centroid of the mover are in the opposite directions, and thus cancel each other out. From the simulation analysis it can be obtained in the magnetic levitation linear motor current can offset the additional torque ripple. V. CONCLUSIONS In this paper, a new-structure magnetic levitation linear motor is proposed to reduce the additional torque generated by coil. The new topology makes the additional torques generated by two different units cancel each other out. With this problem solved the commonly used *dq* decoupling strategy can be adopted realize the control of the proposed maglev linear motor. The finite element simulation shows that the new-structure magnetic levitation linear motor can effectively reduce the additional torque fluctuation.

CU-11. A Robust Multimodal Optimization Strategy for a Tubular Voice Coil Motor Design in Linear Slit Stage.

J. Lim[1] and D. Lim[2]

1. Magnetic Levitation and Linear Drive, Korea Institute of Machinery & Materials (KIMM), Daejeon, The Republic of Korea; 2. Electrical Engineering, University of Ulsan, Ulsan, The Republic of Korea

Introduction This paper describes the design optimization of the voice coil motor(VCM) for linear slit stage. Linear slit stage is a device that serves the aperture of the laser equipment for removing defective pixels in the LED display panel. The VCM acts to open and close the aperture at high speed. The slit stage itself is driven by a gantry system to find the approximate location of the large display. After gantry system finds approximate position, the VCM corrects precise location to determine the position and size of laser beam. The gantry system of the operating equipment moves at high acceleration to shorten a tac time. Due to the lack of thrust to overcome the high acceleration of the gantry, the VCM often loses its exact position. In order to solve this problem, it is necessary to maximize the thrust of the VCM. The VCM should have a thrust that can overcome the acceleration of the gantry so that it can maintain precise position even when moving in a high speed. The problem of reducing the thrust losses at both ends of the stroke and reducing the settling time should also be considered, which are related with minimizing thrust ripple and minimizing mass respectively. Therefore, optimal design considering various objective functions such as thrust, thrust ripple, and mass is required. Main Body The 3D modeling of linear slit stage and optimization flow chart are shown on Fig. 1. The VCM's stator consists of a cylindrical magnet and a linear scale. A mover of the VCM is made up of moving coil and a linear encoder head. In order to reduce the tac time, a settling time minimization is required, which can be achieved by a large thrust, a small moving mass, and a low time constant of the moving coil. Since VCM has various design variables and objective functions, it is impossible to apply optimization to all variables of VCM. For this reason, we propose a robust multimodal optimization (RMO) strategy that can consider for various objective functions and a robust solution with minimal analysis. The objective function of the design is the force, force ripple, and mass that are most important in the design of the VCM, and the design variables are the dimensions of VCM components. In the first stage of the RMO strategy, the Taguchi method [1] is used to derive initial design and select sensitive design variables. The residual magnetic flux is selected as a noise factor because it is an uncontrollable factor that has a great influence on the distribution of performance and the objective function. Through the calculation of the synthetic SNR, a rough optimal design for seven design variables is derived, and two sensitive design variables are selected. In the second stage of the RMO strategy, kriging assisted multimodal optimization[2] is applied to search multiple optima of the two sensitive variables sorted by the initial stage. The initial surrogate model is constructed by applying the objective function values of the Latin Hyper Cube Sampling[3]. After searching the local peaks of the generated surrogate model, the object function values are calculated for the local peaks of the surrogate model. Then the surrogate model is updated with the calculated object function values. This process is repeated until the global peak value converges to within a certain criteria. In order to solve the problem of being trapped at the local peak, perform a blank fill algorithm[1] which can scatter the variables to unrevealed area. In the third stage optimization, the robustness of the solution is evaluated to analyze the noise factor. The final solution should have a high value of the objective function and a robust value for the change of the variable. In this digest, Robust algorithm is verified by test function. In order to determine the optimal solution, we introduce k which internally divides the maximum and minimum values for a certain peak range. The internal division value determines the weight value at maximum value and difference of maximum and minimum. The test function and the objective function are shown below. The results are shown in Fig. 2. The largest 6 peaks are described. $F(X,Y) = X^{0.25}*\sin(X^2)*Y^{0.25}*\sin(2*Y^2)$ opt = k * Max + (1-k) * MIN The first and third candidates show that the rank is changed according to the sensitivity domain of the peak. Peak value of candidate 1 is high, but candidate 3 can be better solution when sensitivity is considered. Therefore, candidate 3 can be an optimal solution to reduce variation in performance of equipment caused by uniformity and production tolerance of control gains of mass-produced VCMs. Conclusion In the design for the VCM applied to the linear slot stage, various design variables, objective functions, and design reliability should be considered simultaneously. In order to derive the robust optimal design result of the VCM, we propose a RMO strategy. Furthermore, we analyze the robustness of the proposed peak and present the criterion for selecting the optimal solution. The proposed optimal design strategy is very meaningful because it can not only consider various design variables and objective functions but also derive a robust solution with minimum analysis. In the final paper, we will present the details of the proposed design including the verification of manufactured product.

I. Introduction Development of humanoid is actively proceeding with increasing interest in robot development around the world. Eyeballs and joints of the humanoid are implemented with multi-degrees-of-freedom (DOF) systems using multiple actuators to achieve similar degrees of freedom to the human body.[1]-[2] However, these systems have the weak point of increasing size and weight. Therefore, in recent years, researches have been actively conducted on motors capable of multi-axis drive with one motor in order to replace several actuator systems. [3]-[5] This paper presents a spherical multi-DOF motor as the motor for application to the eyes of robots. It is possible to operate three axes with one motor. In addition, research was conducted to improve the output characteristics of the spherical multi-DOF motor and tilting stability analysis for stable tilting drive. II. Study on performance improvement of multi-DOF motor A. Basic model The structure of the spherical multi-DOF motor proposed in this paper is shown in Fig. 1. In order to reduce the eddy current loss, the inner rotor and the outer rotor are composed to move at the same time. The stator has coils for tilting driving and coils for rotational driving. Since the spherical multi-DOF motor is driven by three axes, the three-axis coordinate system is defined as shown in Fig. 2. B. Output characteristics according to change of the number of phases and pole arc angle In order to improve the output characteristics of the spherical multi-DOF motor, the characteristics of the output according to the change of the number of phases and pole arc angle under the same magneto-motive force condition were analyzed. The currents of the coils for tilting and rotating are applied as shown in equation (1). The analysis results of the output characteristics according to the change of the number of phases and pole arc angle are shown in Fig. 3. It can be seen that the three-phase system is superior in terms of average torque and torque ripple characteristics. C. Tilting stability according to change of the number of phases and pole arc angle Since the spherical multi-DOF motor is driven by three axes, it is essential to analyze the stability according to the command position. Fig. 4 and Fig. 5 show the stability characteristics of 3-phase and 4-phase motors when α and β are 0 ° at arbitrary positions. From these figures, it can be confirmed that a torque curve having a negative slope is formed and the generated torque is 0Nm at a point of α = 0 °. III. Conclusion This paper presents the spherical multi-DOF motor for three-DOF implementation. The analysis was performed according to the change of the number of phases and pole arc angle to improve the output characteristics. Through these process, it was confirmed that the three-phase system has better output characteristics than the other phase systems, and the output torque improved through detailed design of the pole arc angle. Further, stability analysis for three-axis drive was carried out, and it was confirmed that the proposed motor can drive three-axis drive. The full paper will provide additional analysis for improving output torque, and additional stability analysis based on the position of the coils and permanent magnets.

CU-13. A novel Switched Halbach Electro-magnetic linear actuating valve for Aerospace vehicle.

V.R. Bommadevara[1]
1. Electrical Engineering, IIT, Hyderabad, India

Abstract—A novel Switched Halbach electro-magnetic linear actuating valve is proposed to reduce the battery power consumption and improve the reliability of the total system.2-D Finite element analysis is carried out on the proposed topology and simulation results are promising which make this novel valve as an efficient solution in place of conventional solenoid valves. The hardware is realized and tested for its performance. I. Introduction:Reliability and energy efficiency are two major important areas in any aerospace vehicle. In satellite launch vehicles and guided missiles Reaction control system (RCS) is widely used in exo-atmospheric region for attitude control of the vehicle [1].Actuating valve is major element in the reaction control system which controls the oxidizer/fuel flow and hence the thrust in on/off control mode. Solenoid valves are used widely in RCS as control element. Continuous research in the area of solenoid valve to improve its response time, reliability and energy efficiency of total system is on and arrived at various configurations in terms of control and valve topologies [2]-[6]. In this paper a novel linear actuating valve based on switched Halbach topology is proposed which improves the energy efficiency and reliability of the total system. II. Proposed Topology: Fig.1 shows the complete model of Halbach magnetic valve (HB-valve). The stationary member of the valve is built with two co-axial permanent magnets magnetized along horizontal axis. Soft Magnetic material is embedded in between two magnets which is magnetized by a coil in the required direction along vertical axis. The moving member is plunger made of soft magnetic material. A. Principle of operation: The operation of this valve can be divided into three stages as shown in fig.1(c), (d) & (e). Stage-I: Coil is not powered on: In this stage the flux density in both top and bottom air gaps will be same as the flux from both the magnets distribute equally in both sections of plunger through air gaps. Equal and opposite forces F1 and F2 are exerted on the plunger in vertical direction (y-axis) and hence the plunger will be its Null position. Stage-II: Coil is excited with negative polarity: In this stage the flux density in top air gap is less than flux density in bottom air gap as the soft magnet is magnetized in -ve y-direction due to coil excitation. This makes both magnets and soft magnet as an Halbach array and the force F1 is less than force F2 and the net force tends to move the plunger up along vertical direction (+ve y-axis) and this is valve off position. And once the excitation is removed the Halbach is switched off and there is asymmetry in the top and bottom air gaps (bottom air gap is less than top). This makes F2 more than F1 and always there is force to move plunger up. The same function is done by a mechanical spring in conventional solenoid valve during off condition. Hence in HB-valve no spring is required. Stage-III: Coil is excited with positive polarity: In this stage the flux density in top air gap is more than flux density in bottom air gap as the soft magnet is magnetized in +ve y-direction due to coil excitation. The force F1 is more than force F2 and the net force tends to move the plunger down along vertical direction (-ve y-axis) and this is valve on position. And once the excitation is removed the Halbach is switched off and there is asymmetry in the top and bottom air gaps (top air gap is less than bottom). This makes F1 more than F2 and always there is force to move plunger down. This means there is no power required to hold the valve in on condition which improves the reliability and overall energy efficiency of the system. B. 2-D Finite element analysis (FE): Non linear magnetic analysis is carried on the HB-valve using FE (finite element) analysis to validate the design concept. The HB-valve is modeled as a 2-D axis-symmetric model along y-axis. The FE analysis results are shown in fig.2 for different stages of the valve operation. Electrical design is carried out to arrive at important parameters of winding i.e. Current density, resistance and inductance. The maximum current density of the coil required to switch the Halbach array direction is 80AT/mm^2. FE analysis on load is carried out to arrive forces exerted on plunger during transient and hold conditions of valve. III PRoTOTYPE HARDWARE: Proto hardware has been realized based on the design of HB-Valve. The hardware is shown in fig.3.The performance evaluation on hardware is carried out and test results are matching with design parameters. IV. Conclusion: Concept of a novel Switched Halbach electro-magnetic linear actuating valve (HB-valve) is proposed which can be used as an alternative to conventional solenoid valves for Reaction control system in aero-space vehicles. The design concept is validated using FE analysis and all stages of operation are analyzed by deriving the air gap flux densities and forces on the plunger. The main advantage in this valve is it eliminates use of mechanical spring and requires no power during hold condition of valve. The proto hardware is realized and tested for its performance which fairly matches with design.

CU-14. Electromagnetic optimization and minimization of detent force for linear permanent magnet vernier motor.

Y. Shao[1], *H. Zhang*[1] and B. Kou[1]
1. Harbin Institute of Technology, Harbin, China

I. Introduction Currently, linear motors have widely applications in direct drive system due to the advantages of transmission chains elimination. The detent force is an essential parameter for linear motors which is relative to the resultant thrust ripple. In this paper, a linear permanent magnet vernier motor(LPMVM) is analyzed which has high thrust density and low thrust ripple. Meanwhile, and the detent force is analyzed by Maxwell's tensor method. Finally, detent force and electromagnetic thrust are analyzed by a simplified three-phase model with a symmetry boundary in the 3-D finite element analysis (FEA) [1]-[3]. II. Basic Structure The basic structure of LPMVM is shown in Fig. 1. The proposed motor has double-sided structure which is comprised of one primary and two secondaries. The primary is comprised of one primary core and three-phase toroidal armature windings. The secondary is comprised of two iron yokes and permanent magnets (PMs), while the PMs are parallel magnetized and fixed on the surface of iron yoke, and the double-side structure adopts N-N relative arrangement form. The 6-slots/10-pole structure is used in this motor, which can generate 5th harmonic in air-gap magnetic field. III. Analysis and Optimization Detent force consists of cogging force and end force. Cogging force is generated by the interaction between primary tooth and secondary PMs. In this paper, through the shape optimization of the stator teeth and the permanent magnet to reduce the detent force. End effect is an important problem of linear motor electromagnetic properties. In this paper, the Maxwell tensor method is used for analyzing the end force. The relationship between the end force and the length of the primary core is obtained. For linear servo system, both thrust density and thrust ripple features should be taken into account. Among them, the influences of relative parameters on thrust and thrust ripple are shown in Figure 2. IV. Conclusion The proposed LPMVM has advantages of high thrust density and low thrust ripple. By comparison, the electromagnetic character is better than traditional linear permanent magnet synchronous motor. Moreover, the method of detent force analysis and optimization can be used to relative linear motor design.

Abstract—Linear Switched Reluctance Motor with Segmental Stator (LSRMSS) has been studied and proved to provide higher efficiency and force density than conventional LSRM. Since LSRMSS features significant local saturation and fringing effects, the geometric dimensions of the machine can not be determined by analytical design method. This paper introduces an overall design optimization process of LSRMSS which aims to improve the payload ratio of the machine both considering the copper loss and force ripple ratio. The optimization algorithm is combined with FEA to determine the optimal region of the machine dimensions. The results show that the active payload ratio of the machine is significantly enhanced by the design optimization process as well as the commutation force and force ripple ratio. INTRODUCTION In recent years, there is a surge of interests for Linear Switched Reluctance Motor (LSRM) due to the features of the robust and simple structure, the capability of fault tolerance and working under hostile environment [1]. LSRMSS has been studied and proved to be an alternative to the linear driving system due to its high efficiency, high force density and low cost [2]. In addition, LSRMSS is more applicable to long distance translations due to its low manufacturing and maintenance cost [3]-[5]. This paper is focused on the optimization process of geometric parameters of the original LSRMSS mentioned. The main target is to make progress in some propulsion forces calculated by different methods. OPTIMIZATION PROCEDURE A. Establishment of Geometric Parameters The 3D view of the original LSRMSS model and the experimental machine is pictured in Fig. 1. This is a LSRMSS with 3 phases, 2 stator poles and 4 mover teeth, which stack length is 60 mm. Several parameters are proposed to determine the final geometric model of the LSRMSS. The parameters within the range have some constrains with each other to make the LSRMSS feasible. The authors have updated the Constraints during the process of optimization. B. Optimization of Single Objective On the basis of the original motor, the authors optimize the machine dimensions to enhance the 3 objectives which are mean thrust, commutation thrust and thrust density. Firstly, mean thrust is the average of one single-phase operating thrust in one period, and is, to a certain extent, one of a basic performance in LSRMSS. Secondly, commutation thrust is the thrust obtained by the motor by controlling the switch of the three-phase electrical circuit. Then, the thrust density is defined as the thrust per unit mass of the mover, and it is considered vitally when the LSRM is used in vertical conditions. Finally, the authors have also considered the copper loss, which is a crucial performance in the fields of energy saving. The data results have been combined with Design of Experiment (DOE) and Finite Element Analysis (FEA). RESULTS ANALYSIS The results of the 3 optimization objectives are displayed in Fig. 2. The contour graphs of every optimization objective are also showed as well as the scatter plot 2D graphs. It reflects the relation between the parameters in the optimization algorithm and the optimization objectives. Every proposed LSRMSS model has a superior performance in a certain objective above. The analysis of LSRMSS by FEM showed an obvious improvement. Mean thrust is increased by 20.6%, commutation thrust is increased by 16.6% and thrust density is increased by 37.4%. In addition, the optimal solution of the approximate function is verified by the magnetic circuit and finite element analysis, which further proves the rationality of the range of the parameters. CONCLUSION This paper presents design optimization of the LSRMSS by using the DOE and FEM. Three new geometric models are proposed, which have superiority over the original model in terms of mean thrust, commutation thrust and thrust density, validating the rationality of the design optimization.

CU-16. Design of 2-Phase Slotless Actuator with New Winding Structure for Position Control of Multi-DOF Motor.

H. Hong[1], *H. Kim*[1], S. Oh[1] and j. Lee[1]
1. Hanyang University, Seoul, The Republic of Korea

An electric motor, which is a typical energy conversion device that generates mechanical output by receiving electrical input, is now an indispensable device in our daily life and is being used in many fields. Applications range from highly efficient direct drive motors for industrial and consumer applications to traction motors for vehicle and train applications. In addition, multi-degree-of-freedom motors, which are emerging as the next generation of motor technology, are capable of driving three-dimensional motions of more than 2 degrees of freedom and are currently undergoing research in leading countries such as the US, Japan and Germany. The multi-degree-of-freedom electric motors have been studied focusing on spherical electric motors in which the driving axes rotating in three directions of yaw, pitch and roll are matched to one driving point. In recent years, multi-degree-of-freedom systems having three drive axes and three drive points have been actively applied to various industries. However, spherical electric motors have limitations in practical use due to their difficult fabrication and controllability, and the multi-degree-of-freedom system applied to industry has a complicated structure by combining a general single-axis drive motor and a drive shaft structure in degrees of freedom. In order to solve the problems of existing multi-degree-of-freedom systems, the proposed structure is the hybrid type discussed in this paper. This paper introduces the advantages and disadvantages of various types of position control actuators that can be applied to such a hybrid multi-degree of freedom system, and studies on the design of slotless actuators and tilting structure for more precise and improved position control performance. For this purpose, a 3phase actuator with a cogging torque applied to a conventional hybrid type multi-degree of freedom system is replaced with a 2phase slotless actuator which has no cogging torque and can be advantageous in terms of responsiveness. In the design, a new winding structure that can solve the difficult manufacturing and proprietary technical rights of the advanced companies, which was the problem of the existing slotless winding, was applied to the 2phase actuator. And the validity of this is verified by theory, interpretation and experiment. In addition, unlike the 1st generation hybrid type multi-degree-of-freedom system, which applied inner rotor actuator, the proposed 2nd generation system enables the improvement of the output density by improving the position drive range and joint structure by applying the outer rotor actuator. Finally, the validity of this paper is verified by performing no-load test for design verification of the designed 2phase slotless actuator, speed control for position characteristic verification, and position control test.

CV-01. Nondestructive Testing for Shallow Defect of Ferromagnetic Objects Based on Magnetic Probe Structure.

S. Pan[1], D. Zhang[1] and E. Zhang[1]
1. Power Electronic and Motion Control Research Center, Harbin Institute of Technology Shenzhen Graduate School, Shenzhen, China

I. INTRODUCTION The Electromagnetic inspection technique plays an important role in the nondestructive testing (NDT) for many decades. Today, this NDT area is rather wide and significant. The magnetic flux leakage (MFL) technology is one of the most widely used electromagnetic nondestructive testing (NDT) techniques. MFL tools use permanent magnets to magnetize the detected object near to saturation flux density [1], [2]. Generally, the magnetizer mechanism of MFL are bulky and heavy. Although the shape of the opening and the depth profile of an arbitrary three-dimensional (3-D) defect from MFL measurements can be estimated [3], the inversion method is complicated and susceptible by the magnetization factors. For different shapes and different sizes of detected object, the magnetizer mechanism of MFL should be designed individually, and this requires a lot of time and experimentation. In this paper, a simple and portable magnetic detection device is designed with permanent magnets, magnetic probe structure and the Hall sensors. Compared with the magnetizer mechanism of MFL, the magnetic detection device is very light, low cost and easy to design and manufacture. The magnetic detection device can make qualitative, and quantitative evaluation for shallow defect of ferromagnetic objects. II. DESIGN PRINCIPLES AND SIMULATION The designed magnetic detection device is made of permanent magnets, magnetic probe structure and the Hall sensors in Fig. 1a. The designed magnetic detection device is not to magnetize the detected object near to saturation flux density, instead use the permanent magnets to generate the magnetic field that perpendicular to the surface of the detected object. The magnetic probe structure is made of high permeability materials, is used to gather the magnetic field. Through the magnetic probe structure, the direction of magnetic field is better, and the magnetic field intensity is stronger than generated by permanent magnets. During the testing process, there is no defect on the detected object, and there is no change of the direction of magnetic field under the probe structure. If there is defect on the detected object and nearby the magnetic probe structure. Because the magnetic resistance of the defect is far greater than the magnetic resistance of the intact surface, the balance of the magnetic circuit of detection system is destroyed, it causes the direction of magnetic field under the probe structure be changed. The Hall sensors detect the changes of the magnetic field under the probe structure to qualitative and quantitative evaluation the shallow defect of ferromagnetic objects. In this paper, the above phenomenon is analyzed by FEM in Fig. 1b, and through the simulation analysis, we optimized the magnetic circuit to high sensitivity and precision of the detection system. III. EXPERIMENTAL RESULTS The magnetic detection device based on magnetic probe structure for the plate, wire-rope and pipe are designed (in Fig. 2a and 2b). Through simulations and experiments, we find the magnetic detection device can make qualitative and quantitative evaluation for shallow defect of ferromagnetic objects. The waveform of defect on the plate is shown in Fig. 2c, and the result of detection of wire-rope is shown Fig. 2d. For wire-rope detection, the weight of the detection device is one thirtieth of the weight of the magnetic leakage detector, and the qualitative detection rate of defect is the same as the magnetic leakage detection. At the same time, it has certain quantitative detection precision.

1. Introduction An arc fault establishes a current path in the air which may cause malfunction of DC system and even a fire hazard. Arc fault detection is essential to improving the reliability, efficiency and safety of the DC system. However, the randomness of DC arc faults makes it difficult to define their characteristics [1]. Various detection techniques have been widely researched. There are mainly three methodologies to detect DC arc faults: frequency-spectrum analysis, wavelet transformation and electromagnetic radiation. The wavelet transformation attains the arc information in a time-frequency domain for arc detection but the accuracy depends on the correct selection of the 'mother wavelet' [2]. The electromagnetic radiation of DC arc from 1 MHz to 100 MHz could be used for arc detection [3]. However, the appearance and amplitude of the arc signals are arbitrary leading to the difficulties in identifying DC arc. Although the frequency-spectrum analysis detecting arc through the signatures of the frequency domain is of higher accuracy and is widely adopted [4, 5], the aimed frequency range and the threshold of power spectra to differentiate between DC arc and normal operation are unspecific. Thus, reliable techniques to detect DC arc faults are still lacking. In this paper, a magnetic-sensing-based technique is proposed to detect DC arc. This work developed a promising DC-arcing detection technique based on the analysis of frequency domain features of the magnetic field measured by a magnetic sensor. This technique is cost-effective because it can be implemented with low-cost magnetoresistive sensors which are capable of measuring electric current [6], and it does not require expensive current transformers. In the presence of an arc fault, the frequency spectrum of the load current is composed of both pink and white noise [7]. The frequency spectra from 0 to 50 kHz can be numerically fitted by a superposition of pink and white noise characterized by the fitting parameters of slope (γ) and magnitude (*A*). These fitting parameters can then be used to distinguish the characteristics of arc. The effect of supply voltage on the frequency domain of the arc current was investigated. The effects of the load current and electrode diameter were also examined. The detection technique was tested under various load conditions to demonstrate that the detection technique could reliably discriminate the normal operation and arc fault. The measurement results obtained with tunnelling magnetoresistance (TMR) sensors were compared with that obtained with a current probe to verify the effectiveness of the proposed technique. 2. Experiments The experimental setup mainly consists of an arc generator, a 10-kW DC power supply, a TMR sensor (TMR2001), the current probe, and an oscilloscope as shown in Fig. 1 (a). The DC arc was induced between the two copper electrodes by operating the stepper motor to create a gap length of 0.3 mm. As shown in Fig. 1, from a period of 0.5 s of their time-domain current waveforms respectively (Fig. 1b), the frequency spectra (Fig. 1c) of normal operation current and sustained arcing current were extracted. The characteristics of arcing were investigated from 48 V to 300 V in step of 12 V. The experiments were carried out at a load current of 5 A with the 3-mm diameter of copper electrodes. The pink noise equation (1) was applied to fit the FFT spectra of the current in normal operation and sustained arcing. $S(f) = A/f^{\gamma} + c$ (1) where f is the frequency, A, γ and c are constants. 3. Results and Discussion The measurement results in Fig. 1 (b) suggest that the current in normal operation and sustained arcing can be measured by both the TMR sensor and the current probe. Although the arc current detected by TMR sensor is larger in oscillations, the magnitude and variations are consistent with the results from the current probe. Therefore, the FFT spectra of the current waveform measured from the TMR sensor and the current probe are similar as Fig. 1 (c) depicts. According to Fig. 1 (c), the presence of arc causes a significant increase of the power spectral density (PSD) from 0 to 1 kHz which can be attributed to the pink noise. This phenomenon is particularly pronounced for the arcing at a lower voltage (e.g. 48 V). As the voltage increases, the arc current becomes more similar in nature to the normal operation current. Thus, the strength of the pink noise of the arc current decreases with the voltage. This trend is shown by the results at 48 V, 108 V, 180 V and 300 V in Fig. 2 (a). The effect of voltage on arcing was investigated from 48 V to 300V as shown in Fig. 2 (b) and (c). The parameter differences between normal operation and arcing can be applied to determine arc. The parameter P derived from γ and A using equation (2) (Fig. 2 d) is capable of identifying arc from 48V to 300V as Fig. 2 (e) shows. 4. Conclusion The TMR sensor can effectively measure the frequency spectrum of the arc current by sensing the magnetic field emanated. Since the differences of the parameter P between normal operation and arcing are unambiguous, it is ideal for determination of the DC arc. In the full paper, the influences of load current and the electrode diameter on the proposed technique will be reported. The details of the experimental results on arc detection of DC system from 48 V to 300V with the current up to 30 A will be presented.

CV-03. Structural Health Monitoring using magnetostrictive sensors.

Z. Leong[1], L. Chan[1], W. Holmes[1], J. Clarke[1], N. Walters[1], S. Hayes[1] and N. Morley[1]

1. Materials Science and Engineering, University of Sheffield, Sheffield, United Kingdom

Composites, although possessing good structural properties are subject to complicated modes of failure. These damages are often barely visible as they may be located between composite layers. Thus Structural Health Monitoring (SHM) of aircraft composite is required to determine when barely visible impact damage (BVID) occurs during flight, as if caught early before the damage becomes irreparable, it can be repaired *in-situ*, so saving money and time. BVID causes a strain within the composite, which can be measured, using surface mounted techniques such as fibre optics and piezoelectric sensors [1]. This project investigated an alternative technique using magnetostrictive ribbons in a sensor-actuator setup (henceforth referred to as sensors) to measure the BVID of carbon composites. Computer modelling and experimental research were used to determine the sensitivity and limitations of these magnetostrictive sensors. Composite samples were fabricated from a 2×2mm twill weave pre-impregnated carbon fibre epoxy system (VTC401®) from SHD Composites, with $Fe_{77.5}Si_{7.5}B_{15}$ (FeSiB) magnetostrictive ribbons mounted on both the surface and within the composite in different grid arrangements as sensing elements. Two methods were used to measure the strain response of the fabricated composite samples: through induction measurements, as well as a Hall-effect sensor. Tests were performed to determine if the magnetostrictive sensor could detect composite damage, strain in different conditions and composite delamination. The uniform strain sensitivity of the magnetostrictive sensor was tested using an inductance method utilising a 112 turn pick-up coil connected to an Atlas LCR45 analyser [2]. Passive induction measurements were used to determine how the magnetostrictive sensor responded to a uniform strain applied via bending jigs with different bend radii [3]. Further investigations into the magnetostrictive sensor strain response after mechanical vibrations and temperature cycling were also carried out. Local damage was achieved using impact testing and Figure 1 shows the change in response of the magnetostrictive ribbon before and after damage to the composite. It is observed that for while undamaged (solid shapes), the variation in the inductance is ±2 μH across the length of the composite. After damage, there is a change of 6 μH when the damage is between the ribbons and 14 μH when the damage is on the ribbon. Thus this shows that BVID can be detected using magnetostrictive ribbons. Another consideration is the amount of ribbon attached to the composite for detecting damage, thus an optimised grid design is necessary, which has a spacing that is small enough to detect damage, but not too small that large quantities of ribbon are required, which increase the composite mass. It was found from both modelling and experimental work (Type A in Fig. 1) that 20 mm spacing between the ribbons, provided the ideal weight trade-off for the required detection level. To determine whether the magnetostrictive sensors could detect delamination (which is a primary source of aerospace damage), a series of *in-situ* measurements using a Hall-effect sensor were carried out to measure the change in magnetisation of the magnetostrictive ribbons, during a stress-strain measurement of a composite sample (Fig. 2) obtained from three-point bending tests on an Instron machine. It is observed in the stress-strain curve that delamination occurs at a strain of 0.004, which corresponds to a change in the magnetisation gradient at ~140 secs. At 0.014 strain the composite breaks, and this is observed as a large positive jump in the magnetisation. This was repeated for a large number of samples, and it was determined that the magnetostrictive sensor can give a measurable change in magnetisation that corresponds to a delamination in the composite. Thus, the magnetostrictive ribbons are also able to detect delamination of composites, before failure. In conclusion, magnetostrictive ribbon sensors for structural health monitoring are a real alternative to existing methods. They are able to detect both barely visible damage and delamination within composites. CV-04. Serial MTJ sensors for detection back-side defects by eddy current testing.

Z. Jin[1], M. Oogane[1], M.b. Mohd Noor Sam[1], K. Fujiwara[1] and Y. Ando[1]
1. Applied Physics, Tohoku University, Sendai, Japan

In recent years, magnetic tunnel junctions (MTJs) based on MgO barrier have been attracted attention due to their high tunnel magneto-resistance (TMR) effect. MTJ based sensors enable us to measure very small magnetic field because of their high sensitivity and can be used in various industry fields [1]. Nondestructive eddy current testing (ECT) have been investigated using MTJ sensors for detection of surface defects. However, it is necessary to develop sensors to detect defects not only on the surface but also in deep. A serial MTJ sensor can realize a high signal-to-noise ratio (SNR) during inspection of deep defects due to improvement of sensitivity by optimizing number of MTJs [2]. In order to obtain high SNR for detection of deep defects in ECT measurements, we fabricated serial MTJ sensors with various numbers of MTJ. Furthermore, we systematically investigated their sensor performance on ECT measurements. The film structure of MTJ devices was SiO_2-sub./Ta(5)/Ru(10)/Ta(5)/$Ni_{80}Fe_{20}$(70)/Ru (0.9)/$Co_{40}Fe_{40}B_{20}$(3)/MgO(2)/$Co_{40}Fe_{40}B_{20}$(3)/Ru(0.9)/$Co_{75}Fe_{25}$(5)/$Ir_{22}Mn_{78}$(10)/Ta(8) (in nm). The series of 4, 16, 28, 40, and 52 MTJs with 10×10 μm^2 top pinned layers and 15×60 μm^2 bottom free layers were fabricated with photolithography and ion milling processes. After fabrication, the fabricated MTJs were annealed twice in a vacuum chamber using different directions and temperatures for obtaining a linear *R-H* curve [3]. An automatic ECT system was composed of an excitation coil with a function generator and sensing probe with the prepared MTJ device. The back-side pits with various diameter (from 4 mm to 8 mm) and depth (2.5, 5.0 and 7.5 mm from the detection surface) in 10 mm-thick copper specimens were inspected by using fabricated MTJ sensors. Figure 1(a) shows the MTJs number (*N*) dependence of detectivity in serial MTJ sensors measured by uniform magnetic field using a Helmholtz coil. The result shows that detectivity of MTJ sensors improves with increasing number of MTJs, which indicates that the fabricated sensor with 52 serial MTJs can offer high SNR for the uniform magnetic field. As shown in Fig. 2(b), the defect signal is observed when using ECT probe with a serial MTJs sensor ($N = 28$). However, since the secondary magnetic field induced from eddy currents in specimens is not uniform, the SNR strongly depends on distance between MTJ sensors and specimens. As shown in Figure 2(a), when an excitation field with low frequency (100 Hz) was used to detect back-side pits with various depths, the signals were almost saturated at $N > 28$. Fig. 2(b) shows SNR for inspection of defects with various depths. The serial MTJ sensor with 28 serial MTJs exhibited the highest SNR for detection of back-side pits regardless of the depth. This study confirmed that the optimized MTJ sensor can be used to detect deep defects in conductive materials with a high SNR in ECT measurements.

INTRODUCTION Ferromagnetic materials such as steel have high magnetic permeability, and thus their skin depth is shallower than that of non-ferromagnetic materials. Therefore, inspection at low frequency is required to examine a thick steel plate using eddy current testing (ECT) [1], [2]. Previously, we have demonstrated, using an electromagnetic simulation in conjunction with the finite element method, that the slit defect in the backside of the steel plate can be detected when the excitation frequency is low enough [3]. In this study, we propose a system that detects slit defects in the backside of the steel plate using low-frequency-ECT (LF-ECT). *METHODS* Figure 1 shows the developed LF-ECT system. Two excitation coils were arranged on the upper side of the steel plate, and one detection coil was placed between these excitation coils to obtain the magnetic flux density B. The amplitude and frequency of the excitation were set to 2 A and 4 Hz, respectively. The output voltage of the detection coil was amplified with a low-noise preamplifier (SA-400F3, NF Co.) and then fed to a lock-in amplifier (LIA) (LI5640, NF Co.) to obtain the in-phase (real part of the magnetic flux density) and out-of-phase (imaginary part of the magnetic flux density) components. The excitation and detection coils were moved simultaneously by 5 mm using two-axis motorized stages (OSMS26-300(XY), Sigma-koki Co., Ltd.). We used an SM490A steel plate as a test specimen. The thickness of the steel plate was 10 mm. A crack of length 50 mm and width 10 mm was made on the back of the steel plate. The thickness of the crack, d, was 6 mm. In this study, we also established the more suitable current direction to detect the defects in these coils, as shown in Fig. 1. *RESULTS* Figure 2 shows the imaginary part of the magnetic flux density distribution Im[B] obtained by the detection coil. The distribution when the excitation current is in opposite direction in the two excitation coils is shown in Fig. 2(a), whereas the distribution when the excitation current is in the same direction in the two coils is shown in Fig. 2(b). In Fig. 2(a), the positive and negative values of Im[B] are observed in the vicinity of the edges of the defect. In contrast, only the positive value of Im[B] is observed at the defect in Fig. 2(b). These results suggest that the method to flow the excitation current in the same direction as shown in Fig. 1(b) is more suitable to detect the position of the defects. *ACKNOWLEDGMENTS* This work was supported in part by the Cross-Ministerial Strategic Innovation Promotion Program (SIP), Cabinet Office, Government of Japan.

CV-06. Detection and identification of object based on a magnetostrictive tactile sensing system.

B. Zhang[1], B. Wang[1], Y. Li[1], W. Huang[1] and L. Weng[1]
1. Hebei University of Technology, Tianjin, China

Tactile sensing is important for the exploration and manipulation of object, and a lot of research work has been done on the design and characteristic testing of the tactile sensor[1]. The research work mainly focuses on piezoresistive and piezoelectric tactile sensors[2-4], while theoretical and experimental studies are a little on piezomagnetic tactile sensors. In fact, the piezomagnetic tactile sensor has the advantages of high precision, simple signal processing circuit and less influence on temperature, compared with piezoresistive and piezoelectric sensors. The tactile information can be used to detect the hardness of objects, and then, to identify the degree of hardness. Here, a magnetostrictive tactile sensing system has been founded for acquiring tactile information corresponding to the pressure and stiffness. The magnetostrictive tactile sensing system can be used to test the grasp force of manipulator and detect the stiffness of object. The system consists of magnetic field regulating device, sensor, oscilloscope, manipulator, signal acquisition and control circuit. The core component is a tactile sensor based on the inverse magnetostrictive effect, and it is mainly composed of hard touch rod, Galfenol cantilever beam, permanent magnet and Hall element. The magnetic flux loop formed by permanent magnet and Galfenol cantilever beam. The sensor is mounted on a mechanical finger and move toward the sample object slowly. When the fingers touch the surface of the object, the mechanical fingers press a distance of 6mm. The mechanical finger torque controller provides a clamping force correlating to control value. We record the time series that the sensor provides during a full palpation procedure. Based on this dynamic information, different objects can be detected and identified. Fig.1 shows the relationship between the tactile sensor output voltage and time for four samples of different hardness, in the bias magnetic field of 2.56 kA/m. Four samples are sponge, foam 1, silica gel and foam 2 respectively. Simultaneously, the four samples are cubes with size of 3 centimeters. The steady-state output voltage of sponge, foam 1, silica gel and foam 2 is about 54 mV, 130 mV, 165 mV and 225 mV respectively. From Fig.1, the output voltage rising gradient and steady-state voltage of the sensor increase with the hardness of the samples, which is able to reflect the hardness degree of samples. A robotic gripper with sensor mounted on its finger performs a palpation procedure on a set of objects. By gripping an object, the robot explores the material properties, and acquires tactile information. Each object is grasped 30 times, and the corresponding sensor characteristic distributions of the four objects with different hardness are obtained as shown in Fig. 2. A number of training examples are stored for each object, and the objects are divided into four hardness grades of A, B, C and D. After the training samples are determined, a new observation is compared to the training data, and is assigned the label using the Extreme Learning Machine classifier algorithm. Because the shape of the observations are not the same, grasping process is slightly changed. After the object is detected to be contacted, it is further pressed into 6mm for hardness identification. An object is detected and identified, based on the Extreme Learning Machine classifier algorithm, the output voltage rising gradient and steady-state voltage. The complex matrixes at the best classification accuracy are plotted to show the recognition rate of each object. This kind of algorithm can be applied to real time operation, and the object can be recognized during the grasping process. It means that the system is able to identify object successfully.

CV-07. Strategy for determining a magnet position in a 2D space using 1D sensors.

P.M. Ribeiro[1], M. Neto[1] and S. Cardoso de Freitas[1]
1. INESC - Microssistemas e Nanotecnologias and IN, Lisbon, Portugal

Various useful applications arise from detecting the position of a magnet (e.g. encoders) [1], or transduce this position into another interesting physical quantity (e.g. force) [2]. To determine these quantities, the magnetic field of the reference magnet is measured in all spatial directions, using one magnetic sensor to measure the magnetic field generated by the magnet on each of the spatial directions. However, the fabrication of monolithic 2D and 3D magnetic sensors pose some fabrication challenges [3], particularly, the inability to anneal these sensors and retain two or three dimensional sensitivity, limiting the fabricated sensors performance and behaviour uniformity over large area samples or wafers. In this work, we present a strategy to detect the position of a magnet within a plane through the magnetic field it generates in another parallel plane in space, detected using an array of strategically placed TMR (tunnelling magnetoresistive) sensors. This strategy consists in placing the magnet over the sensor, with its magnetic moment direction (Y direction) orthogonal to both the sensor plane normal vector (Z direction) and sensitive direction (X direction). When placed in this configuration, the magnetic field intensity in the sensor sensitive direction will be that of a quadrupole, within the sensor plane (Figure 1). The magnetic field data is then captured at four points in the sensitive plane and used as the input parameters of a magnetic field vs position fit, which can then be used to determine the position of the magnet that would generate the magnetic field measured at each of the four sensitive elements. To optimize the design of this setup, a simulation was performed using COMSOL Multiphysics, assuming the magnetic field was generated by a cylindrical NdFeB magnet with 1 mm in diameter and height and characterized by a remanence of 13.2 kG. From this analysis, we determined that the best configuration to take advantage of the whole sensitive range of the sensor without reaching saturation would be to place this magnet at a 3 mm distance from the sensitive plane, which in turn resulted in the maximums and minimums of the quadrupolar field to be located at 1.5 mm in the X coordinate and 1.5 mm in the Y coordinate from the centre of the magnet, with intensities of $\pm$ 15 Oe. By placing four sensitive elements approximately where the maximum and minimum magnetic fields generated by the quadrupolar field are, one can achieve the maximum variability of the signal and therefore, the maximum sensitivity. The TMR sensor stack (from bottom to top: Ta 50/[Ru 150/Ta $50]_{x3}$/NiFe 30/CoFe 30/Al_2O_3 14/CoFe 30/Ru 6/NiFe 30/MnIr 180/Ru 150/Ta 50, thicknesses in Å) was deposited at INESC-MN by ion beam [4] and patterned into 4 sensitive regions, at a distance of 1.5 mm from the centre of the die in both X and Y, with each sensitive region consisting of 49 magnetic tunnel junctions (with 20x2 μm^2 area) in series, yielding a sensitivity of 886 Ω/Oe. The magnetic field was generated by a cylindrical magnet with the aforementioned characteristics. This magnet was fixed 3 mm over the sensor, which was attached to a precision motorized stage that moved within an area of 2x2 mm^2 with a step resolution of 20 μm in both planar directions. 10000 experimental resistance/position points were acquired for each of the four TMR sensors, which were used to train various predictive algorithms, while an ensemble of 100 resistance/position points were measured independently from the training ensemble to test the data fits. The best performing algorithm consisted in using two bootstrapped-aggregated prediction trees [5], one for each output coordinate, yielding a root mean square (RMS) error of 96 μm between the real position of the magnet and the value predicted by this method (Figure 2). The use of artificial neural networks (ANN) [6] was also tested. The ANN architecture yielding the best fit was a feed-forward network comprised of a 4-neuron input layer (one for each sensor signal), a hidden layer of 20 neurons, and a 2-neuron output layer (for the X and Y positions of the sensor). The RMS error achieved by this method was of 191 μm between the real position of the magnet and the position predicted by this method. Despite the loss in precision, it is computationally less demanding to extracting predictions, and requires less memory (2.9 kB vs 10 MB required by the prediction tree), allowing the possibility of being implemented on embedded processors, and consequently, in miniaturized devices.

CV-08. Analysis of a Defect Signal Deformations Induced by Eddy Current in RFECT System for Pipeline Inspection.

H. Kim[1], H. Yoo[2] and G. Park[3]
1. Electrical and Computer Engineering, Pusan National University, Busan, The Republic of Korea; 2. Korea Gas Corporation, Incheon, The Republic of Korea; 3. Electrical Engineering, Pusan National University, Busan, The Republic of Korea

1. Introduction The remote field eddy current testing (RFECT) system is generally used for inspection of ferromagnetic and conductive tubes such as pipelines. One main advantage of this technique is the high sensitivity to detect a defect on the external surface of pipe wall even if systems are located inside the pipelines [1]. This system consists of an exciting coil to generate the alternating magnetic field and receiving sensor coils for detecting defect signals. Both coils could be wound coaxially or vertically with respect to the tested pipe. Based on the RFEC phenomenon, there is remote field zone that the circumferential eddy currents induced by the source field are spread in the external surface of the pipe [2]-[3]. In general, this remote fields are located about two times of pipe diameters from the exciter coil [3]-[5]. Hence, the receiving coil should be placed in the remote field zone to detect the defect signal efficiently. In previous study, the unknown defect size is being mainly estimated by using phase angle difference between sensing signal and reference input signal because the amplitude of sensing signals is too small [6]-[7]. In such a small signals, eddy current signals imposing the size and shapes of defects are mixed with induced magnetic fields of defects, which causes the distortions of sensing signals. To increase the sizing accuracy of defects, it is important to measure the peak amplitude variation of defect signals at receiving coils exactly and analyze the distribution patterns of eddy currents in the pipeline. In this paper, the distribution of eddy currents on the pipe wall is computed by finite element method to predict the electromagnetic field signal deformations in the vicinity of the defect. And then, the effects of the induced magnetic field on defect signals in receiving coils are analyzed with respect to the different depth size of defects. The amplitude and the distribution pattern of defect signals are computed by 3D finite element method and the method to eliminate the signal distortions caused by induced magnetic fields are presented. Simulated results in this paper agreed well with measuring ones. 2. The Structure of RFECT System Fig. 1(a) shows the basic structure and diagram of RFECT system for inspecting 8 inches gas pipelines. An exciter coil is fed the AC voltage source with a low frequency to induce the alternating magnetic field on the pipe wall considering effects of wall thickness and eddy current distribution. Sensing coils are arranged along the full periphery in the interior of the pipe for detecting localized defects. Both coils are separated by a distance greater than twice the diameter of pipe. 3. Analysis of Defect Signal Deformations 3.1. Numerical analysis To predict electromagnetic field signal at the position of receiving coils efficiently, it is necessary to analyze the distribution of eddy current density on the pipe wall near the defect. The variation of eddy current distribution around the defect causes the magnetic field induced on the receiving coils to be distorted. As a result, both the amplitude and phase difference of the induced voltage on the receiving coils are affected by the reduction of pipe thickness. The distribution and magnitude of magnetic flux density for inspection system are computed by numerical analysis to derive defect signals. Assuming a quasi-stationary approach, the eddy current analysis is performed by 3-D finite element method. 3.2. Effects of induced magnetic field on the defect signal The background voltage signal in a receiver coil is defined as the offset of induced magnetic fields caused by eddy currents on the pipe wall with no defects. In general, both the amplitude and distribution of offset signal are changed with respect to the defect depth. Therefore, the defect signal is determined by combining the offset signal with the effects of induced magnetic field distortion in the vicinity of a defect. However, the pattern of defect signal distribution varies with the depth size. 4. Experimental Verification Fig. 1(b) show the experimental setup of RFECT system to verify the characteristics of defect signals. The RFECT system is pulled by the traction system from one side to the other side of the pipe specimen. Measured signals passing through the lock-in amplifier board from the receiving coil is converted as DC output voltage signals. Fig. 2 shows results that patterns of defect signals depend on defect depth. The defect signal includes the background offset with components of signal deformations. 5. Conclusion The advantage of RFECT is to detect the defect on the external surface of the pipe wall. It is used to be good method for inspecting gas pipelines. For the maintenance, it is essential to predict and analyze the amplitude variation of defect signals precisely because the amplitude of defect signals includes a lot of information to estimate the size of defects. This paper focused on the analysis of defect signal deformations induced by eddy current on the pipe around sensor coils with respect to the different depth size of defects. From the result of numerical simulation and experimental measurement, the defect signal was determined by the background offset with components of local field distortion. Eventually, it turned out that the pattern of defect signal distribution could be varied with defect depth.

CV-09. Fault Line Identification of HVDC Transmission Line by Frequency Spectrum Correlation Based on Capacitive-Coupling and Magnetic-Field-Sensing.

K. Zhu[1], W. Lee[1] and P. Pong[1]
1. Electrical and Electronic Engineering, The University of Hong Kong, Hong Kong, Hong Kong

The proliferation of high-voltage direct current (HVDC) system is growing fast thanks to its distinct technical advantages such as long-distance bulk-power delivery at a lower cost, asynchronous interconnections, and reduced power loss [1]. The protection system of HVDC system must detect, identify and isolate the fault quickly to keep the system stable by isolating only the components that are under fault, whilst leaving the rest of the network in operation [2]. However, the criteria of under-voltage and voltage derivative protection systems may fail because there also arises a large voltage drop/variation on the healthy transmission line due to the electromagnetic coupling between HVDC transmission lines incurred by the sharp transient current from the faulty one [3, 4]. Thus the healthy line could be mistakenly identified and isolated, resulting in further disruption and delaying system restoring time. In order to distinguish the healthy HVDC transmission line from the faulted one, a fault line identification technique based on the frequency spectrum correlation is developed in this paper. Firstly, the equivalent circuit of a single-circuit HVDC system was established in Fig. 1(a) to analyze the electromagnetic coupling between HVDC transmission lines based on voltage and current of the positive (U_p, I_p) and negative (U_n, I_n) polarity, respectively (Fig. 1(a)). As such, the voltage of one transmission line can be correlated with the current of the other line as (taking the voltage of negative polarity as an example) [3] $U_{n\_m}(t_2) = U_n(t_2)-(I_n(t_2) \times R_n + L_n (dI_n/d_t) - M_{pn}(dI_p/d_t))$ (1) where R_n (L_n) is the line resistance (self-inductance), M_{pn} is their mutual inductance, dI_n/d_t (dI_p/d_t) is the current change rate within a time from t_1 to t_2. By taking the Fourier Transform of Eq. (1), the frequency spectrum of voltage (£($U_{n\_m}(t_2)$)) must exhibit a similar pattern with the one of the varied current (£(dI_p/d_t)) if this voltage variation is incurred by the current change. For example, the frequency spectrum of line current (I_p, I_n) and voltage at the measurement point (U_{p_m}, U_{p_n}) after a grounding short-circuit (lasting 0.03s) of the negative transmission line is analyzed in Fig. 1(b). Since the voltage variation of the positive pole is incurred by the current change of the negative pole, the frequency spectrum of the voltage for positive pole (U_{p_m}) exhibits a high similarity with the current of the negative (I_n) while the voltage of negative pole (U_{n_m}) with the current of positive pole (I_p) is not. Therefore, the similarity degree of frequency spectrum between voltage of a line and current of another can be used to identify reliably whether the voltage variation is incurred by electromagnetic coupling or fault, and thus avoiding false operation of protection system. In order to verify this technique, a single-circuit HVDC system was established in PSCAD/ EMTDC [5] as shown in Fig. 2(a). A grounding short-circuit fault was simulated with the system operating in the normal status under 2 kA rated current. The frequency spectrum correlation coefficient (C_1 describes the spectrum similarity between the voltage of positive polarity and current of the negative polarity, and C_2 vice versa) after the fault was calculated (Fig. 2 (b) and (c)). The result shows that the voltage of the positive polarity and the current of the negative polarity are highly correlated (C_1 remains large and C_2 drops sharply) after the fault happens at 1.00 s, indicating this voltage is induced by the current variation of negative polarity rather than by the short-circuit fault itself. As such, despite the fact that a large voltage variation on the positive polarity occurred by electromagnetic coupling, this healthy line would not be identified as the faulty line. By comparing the sampling window of 0.01, 0.005, 0.001s, it can be observed that the shorter time window for frequency spectrum analysis can provide a faster response time based on a higher spectrum resolution [6]. A capacitive-coupling and magnetic-field-sensing assisted platform composing of two paralleled induction bars, and an array of magnetic sensors at both ends was previously developed in [7, 8], and it is capable of measuring overhead line voltage and current. This platform was adopted to implement this identification technique, and the details of simulation results will be reported in the full paper. This identification technique can further enhance the reliability of HVDC system by avoiding the unnecessary outages due to accidental shut down of healthy lines, fostering the interconnection of load centers with the use of HVDC system for increased power transmission capacity.

CV-10. Searching an avalanche victim using a transmitter with a rotating magnetic dipole.

A. Chiba[1] and T. Nara[1]
1. The University of Tokyo, Tokyo, Japan

1. Introduction Avalanche beacons are transmitters and receivers of 457 kHz magnetic field which are widely used for rescue of avalanche victims. Conventionally, a dipolar magnetic field is created by using one of three, orthogonal coils in a victim's transmitter, and then a searcher measures its magnetic flux density by using all three coils of a receiver to find a victim. A problem, however, is that a searcher should make a detour along the magnetic line of force to reach the victim. In this paper, we propose to use all the three coils of a transmitter in order to navigate searchers linearly to a victim. Detecting the posture of a transmitter by using accelerometers, we create a magnetic dipole equivalently rotating in the xy-plane. Then, the searcher can determine the direction to linearly proceed toward the victim by quadrature detection of the x- and y-components of the magnetic flux density. Although the use of a rotating magnetic dipole was proposed by Paperno [1] for magnetic tracking, their method needs to know the phase of a signal input to the transmitter, which is not applicable to avalanche rescue. Our method can navigate the searcher irrespective of the phase of the transmitter's signal. 2. Method As shown in Fig.1, the xyz-axes are set along the receiver's orthogonal coils, where the xy-plane is a searching plane. The aim is to find a direction of a transmitter viewing from the receiver, ϕ. By putting three orthogonal accelerometers, a rotating matrix R from the xyz-frame to the transmitter's XYZ-frame can be obtained. Then, in order to create a magnetic dipole rotating in the xy-plane with frequency of $f = \omega/(2\pi)$, the current proportional to Ri is input to three orthogonal coils of the transmitter, where $i = \cos \Omega t * (\cos(\omega t + \theta_0), \sin(\omega t + \theta_0), 0)^T$ where $F = \Omega/(2\pi)$= 457 kHz and θ_0 is an initial phase. As shown in Fig.1, denote the envelopes of the x- and y-components of the magnetic flux density measured by a receiver by Bx and By, respectively. Let $I_k = \int B_k \cos \omega t\, dt$ and $Q_k = \int B_k \sin \omega t\, dt$ for $k = x$ and y. Then, we can show that $\tan 2\phi = \{(Q_x+I_y)(I_x+Q_y)+(I_x-Q_y)(I_y-Q_x)\}/\{-(Q_x+I_y)(I_y-Q_x)+(I_x-Q_y)(I_x+Q_y)\}$. Note that this equation holds irrespective of θ_0, showing that the direction of a line along which the searcher should proceed to reach the victim can be determined from the quadrature detection of the magnetic flux density without knowing the initial phase of the transmitter signal. Although ϕ itself is determined up to π, the direction to proceed can be decided by measuring $|B|$. The goal of search, that is, the place just above the victim, can be also judged by detecting the maximum of $|B|$. 3. Experimental results The orthogonal bar coils (BA-200) and variable capacitors (CBM-223) tuned with F = 457 kHz were used as a transmitter. Modulation frequency $f = \omega/(2\pi)$ was 5 Hz. The other, same-type coils were used as a receiver to measure the magnetic flux density. After obtaining its envelope by a quadrature detection with frequency F, the quadrature detection with frequency f was conducted to obtain I_k and Q_k, from which $\tan 2\phi$ was estimated. The transmitter was moved on circles of radius r = 300 mm centered at the receiver, where ϕ = 0, 45, 90, 135, and 180 degrees. Fig. 2 shows the angle errors between the estimated line and the line connecting the transmitter and receiver. The mean and maximum error was 10.7 degrees and 24.3 degrees, respectively, which shows the validity of our method. Experimental results for wider search range has been preliminarily conducted and will be shown in the paper.

CV-11. Determination Scheme for Accurate Defect Depth in Underground Pipeline Inspection by Using Magnetic Flux Leakage Sensors.

H. Kim[1], C. Heo[1], S. Cho[3] and G. Park[2]
1. Electrical and Computer Engineering, Pusan National University, Busan, The Republic of Korea; 2. Electrical Engineering, Pusan National University, Busan, The Republic of Korea; 3. Korea Gas Corporation, Incheon, The Republic of Korea

1. Introduction The magnetic flux leakage (MFL) type nondestructive testing (NDT) has been applied for inspection of defects in ferromagnetic materials such as underground gas pipelines [1]. In this system, the magnetic field is applied to magnetize a steel pipe so as to induce the magnetic leakage fields in the vicinity of defects on the pipeline. A strong magnetic field produced by the permanent magnet could saturates the pipeline so as to leak the magnetic field around the defect sufficiently. Hall sensors equipped along the pipeline measure the leakage fields, then the size of defects could be estimated by the measured signals [2]-[3]. Form the measured sensing signals, decomposing or estimating sizes and shapes of defects are necessary because sensing signals contain the size and shape information of defects [4]-[5]. For the maintenance of pipelines, the estimation of depth size is the most important procedure for the management of safety accident. However, the previous depth estimation contains high error rate inevitably because the depth signal implies the width and length error simultaneously [5]. In conventional method, the depth size of defect is depend on the variables for the axial length and circumferential width of defects, which makes it hard to estimate defect depth independently. So, the previous work for depth estimation showed some errors especially in the large size of depth [5]. This paper focused on the enhanced method for the depth sizing in various defects by using decoupling algorithm to improve the sizing accuracy of defect depth. The functional relationship between signal amplitude and shape factors of defects are derived by the polynomial surface fitting with respect to defect's length and width so as to decouple the errors. To derive a decomposing algorithm, magnetic leakage signals are computed by nonlinear 3-D FEM and measured by hall sensors from standard defects on the 16 inches diameter pipe specimen. Estimated results show good agreements with measured ones. 2. System Structure The structure of MFL system is shown in Fig. 1. It is designed for inspection of the small diameter gas pipeline. Because small pressure of a gas inside the small pipeline is not enough to push and run the NDT system, it is necessary to adopt snake type robot modules to drive the NDT system as shown in Fig. 1(a). NDT system has ten MFL modules inside the pipe. In Fig. 1(b) and Fig. 1(c), every module consists of Nd-Fe-B magnets with steel back-yoke for generating a magnetic field on the pipe. Hall sensors are arranged along the full periphery of each MFL module to detect axial component signal of magnetic leakage flux. 3. Estimation of Defect Depth 3.1. Numerical analysis of defect signal The distribution and magnitude of magnetic flux density for MFL system was computed by using 3D finite element analysis. From simulated results, it is possible to predict the distribution and magnitude variation of defect signal with respect to various shapes of defects by computing the leakage flux density at the sensor position. 3.2. Measurement of defect signal From both FE simulation and experimental measurement, the peak amplitude of defect signal is detected by a hall sensor passing through the center of defects. The signal amplitude of leakage fields is dependent on the shape of defects such as length, width and depth. Especially, the peak amplitude of leakage signal with respect to axial distance is closely dependent on the variation of defect depth. It has a quadratic functional relationship between depth size and peak amplitude of leakage signal when it comes to various shapes of defects. 3.3. New Algorithm for estimating the defect depth A new estimation algorithm to enhance the sizing accuracy of defect depth is presented in this paper. The key point is that if each peak value of maximum depth size could be determined from known data groups instead of obtaining each incorrect coefficient, estimated results could be more reliable. Proposed method is attributed from that the rate of amplitude variation with respect to depth size is almost same even if the shape of defects is different. It is easily verified by using normalization method to data groups about peak amplitude. 4. Experimental Verification Fig. 2 show the experimental results that estimated sizes of defect depth are compared to actual sizes of defect depth. Estimated results are presented by using both the previous and enhanced mechanism for depth estimation. The admitted error bound for defect depth is generally 20%. In Fig. 2(b), most estimated results are well fitted within bound to the actual size, whereas there are some errors in case of more than 50% depth of defects as shown in Fig. 2(a). 5. Conclusion In this paper, an enhanced estimation algorithm is presented for the sizing of defect depth which has coupled error mixing data in pipeline inspection. By using decoupling algorithm, the functional relationship between signal amplitude and shape factors of defects are derived by the polynomial surface fitting with respect to defect's length and width. Magnetic leakage signals computed by nonlinear 3-D FEM are correlated with enhanced algorithm. The experimental results showed that the estimated values from enhanced algorithm reduces error efficiently than conventional works.

CV-12. ***Detecting method of hardened depth in surface hardened steel by magnetic field on steel.***

Y. Gotoh[1], S. Onita[2], T. Horino[2] and Y. Misaka[2]
1. Innovative Engineering, Faculty of Science and Technology, Oita University, Oita, Japan; 2. Research and Development Center, Neturen Co., Ltd., Hiratsuka, Japan

Introduction The surface hardened steel is used in a large-sized ball bearing part or the gear part in a large-sized heavy industrial machine, etc. The inspection of the surface hardened depth is important in the intensity or the guarantee of quality of these parts. Especially, since the size of the hardened steel parts in a large-sized heavy industrial machine is large, the destructive inspection using the Vickers hardness tester, etc. is made difficult. Therefore, the non-destructive inspection method is needed for the evaluation of its hardened depth. The maximum permeability and the conductivity of the hardened domain are smaller than the non-hardening domain inside the steel [1]. Therefore, the electromagnetic non-destructive methods for detecting the surface hardened depth by the difference of flux density inside the surface hardened steel are proposed [2,3]. In this paper, the high sensitivity inspection method using the detecting of the magnetic field on the surface of the hardened steel is investigated. The detection sensitivity of this proposal technique is higher than the method [3] of detecting the flux density inside the hardened steel. The magnetic field is estimated by 3-D nonlinear finite element method (FEM) taking account of the electromagnetic characteristics of the layers with and without hardening. Moreover, the optimal design of the search coil in the proposal sensor for raising detection sensitivity is carried out using the evolution strategy method [4]. The usefulness of this proposal inspection method is shown also from comparison with an experimental verification. Inspection method and modeling of magnetic properties Fig.1 shows the 1/2 domain of the proposed the inspection model for detecting the surface hardened depth inside the hardened SCM440 steel plate. The proposal electromagnetic sensor is composed of a magnetic yoke of lamination of silicon steel plates with an alternating exciting coil, and a search coil for the detecting of the magnetic field on the surface of the hardened steel. As for a search coil in this sensor, the *x*-direction of the magnetic field (B_x) on the surface of the steel plate is detected. The width (*Sw*), length (*Sl*) and height (*Sh*) of the search coil are 9.4mm, 6mm and 1.2mm, respectively. The distance (lift-off : L_o) between the yoke of the sensor and the surface of the hardened steel is equal to 0.5mm. The exciting frequency and ampere-turns are 15Hz and 126AT, respectively. Fig.2 shows the initial magnetization curves of the layer with and without hardening inside the SCM440 steel. And, since the conductivities of the steel plate with and without hardening are 3.61×10^6 S/m and 3.98×10^6 S/m, the permeability and conductivity are decreased with the increase of the hardness. The flux density and eddy current density are analyzed by 3-D electromagnetic FEM taking account of the initial magnetic curves and conductivities of the layers with and without hardening inside the steel. Moreover, the initial magnetic curve and conductivity in the layer between the hardened layer and non-hardened layer in the steel are calculated by interpolation using the electromagnetic property of each layer. Inspection of surface hardened depth in steel plate Fig.3 shows the distribution of flux density inside surface hardened steel plate when the hardened depth is 0mm and 3mm, respectively. This figure denotes that since the permeability and conductivity in surface hardened domain is decreased the flux density in the surface domain in the steel plate is decreased when the hardened depth is increased. Fig.4 shows the effect of the surface hardened depth on the value of the change rate of B_x in the search coil. The figure denotes that B_x is increased when the hardened depth is increased. This is, because the B_x from the impression magnetic field is increased since the permeability and conductivity in surface domain of the steel plate is decreased when the hardened depth is increased. As for B_x in the search coil, the calculated result is in agreement with measurement. In this research, comparison of the detection sensitivity of the inspection method [3] by the detecting of the flux density (B_z) inside the magnetic yoke as shown in Fig.5, and this proposal method by the detecting of the magnetic field (B_x) on the steel is investigated. In this model of Fig.5, a magnetic closed loop is formed between the sensor and the steel, and the flux density in the steel is detected with a search coil of the yoke. Fig.6 shows the comparison result of absolute values of B_x and B_z for the detecting of the hardened depth of the surface hardened steel by experiment. This figure denotes that the detection sensitivity of the proposal method by $|B_x|$ is higher than the method by $|B_z|$. Optimal design of search coil The optimal dimension of a search coil for detecting the magnetic field B_x in the proposal sensor is determined using the evolution strategy [4]. Fig.7 shows the inspection result in the optimal search coil form determined by the evolution strategy. The width (*Sw*), length (*Sl*) and height (*Sh*) of the optimal search coil are 20.36mm, 6mm and 1.8mm, respectively. The inspection result by the initial search coil model as shown in Fig.1 is also shown in this figure. This figure denotes that the detection sensitivity of the optimal search coil is increased from the initial model. The optimal search coil is the form which detects more magnetic fields on the steel plate distributed between the magnetic poles of the magnetic yoke.

CV-13. Electromagnetic inspection for detecting defect of underground part in road sign pillar.

Y. Gotoh[1], *M. Tohara*[2] and R. Nakamura[3]

1. Innovative Engineering, Faculty of Science and Technology, Oita University, Oita, Japan; 2. Mechanical and Energy Systems Engineering, Oita University, Oita, Japan; 3. Division of Technical administration, Japan Non-Destructive Inspection Inc., Kurashiki, Japan

Introduction The steel pipe in a road sign pillar and an illumination pillar is built on the ground. Since the road sign pillar etc. was built and many years have passed, the underground part of its steel pipe may be corroded. In recent years, the accident from which the road sign pillar falls down is increased owing to the generating of the corrosion or the defect in the underground part of the steel pipe. Therefore, the inspection of the corrosion or the defect in the underground part of its steel pipe is demanded. However, since the position of its defect etc is underground part, it is necessary to dig up the ground for the inspection of its part. On the other hand, the non-destructive inspections by the ultrasonic wave method using the guided wave or the electromagnetic acoustic transducers (EMATs) are examined [1,2]. However, by these methods, since the detection signal is changed by the adhesion degree of the ground and the steel pipe, the quantitative evaluation of the defect is made difficult. In this paper, the non-destructive inspection method using the alternating magnetic field by low exciting frequency is proposed for the quantitative evaluation of the defect. Since the position of the defect in the steel pipe of a road sign pillar is in the underground part, it can't see the defect position from the ground. Therefore, in the actual inspection, it is necessary to detect both the distance (d_i) from a sensor to the defect position and the depth (d_e) of the defect. In this research, both the distance (d_i) from the proposal sensor to the defect and the depth (d_e) of the defect are presumed. The flux density and eddy current in the steel pipe is estimated by 3-D nonlinear finite element method (FEM). The usefulness of this proposal inspection method is shown also from comparison with an experimental verification. *Proposed electromagnetic sensor and detecting signal* Fig.1 shows the inspection model for evaluating both the distance (d_i) from a proposed electromagnetic sensor to the defect and depth (d_e) of the defect in the steel pipe (STK400). This inspection sensor is composed of two magnetic yokes of steel material (SS400) with an exciting coil, and a search coil. The search coil is arranged at the yoke of the side of the defect. The exciting frequency and ampere are 20Hz and 6A, respectively. The distance (lift-off : L_o) between the sensor and the steel pipe is equal to 0.1mm. Fig.2 shows distribution of flux density near the sensor when there is the steel pipe without defect. The flux density is analyzed by 3-D finite element method (FEM) of the step-by-step method taking account of B-H curves of the steel pipe and magnetic yoke. The figure denotes that the impressed magnetic field from two yokes is distributed to both of ±z-direction of the steel pipe. Fig.3 shows the effect of the defect depth (d_e) on the calculated output voltage in the search coil when the distance (d_i) from the sensor to a defect is changed. The figure denotes that since the ferromagnetic domain in the steel pipe is decreased when the defect depth (d_e) is increased, the flux density in the search coil is decreased. Moreover, when the distance (d_i) between a sensor and the defect is increased, the output voltage in the search coil with defect depth (d_e) is decreased. *Evaluating both the distance (d_i) from the sensor to the defect and depth (d_e) of the defect* In this research, the output voltage of the arbitrary two positions on the z-axis line in the steel pipe is measured at the intervals of 10mm by one sensor as shown in Fig.4. Then, both distance (d_i) and the depth (d_e) are presumed from these two measured output voltages and the calculated curves as shown in Fig. 3. Table I show the presumed results of both distance (d_i) and the depth (d_e) when the defect depth is 40% and 60%, respectively. This table denotes that the maximum error of the distance and depth are 3mm and 1.6%, respectively. Therefore, the usefulness of this proposed method using alternating magnetic field was shown in this table.

CV-14. Investigation of Magnetic Tunnel Junction Sensor for Magnetic Flux Leakage Testing of Reinforced Concrete.

M.b. Mohd Noor Sam[1], Z. Jin[1], M. Oogane[1], K. Fujiwara[1] and Y. Ando[1]
1. Applied Physics, Tohoku University, Sendai, Japan

Magnetic flux leakage (MFL) testing a popular method for detection of defects such as the metal loss due to the corrosion in steel bars located in reinforced concrete. The magnetic flux leak cause by the defect is then measured by a magnetic sensor, which gives information to the user of the presence of the defect [1]. However, as the distance between the defect and magnetic sensor (lift-off) increases, the strength of the leaked magnetic flux drops significantly, making it difficult to detect. A candidate of highly sensitive magnetic sensor to detect defects at the condition of large lift-off is the magnetic tunnel junction (MTJ) sensor. In this research, the MFL testing was carried out by MTJ sensor with high sensitivity. The MTJ structure used in this research consists of a film structures of SiO_2sub./Ta(5)/$Ni_{80}Fe_{20}$(70)/Ru(0.85)/$Co_{40}Fe_{40}B_{20}$(3)/MgO(2)/$Co_{40}Fe_{40}B_{20}$(3)/Ru(0.8)/$Co_{75}Fe_{25}$ (5)/$Ir_{22}Mn_{78}$ (10)/Ta (8) (in nm) with a sensitivity of 87.8 mV/mT. Each MTJ was fabricated into the device with an area of 8080 μm^2 and 5550 MTJ devices (1110 in series and 5 in parallel) were integrated to obtain a high signal-to-noise (SNR) ratio [2]. The fabricated sensor was attached to an acrylic push car and the scan was done along the length of reinforced concrete specimen (length is 2.0 meter with the defect at the 1.0 meter mark). The output of the MTJ sensor was measured by conventional DC four-terminal method. Fig. 1 shows the change of the output voltage from the MTJ sensor measured at various lift-off values according the magnetic flux leaking from the specimen. As shown in Fig. 1, the defect's location can be identified as the change of the voltage from the MTJ sensor. Fig. 2 shows the SNR for measurements with and without a magnetic flux concentrator. Averaging of 50 times measurements was carried out to improve the SNR. The result indicates that the defects were detected by our MTJ sensor with a high SNR and installing a magnetic flux concentrator significantly improved the SNR until lift-off of 18 cm. We demonstrated the MFL testing with a high SNR using the MTJ sensor and the detection of defects under the condition with larger lift-off value can be realized by the improvement of sensitivity of the MTJ sensor. This work was partly supported by the Center of Innovative Integrated Electronic Systems (CIES) and the Center for Spintronics Research Network (CSRN).

CV-15. A New Design of MFL Sensors for Self-Driving NDT Robot to Avoid Getting Stuck in Curved Underground Pipelines.

H. Kim[1], H. Yoo[2] and G. Park[3]
1. Electrical and Computer Engineering, Pusan National University, Busan, The Republic of Korea; 2. Korea Gas Corporation, Incheon, The Republic of Korea; 3. Electrical Engineering, Pusan National University, Busan, The Republic of Korea

1. Introduction Magnetic Flux Leakage (MFL) type Pipelines Inspection Gauge (PIG) is commonly used to detect defects on underground pipeline as one of nondestructive testing (NDT) instruments. In-line inspection of MFL PIG is commonly used to examine a large portion of the long distance transmission pipeline which transports natural gas from gathering points to local companies [1]-[3]. The operating pressure of this pipeline is over 20 atm and the diameter of pipe is more than 20 inches. So, MFL PIG which is called MFL sensor could be driven automatically by operating gas flow inside the pipe and it has been proved to be a reliable and effective ways for inspection of pipelines. Although it is effective for the inter-city scale large size pipelines, it is hard to be applicable for the curved pipelines with small size installed inside the city. That is because these pipelines have limited gas pressure and flow conditions, some obstacles such as bent region, welded joints, 90 degree miter. For these reasons, it is necessary to adopt self-driving robot system to drive MFL sensors as shown in Fig. 1. The basic principle of MFL method is that it generates a strong magnetic field on the pipe wall to be magnetically saturated. That's because the leakage field signal from defects on the pipe could be maximized [4]-[5]. The common structure consists of a fixed permanent magnet as the source of magneto-motive force and it cannot change the path of magnetic fields on the pipe. In the previous structure of MFL PIG, a strong magnetic attractive force is always generated between the pipe and MFL PIG [5]-[6]. Even though the previous MFL sensor is enough to pass in straight line, when this module passes through curved pipelines, the magnetic force between pipe and inspection module is increased sharply so that the PIG module could be stuck eventually. This paper proposed a new design structure of MFL PIG to decrease stuck forces on the pipe wall. All structural parameters for MFL sensors were designed to minimize the magnetic force and maximize the detection sensitivity of defect signals. The magnetic forces on the pipe was computed by numerical analysis to estimate necessary traction forces in self-driving robot. Also, the performance of proposed system was verified by experiments in the pipeline simulation facility. 2. Design and Structure The structure of MFL sensors with in-pipe robot system is shown in Fig. 1(a) and Fig. 1(c). The system is designed for inspection of 16 inches diameter pipelines and it consists of ten MFL modules, every module has Nd-Fe-B magnets with back yokes which are used to generate and transfer the magnetic field on the pipe. Also, every MFL Module has hall sensors to detect axial component of flux leakage signal. Fig. 1(d) shows the structure diagram of a conventional MFL module and that of a proposal module. The proposed system is designed to minimize the attachment force on the pipe and maximize the detection sensitivity of defect signals. In proposed system, each magnet has rotary magnets for the shunting mechanism so that it prevents the magnetic energy from being channeled into the pipe. 3. Numerical Analysis of MFL Sensors 3.1. Magnetization on the pipe The distribution and magnitude of magnetic flux density of MFL system are computed by using numerical analysis to derive the magnetic force acting on the pipe. The magnetic flux density on the pipe could be analyzed by using conventional 3D nonlinear finite element method. 3.2. Effects of magnetization on the defect signal From both FE simulation and experimental measurement, the peak amplitude of defect signal is detected by a hall sensor passing through the center of defects. The signal amplitude of leakage flux is dependent on the shape of defects such as length, width and depth. 3.3. Effects of magnetic force on the pipe To compute the magnetic force on the pipe in a given MFL module, the equation of magnetic energy stored in magnetic field space is used. There is an air gap between the pipe and MFL module, so the magnetic energy accumulated in an air gap is computed by the numerical results of magnetic flux. The magnetic force is proportional to the square of air gap flux density. 4. Experimental Verification When the MFL module passes through bent pipe or welded pipe joint, the distance of air gap between pipe and module is decreased. At that time, not only the air gap flux density is relatively increased but also the magnetic force is exponentially increased. So, the magnetic force has considerable influence on the traction force of driving robot. In Fig. 2, the proposed system generates sufficient magnetic fields to detect the defect signal even if it didn't saturate the steel pipe magnetically. 5. Conclusion In this paper, we introduced MFL sensors equipped with robotic platforms for inspection of low pressure gas pipelines. First of all, to verify the performance of MFL system, it is necessary to check the magnetization of the pipe wall. There are ten MFL modules in robotic platforms and each module consists of magnet bars. Each magnet bar generates sufficient magnetic fields to detect the defect signal even if it didn't saturate the steel pipe magnetically. Therefore, we propose the novel structure type of MFL module for reducing magnetic force on the pipe.

2. Wafer Front End, MultiDimension Technology Co., Ltd, San Jose, CA, United States

Magnetoresistive sensors combined with permanent magnets are becoming increasingly popular for measuring mechanical displacement, velocity, rotation, etc. [1] In the case of magnetic angle sensors, a permanent magnet is attached to a rotating component, such as a shaft, and a magnetoresistive sensor detects the magnetic field change as the permanent magnet rotates with the shaft. [2] The measured magnetic field value is converted into a measure of shaft rotation angle. Because this is a non-contact measurement, it provides an inherently wear-free means of monitoring the rotation of a mechanical component. There are other advantages, for example, unlike optical sensors that require a powered optical source and transparent medium through which the measurement is made, magnetic sensors are low power and can tolerate dirt, dust, and other unavoidable contamination that may occur during its operational lifetime. Anisotropic magnetoresistance (AMR), giant magnetoresistance (GMR), and tunneling magnetoresistance (TMR) sensors are often used in angle sensor applications, but TMR is preferred due to its higher output and full 360 degree measurement capability. [3] Unfortunately, the accuracy and linearity of 360 degree GMR or TMR angle sensors are known to degrade as the applied field from the moving permanent magnet is increased. [4] Figure 1 illustrates the response of a TMR angle sensor as a function of the strength of a rotating magnetic field. It shows nearly ideal sinusoidal behavior at 50 Oe applied field, but the sensor output becomes a triangle wave with undesired harmonics when a field of 400 Oe is used. This is unfortunate, since the ability to tolerate larger magnetic field makes an angle sensor more immune to external field interference and to displacement between the permanent magnet and the sensor. It is thus desirable to find a means for increasing the operating field range. We will show the reason for the change to the triangular waveform, which degrades angle measurement accuracy, is a result of motion of the pinned layer magnetization in response to the rotating magnetic field. In order to overcome this effect, we modeled, designed, fabricated, and tested a novel 360-degree TMR angle sensor which includes a circular attenuator placed above each TMR element. The design concept is illustrated in the inset of Figure 2. These novel TMR angle sensors consist of a conventional stack comprising Seed/PtMn/CoFe/Ru/CoFe/CoFeB/MgO/CoFeB/NiFe/Cap, which is a bottom-pinned synthetic antiferromagnet pinned layer, MgO tunnel barrier, and simple bilayer free-layer structure. The attenuator is composed of plated permalloy, with thickness of about 5 microns. The attenuation was modeled using finite elements software. Figure 2 compares the angular error measured on an attenuated and a standard TMR angle sensor at various values of applied magnetic field ranging from 50 to 1500 Oe. The angle error is calculated by fitting a sinusoid to the voltage as a function of magnetic field angle curves. Note that the standard TMR angle sensor shows optimal performance over a range of about 25 to 100 Oe. The attenuated angle sensor uses an attenuator with an attenuation ratio of about 12x. As a result, the optimal field range is shifted from less than about 300 to about 800 Oe, but the error remains low, even from 100 to 1400 Oe. This experiment also shows the linearity of the angle sensor seems improved over the standard design. There are likely two main reasons for this. First, the pinning layer is well shielded, which reduces the motion of the pinned layer magnetization. Second, the attenuators may make the field at the location of the TMR elements more uniform. In summary, a 360-degree TMR angle sensor capable of operating with low error and high linearity in magnetic fields ranging from 100 Oe to over 1.4 kOe was designed, fabricated, and tested. The results agree well with modeling, and the resulting sensors are ideally suited for precise angle measurement in magnetically harsh environments.

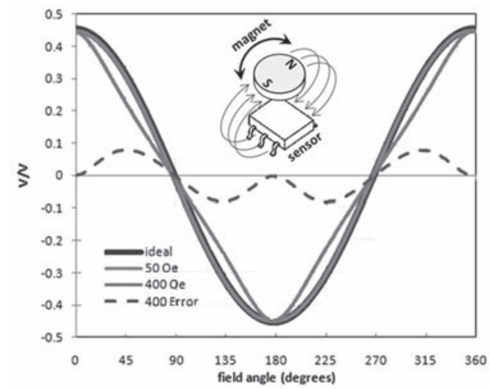

Fig. 1. A plot of the ideal sinusoidal response of a TMR angle sensor, compared with data measured using a 50 Oe rotatingn field and a 400 Oe rotating field. Note the 400 Oe response form the sensor appears as a triangle wave, rather than a sinusoid. The inset of the figure shows the geomery of a rotating permanent magnet with respect to the sensor.

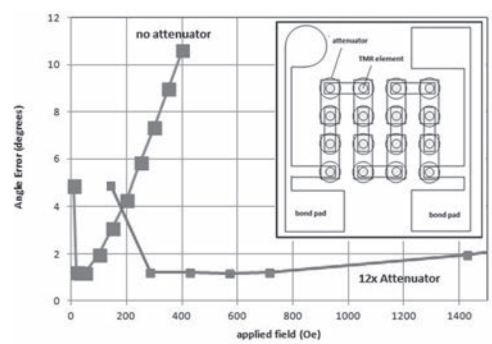

Fig. 2. The inset shows a schematic diagram of a singe magnetoresistor angle sensor die. The die consists of a string of circular TMR element interconnected in series as a two port network. A permalloy disk is placed over top of each TMR element in order to attenuate the external magnetic field. Four such single magnetoresistor dice may be arranced in a semiconductor package in order to implement a full bridge, or alternatively, a full bridge may be built onto a single chip. The blue curve shows angle measurement error as a function of applied field strength measured on an angle sensor with no attenuators. The red curve shows the result measured on an identical angle sensor die that includes attenuators over the TMR elements.

CW-01. Frequency Characteristics of an Optical Current Sensor Based on Rare Earth Materials.

W. Sima[1], *Y. Wang*[1], M. Yang[1] and R. Zheng[1]
1. State Key Laboratory of Power Transmission Equipment & System Security and New Technology, Chongqing University, Chongqing, China

Traditional electromagnetic current transformers are widely used in power systems and have exposed insurmountable weaknesses: large volumetric and heavy weight, ferromagnetic resonance, magnetic saturation, high requirement for insulation, and harmonics. One of the most important problems is that the high-frequency current is hard to be accurately measured by the current transformers due to their poor frequency performance. Many optical current transducers (OCTs) have been proposed and designed to provide solutions to the problem. Now, most of the OCTs are mainly focused on improving the accuracy, practicality, and stability by using low reverse-magnetic materials. The frequency performances of these OCTs cover 0-20 kHz. However, some of the transient currents, such as the lightning current, in power systems contain frequency components as high as MHz. To further increase the high frequency performance of the OCTs to meet the requirement of practical utilization, there is still a room for the improvement of the OCTs. With the rapid development of materials science in recent years, the performance of paramagnetic magneto-optical materials which were neglected in the past has been greatly improved. Application of the rare-earth-doped magneto-optical glass material can improve the response sensitivity and high frequency performance of OCTs. In this paper, an OCT is designed by using rare-earth-doped magneto-optical glass materials. Then, theoretical and simulation analysis are conducted to evaluate the frequency characteristic of the OTCs. Finally, an optical experimental platform is established to verify the analysis above. The OCT is based on Faraday magneto-optical effect: when the linearly polarized light travels through a magneto-optical media along the direction of the magnetic field generated by the current, the polarization direction of the light will be rotated. The overall structure is a straight through path. A linear polarization is generated by a laser,and goes through the optical media. The optical detector converts the light intensity into a voltage to establish the relationship between light intensity and current. The angle between the two polarizers is analyzed theoretically based on Marius's law, the positive (negative) Verdet constant with the included angle equal to $3\pi/4(\pi/4)$ has the perfect amplitude response. The output and input waveforms are the same in a large frequency range and have no phase differences. Combined with the actual situation, the dynamic characteristics of the Faraday rotation angle is different from the static characteristics; the main reasons are the absorption of light and the magnetic loss of materials. The absorption of light by the material causes the outgoing linearly polarized light to become elliptically polarized light, and the magnetic loss will make an alternating magnetization relative to the alternating magnetic field strength have a phase lag. Both of them will change the Faraday rotation angle to a plural form: $\theta=\theta'+i\theta''$, leading to the unsatisfactory frequency characteristics. Therefore, the optical absorption and magnetic loss of the magneto-optical material should be considered for the design of the OCTs. Through the study of the frequency characteristic, the paramagnetic magneto-optic glass MR3-2 doped with rare earth Tb^{+3} ions has a light absorption coefficient which is less than 1% and negligible magnetic loss is applicated to the OCT, it also has high Verdet constant to increase the sensitivity further. Amplitude-frequency characteristics and phase-frequency characteristics of the OCT are evaluated by simulation, they are ideal. Then, an optical experiment platform is built up to test the frequency response. A signal generator and a power amplifier generate a 0-50kHz sinusoidal current with a magnitude of 1.7A. The current flowing through the solenoid (930 turns per meter in double layers) is used to generate a magnetic field, which is equivalent to the magnetic field that 2kA wire at its 10cm position. An oscilloscope is used to acquire the output voltage waveform from the photodetector. The experiments show that the OCT using new materials have a significant increase in sensitivity. The acquired waveforms remain the same amplitude without phase shift and show no distortion in the frequency range from 0 Hz to 50kHz. Therefore, the frequency response is considered to be ideal, which is consistent with the theoretical analysis and simulation results. In this paper, an OCT using rare earth paramagnetic glasses with excellent magneto-optical properties is designed to measure harmonics and transient currents. Experiments show that the OCT has ideal frequency characteristics within 50 kHz range, the maximum measurable amplitude can reach 2000A, it is suitable for measuring most of the currents in the field.

CW-02. Current annealing of glass-coated amorphous wire for noise reduction of low-offset fundamental mode orthogonal fluxgate.

N. Murata[1,2] and R. Nomura[1]

1. Environmental Test Technology Unit, Japan Aerospace Exploration Agency (JAXA), Tsukuba, Japan; 2. Department of Space and Astronautical Science, The Graduate University for Advanced Studies, Sagamihara, Japan

Introduction Several kinds of compact magnetic sensors such as fundamental mode orthogonal fluxgate (FM-OFG) and GMI sensors utilize amorphous wires as magnetic cores [1]. There are mainly two types of amorphous wires: one created by so called in-water spinning method and the other created by Taylor–Ulitovsky method with glass coating over metallic core [2]. The former wire has been commonly used for FM-OFG sensors, and in some cases annealing is introduced to improve the performances of the sensors [3]. However, it is pointed out in [2] that those wires require very sensitive annealing process to obtain repeatable magnetic characteristics, and have disadvantages in cost and fabrication complexity compared to the glass-coated wires. In this research, 60-μm-diameter glass-coated Co-Fe-Si-B-Cr wire bent in hairpin shape was newly adopted to a 45mm-long FM-OFG sensor head. Current annealing [4] was then performed to the wire, and the noise and offset characteristics of the sensor were evaluated. Low-offset FM-OFG FM-OFG is known as the low-noise orthogonal fluxgate invented by Sasada [5] which operates with DC-biased sinuous excitation current, in other words, sinuous AC current (*Iac*) of small amplitude superposed on large DC current (*Idc*), directly passing through a magnetic wire core. However, uniaxial anisotropy in the wire affects the motion of magnetization and causes large offset. A technique called bias switching [6] periodically flips the polarity of DC bias and AC excitation current to obtain induced signals that become complementary to each other in which the offset components attributed to the anisotropy are modulated in the opposite polarity while the sensor sensitivity components are modulated in the same polarity. That way, averaging those two signals by a low-pass filter brings offset-free output. Application of the as-cast glass-coated wire The glass-coated amorphous wire in as-cast form was implemented to the sensor head and operated by FM-OFG circuit in feedback configuration with the following conditions: *Iac* (38 kHz) = 14 mArms, *Idc* = 22 mA, and the bias switching frequency = 2.4 kHz. The circuit was designed to have a cutoff frequency of 20 Hz. Then the sensor head was placed in a 4-layer magnetic shield and noise spectral density was measured. As a result, the measured noise at 1 Hz was 45.8 pT/Hz$^{1/2}$ (dashed line in Fig. 1). To investigate the source of the noise, the bias switching frequency was set to be as low as 0.1 Hz so that two complementary signals obtained under alternating excitation modes directly appear as an output, without being averaged by the low-pass filter. Since the sensor head is placed in the magnetic shield, the output corresponds to the intrinsic offset of the sensor. The result is shown in Fig. 2 (a). In a theory, a completely symmetrical waveform should be obtained under ideal behavior of the bias switching technique, but it can be observed that output levels asymmetrically vary in the order of several mV (which corresponds to several nT) every time the polarity of excitation current returns to the original state after inversion. Those random, asymmetrical variations of the output levels obviously could not be canceled by averaging, and thus lead to increase in the output noise. The variations imply that there is considerable non-repeatability in magnetization when the periodical inversions of excitation field occur, which should be attributed to the fluctuation of M-H curves observed in amorphous cores [7]. Current annealing of the glass-coated wire To improve the magnetic property of the glass-coated amorphous wire, current annealing was performed with very simple method. With the sensor head kept in the magnetic shied, its cable was connected to DC power supply to apply current of 100 mA to the wire core for 40 minutes. The resistance of the wire core was 64 Ω. Then the same experiment as above was carried out. The obtained result shown in Fig. 2 (b) presented more than 10-fold improvements in variations of output levels, showing symmetrical and uniform behavior against periodical inversions of the excitation field. This improvement implies that stress relaxation brought by current annealing changed the magnetic property of the wire to have better repeatability in its M-H curve. The absolute value of output levels, which corresponds to the intrinsic sensor offset, is also reduced, meaning that the anisotropy in the wire is induced strongly to the circumferential direction by the annealing current. The spectral noise density obtained using the current-annealed sensor head is shown in Fig. 1 with a solid line. The noise at 1 Hz was reduced to 11.7 pT/Hz$^{1/2}$ confirming the efficacy of the current annealing. Then current annealing was performed to several sensor heads under different current conditions. It was discovered that 200 mA current deteriorated the magnetic property of the wire, possibly due to partial crystallizations. As far as the current level is kept around 100 mA, noise characteristics of all the five tested sensors improved to similar level as the solid line in Fig. 1, meaning that the current annealing is also an effective way to obtain stable level of performances among sensor heads.

CW-03. High frequency and sensitivity magnetic core with amorphous HB1-M operate at electromagnetic interface characteristic.

C. Hsu[1], C. Chang[3] and C. Tseng[2]

1. Department of Mechanical Engineering, Oriental Institute of Technology, New Taipei city, Taiwan; 2. Division of Physics, Institute of Nuclear Energy Research, Taoyuan, Taiwan; 3. Department of Information and Telecommunications Engineering, Ming Chuan University, Taoyuan, Taiwan

1. Abstract Body: This paper presents the EMI impact on the current transformer with amorphous HB1-M core, printed circuit board (PCB) power transformer and the filter of inductor for Internet of Things (IoTs) device. According to the antenna principle, the radiation emission power responses of PCB transformer and current transformer are estimated and found to be negligible due to the EMI experimental report. The current transformer with amorphous HB1-M core is annealed at 350 °C and soaks for 1.5 h. The simulation results of electromagnetic field is to display the power electronic circuit shield response, which also presented resistance EMI signal for power inductor in magnetic flux density and electric potential. According to the major radiated EMI source in the frequency range between of 50 MHz to 400 MHz is found to be the filter of the power circuit, where antenna emission energy transients occur, rather than the PCB transformer. Experimental results have confirmed that the application of PCB transformer in electronic circuit might not be have seriously EMI problem on the power electronic circuit. 2. Introduction There is the most of important application of Internet of Things (IoTs) in sensor device with high permeability magnetic core material providing a current in its secondary winding proportional to the alternating current flowing in its primary [1-2]. A common development way in metering and protective relaying for smart grid and power substations is useful where it facilitate the safe measurement of large currents, often in the presence of high voltages [3]. Also, some case in electronic circuit application and minor current signal detection is not only provided typically signal measurement but it can transmit stable signal by using communication system and also support as well analog-digital signal to behind receiver to user application [4,5]. It is well-known that basic principle of SMS is satisfied with several characteristics including fast switching of high current and voltage signals within power converter systems. Regarding to the electromagnetic interference (EMI) problems, it becomes more critical problem due to the compromise between efficiency and power density [6]. In aspect of electromagnetic response, the printed circuit board (PCB) with magnetic core device performed SPS induced a significant EMI source; it should face their intrinsic switching properties and the generated EMI noise levels. Moreover, electromagnetic compatibility (EMC) regulations need to satisfy as follow rules, for example, line-current harmonic standards and IEC 61000-3-2 [7]. 3. Simulation, Experimental and Discussion Results This study presents an amorphous alloy with HB1-M and SA1 material which is made by Hitachi Co., This product, the parameter of physics characteristic includes HB1-M and SA1 with thicknesses of 0.025μ-meter and widths of 20 mm. Besides, both magnetic cores annealed at 320°C (for HB1-M) and 350°C (for SA1), and soaked around 1.5 h are performed. For magnetism properties for different material in crystalline phase and microstructure, are measured by using X-ray diffraction (XRD) and a vibrating sample magnetometer (VSM) as shown in Figure 1 (a)-(b). Besides, energy dispersing spectroscopy (EDS) is used to detect material compositions, as shown in Fig. 1 (c). EMI noise sources within power-line or radiation emission of antenna equipment, operated at duty cycle characteristic of currents, is made. The critical PCB continuously turning loops (*di/dt*) and the pulsating voltages of the phase nodes (*dv/dt*) are defined. The common (CM) and differential (DM) noise sources and the corresponding noise propagation paths can be obtained. The inductor need to withstand the rated current without saturating while simultaneously providing the required CM/DM noise attenuation. The core of inductor is chosen from typical material. Also, the permeability curves $\mu r(f)$ is referred by datasheets or impedance measurements. EMI analysis is performed as follows: first, define EMI noise sources, including to identify fast rates of change of currents *di/dt* and voltages *dv/dt*. Next, it should be concerned noise propagation paths, i.e., CM/DM conduction paths. Before that step, it is most well-known that numerical techniques for power inductor and electronics component applications is simulated by finite element analysis (FEA), as shown in Figure 2(a)-(b). This paper presents the EMI impact on the current transformer with amorphous HB1-M core, a fully sensing magnetic core development in core structure and EMI testing results, as shown in Figure 2(c)-(d). According to the antenna principle, the radiation emission power responses of PCB transformer and current transformer are estimated and found to be negligible due to the experimental report of EMI. The major radiated EMI source in the frequency range between of 50 MHz to 400 MHz is found to be the filter of the power circuit, where antenna emission energy transients occur, rather than the PCB transformer. Experimental results have confirmed that the application of PCB transformer in electronic circuit might not be seriously EMI problem on the power electronic circuit.

1. State Key Lab of Magnetism, Institute of Physics, Beijing, China;
2. Tohoku University, Sendai, Japan; 3. Jilin University, Changchun, China

Magnetic tunnel junction (MTJ) sensors have exhibited a strong competitiveness in low-field sensing applications such as biomagnetic sensing and read head for hard disk drives due to their high sensitivity. As is known that ultimate field detection limits depend on both voltage noise character and sensitivity of MTJ sensors, which are thus crucial for ultra-low field (such as nT and pT) detection. Low frequency noise of MTJs is usually dominated by $1/f$ noise which is attributed to either charge traps within barrier or fluctuations of magnetization of free layer [1]. Random telegraph noise (RTN) is observed in the free layer with multi-domain state, resulting in Barkhausen noise in $R(H)$ loop [2]. In order to realize lower detection limit, the above two main kinds of noises should be suppressed as much as possible. Besides, soft magnetic materials with low anisotropy such as NiFe, CoFeSiB, NiFeCuMo have been developed to improve the field sensitivity. Especially, amorphous CoFeSiB alloy shows ultralow anisotropy field and high crystallization temperature (790K), making it a good candidate for sensing layer in MTJ sensors. In this work, the MTJ sensors with CoFeSiB and NiFe were fabricated and linear response to applied field was realized by using two-step annealing process and applying a bias field along easy axis of free layer. The bias field was used to stabilize single domain of free layer and eliminate Barkhausen noise in MTJ sensors. The samples with CoFeSiB electrode show much better thermal stability, higher sensitivity and better detectivity than that of NiFe electrode. A sensitivity of 3.9 %/Oe and detectivity of 4.5 nT/√Hz at 10Hz are achieved for samples with CoFeB/Ru/CoFeSiB free layer under bias field of 10 Oe [3]. Besides, the linear range can be widened as the bias field increases at the cost of sensitivity. This property might be useful for some special application, in which larger linear area is much more important than the sensitivity. With bias field along easy axis of free layer, the noise suppression and sensitivity manipulation are realized, which are beneficial for applications in industrial control, biomagnetic sensing, etc. The MTJ sensors with CoFeSiB amorphous soft magnetic layer can be an excellent candidate for sensors with high sensitivity in weak magnetic field detection applications.

CW-05. Tuning antiparallel pinned spin valves with modified artificial antiferromagnetic layer for full-bridge magnetic sensors.

V. Luong[1], A. Nguyen[1] and H. Tran Thi[1]
1. International Training Institute for Materials Science, Hanoi University of Science and Technology, Ha Noi, Vietnam

A full-bridge magnetoresistive spin valve (SV) sensor scheme for applications of linear magnetic measurement is fabricated and analyzed with the sign of magnetoresistance (MR) can be tuned by the modified the artificial antiferromagnetic (AAF) layer. In the last two decades, SV sensors have shown their crucial roles in the life. The common applications of SV sensors are used in position, angle sensors [1, 2], electronic compasses, and contactless current sensors [3]. To build a sensor, especially for resistive sensors, a Wheatstone-bridge is always a good solution for its advantages of the lessening dc-offset, and temperature errors [4]. In the MR sensor fabrication, the bias direction is also the main factor that decides the sensor architectures. For instance, a half-bridge was realized by two active cells, whereas shielding the other two cells [5, 6] or killing their sense by the roughened surfaces [7]. However, the effective sensitivity and linearity of the sensor are reduced [8]. There are several methods to form a full-bridge that provides a maximum output of the sensor. For example, the current strap was directly fabricated on the surface of the device to induce the local bias magnetic field during the cool-field post-annealing process [9]. Using an appropriate location of MR cells within the gap of the flux guide, a full-bridge could be established [10]. An antiparallel alignment of the pinned direction of the two pairs of MR cells was carried out by a microscopic focused laser heating during cool-field treatment [11]. Another method is that the usage of two deposition processes for two pairs of MR cells in the opposite applied magnetic field [12]. In this work, we propose a method to tune the bias direction of two neighboring meanders in the full-bridge by varying the thickness of Ru in AAF layers of patterned SV cells with a single post-field annealing step. In order to implement the proposed design, the two deposition processes were carried out. First one, two normal magnetoresistance SV cells are the structure of (Si/SiO_2)/Ta(50Å)/NiFe(30Å)/Co(15Å)/Cu(24Å)/CoFe(25Å)/IrMn(100Å)/Ta(50Å), whereas, the other two cells are the inverse magnetoresistance with an AAF layer of structure of (Si/SiO_2)/Ta(50Å)/NiFe(30Å)/Co(15Å)/Cu(24Å)/[CoFe(15Å)/Ru(7Å)/CoFe(25Å)]/IrMn(100Å)/Ta(50Å). The normal MR and inverse MR curves of the different SV structures are shown in Fig. 1. The SV films were prepared by RF magnetron sputtering. The conventional lift-off method was used to pattern the MR cells. A tiny permanent magnet was used to adjust the sensor operating point. To estimate an appropriate MR ratio for an expectation sensitivity, the hyperbolic tangent model was introduced by author *et al.* [13], a required MR correspondences a sensitivity and a saturation field range was given by $MR = (2.(dV/V/dB).B_s)/(G_m-(dV/V/dB).B_s)$ (1) where MR is the magnetoresistance ratio, $dV/V/dB$ is the sensitivity of the bridge (V/V/Oe), B_s is the saturation field, and G_m is the flux amplification factor. Suppose, $G_m = 1$ (no gain flux density), and the B_s is about 50 Oe, in order to yield a sensitivity of 1 mV/V/Oe, the MR ratio should be at least 10.5 %. The SV cells were patterned to the dimensions of 200 μm × 2 μm. The resistance of individual SV cell is about 10 kΩ. The cut chip dimension is 2 mm × 1 mm was attached to a printed circuit (PCB) board using the aluminum wire bonding method. The voltage output of the bridge was amplified by a preamplifier using AD620 from Analog Device, Inc., and connected to a data acquisition device (MyDAQ). The data was recorded using a software coded in the LabVIEW. The performance of the SV full-bridge was verified by setting up the sensor in a sweeping magnetic field of ±150 Oe induced by a Helmholtz coil. The response curve of the full bridge to the external fields are shown in Fig. 2. The obtained sensitivity is 0.23 mV/V/Oe with B_s is about 100 Oe and a patterned MR ratio of 4.5% is in agreement with the hyperbolic tangent model in Eq. (1) [13]. Further experiments to increase the resistance of GMR elements using the advanced microfabrication methods are still ongoing. The sensitivity of the bridge can be further enhanced by the patterning SV cells in series [14] or the usage of a flux amplification (flux concentrators) [15].

Magnetic sensors based on planar and out-of-plane magnetoresistance (MR) response to the applied magnetic field are the objects of interest in modern spintronics. The main advantage of MR sensors based on magnetic metal layers, in comparison with semiconductor Hall sensors is the independence of the carrier concentration on temperature. Magnetoresistance response of NiFe/M/NiFe (M = Au, Ta, Ag) sensors to DC magnetic field is studied for a wide range of angles α between magnetic field direction and sensing current direction. The anisotropic magnetoresistance (AMR) and giant magnetoresistance (GMR) contributions to magnetic field dependence of along with current V_{AMR} and perpendicular-to-current V_{PHE} (planar Hall) voltages are distinguished. The AMR contribution results in the steady changes of V_{AMR} and V_{PHE}, while GMR contribution may result in as steady, as well as jump wise response of V_{AMR} and V_{PHE}, dependently on the angle α. The correlation ratio r between magnetic fields of V_{AMR} and V_{PHE} jumps is found to be governed by the orientation of magnetic field in respect to the current direction. The V_{AMR} and V_{PHE} jumps become uncorrelated (r = 0) at α = 0° and 90°. The angular dependence of the correlation between V_{AMR} (H) and $V_{PHE}(H)$ jumps will be discussed in terms of bidirectional domain wall motion model. This work is supported by the grant of Ministry of Trade, Industry, and Energy (MOTIE, Korea, grant 10064089).

We proposed an arbitrary control method of the anisotropy of magnetostrictive film employing a residual stress of lamination structure after annealing, which was considered mechanical properties such as coefficient of thermal expansion and Young's modulus of substrate, nonmagnetic layer and the magnetostrictive film. In addition, a high sensitive strain sensor using the anisotropy controlled FeSiB film by the method and inverse magnetostriction effect (Villari effect) was realized and demonstrated [1, 2]. This sensor can detects the strain by high frequency impedance change associated with high frequency permeability change of FeSiB. However, because dynamic range and working point of the sensor was in almost tensile strain region, the sensor was required a comparatively large bias stress to use as a vibration sensor. Therefore, we tried to arrange the dynamic range and working point of the sensor to suitable state for using vibration sensor by adjusting structure of the sensor element. The sensor element composed of 1 turn meander-patterned molybdenum (Mo) film as conductive layer and FeSiB magnetostrictive films that laminated a part of the meander. Both ends of the meander-pattern were used as electrodes to measure the high frequency impedance by using network analyzer. The element was fabricated on 150 μm-thick glass substrate by photolithography using lift-off process and RF sputtering. Then, it was annealed at 360 °C for 2 hours under a rotating magnetic field of 240 kA/m. Thickness of Mo layer and FeSiB layer were 1 μm. After annealing the element, the FeSiB films of the sensor element were subject to residual stress from Mo film and thin glass substrate, which induced a magnetic anisotropy to width direction (Fig. 1) of the rectangular shaped FeSiB film via magnetoelastic coupling. Fig. 2 shows the variation of high frequency impedance of the sensor element according to applied strain. The impedance change exhibited a peak value at around 100 ppm of applied strain and decreased steeply until at around 0 ppm. In addition, from the high frequency impedance change of the element under tensile strain the sensor exhibited a gauge factor of about 6,300 at a carrier frequency of 200MHz. Around 100 ppm reduction of working point of the strain sensor was realized. It is thought that the thermal stress to the FeSiB film was weakened by adjusting the ratio of layer thickness. At the conference, further quantitative discussion of properties of the sensor and evaluation results of vibration sensor will be presented.

CW-08. A Self-biased Anisotropic Magnetoresistive (AMR) Magnetic Field Sensor on Flexible Kapton.

C. Wang[1], W. Su[1], J. Pu[1], Z. Hu[1] and M. Liu[1]
1. Electronic Materials Research Laboratory, Key Laboratory of the Ministry of Education & International Center for Dielectric Research, Xi'an Jiaotong University, Xi'an, China

Magnetic sensors have attracted extensive attention due to their highly sensitive, e.g., navigation,[1] medical diagnosis (magnetoencephalography, magneto-cardiography, etc.), [2-4] and data storage.[5] Flexible substrates have received a great deal of attention due to their outstanding portability and wearability. A great fabrication of magnetic sensors on flexible substrates can make a big difference in our lives. AMR magnetic sensor has a simple structure and high sensitivity, when magnetization M and current density J are parallel ($R_{//}$), the resistance of Permalloy is at maximum and when magnetization M and current density J are perpendicular with each other ($R_{\perp}$),[6] the resistance is at minimum. In this work, we fabricated a self-biased anisotropic magnetoresistive (AMR) magnetic field sensor on flexible Kapton and it shows excellent stability and sensitivity even in the case of larger deformation. Here, we designed the Wheatstone bridge and barber pole structures, the current flow can be rotated by an angle of 45° or 135° with respect to the magnetic easy axis. We made AMR magnetic sensors on flexible Kapton by lift-off. First, the flexible substrates were cleaned by sequentially rinsing in acetone and ethanol. Then, we made a specific size of the pattern on the substrate by photolithography. Permalloy, Gold, Pt layers were sequentially deposited by sputtering method with base pressure $<10^{-7}$ torr. The magnetoresistance effect is characterized using typical four point probe resistivity measurement, as shown in Figure 1. Figure 1 shows that when there is an applied magnetic field, the resistance of the magnetoresistive sensor will change, the AMR ratio is probably 1.2%. Figure 2(a) shows that when the applied magnetic field is 114 Oe, the resistance of the magnetic field sensor varies with the angle of the magnetic field with a bending radius of 5 mm. Figure 2(b) shows that when the same magnet passes over the sensor at a same height, the resistance of the sensor have a different change with a different bending radius. In summary, we fabricated flexible AMR sensors on Kapton substrates. It shows excellent stability and sensitivity with a bending radius of 5 mm. With a great advantage of high sensitivity, excellent flexibility, and stability, the flexible AMR sensor provides a platform capable where wearable electrics for navigation, medical diagnosis and health monitoring can be realized.

CW-09. A flexible magnetoelectric transducer based on FeCuNbSiB/ poly (vinylidene fluoride) (PVDF) laminate composites for wearable magnetic sensors.

X. He[1], *J. Qiu*[1], Y. Long[1], Q. Chang[1], Z. Hu[1] and H. Liu[1]
1. College of Optoelectronic Engineering, Chongqing University, Chongqing, China

In recent years, flexible wearable equipment has attracted more and more attentions, and has made great development. Wearable electronics are expected to be one of the most active research areas in the next decades. There are more and more studies about flexible wearable sensors [1] and some of them have been used in life. However, there are few studies on flexible wearable magnetic sensors. Magnetic sensors [2] are useful and influential for human life, and kinds of sensors have been utilized in practice. To date, the new magnetic field detecting technologies with more excellent performance has been still the focused issues and trends. Magnetoelectric (ME) composite sensor was proposed as a candidate for the next-generation magnetic field sensors, due to its high sensitivity, compact size and room-temperature operation. Among the ME composites, laminate composites display the highest ME response, particularly those fabricated with magnetostrictive alloys and piezoceramic materials. However, piezoelectric ceramics have low electrical resistivity, high dielectric losses and are expensive, dense and brittle, which can lead to fatigue and failure, hindering their incorporation into technological applications. The piezoelectric polymer-based ME laminates [3] have several advantages over the ceramic based ones. They are easily fabricated by conventional low-temperature processing into a variety of forms, such as thin sheets or moulded shapes, and exhibit improved mechanical properties. The nanocrystalline FeCuNbSiB was elected as magnetostrictive material owing to its large piezomagnetic coefficient at low magnetic fields, high mechanical quality factor and large interface stress-strain coupling effect. For sensor applications, the optimization of the element responsible for the coupling between magnetostrictive and piezoelectric components plays a crucial role. However, coupling between the different phases is not the only parameter that requires optimization prior to their incorporation into technological applications: characteristics such as size, structure and relative geometry of the components may allow tailoring the applicability of ME composite materials. Furthermore, there is an increasing interest in fabricating smaller devices mainly in communication systems and wearable devices, which reduces the cost and improves the functionality [4]. For these reasons, it is essential to study the influence of the size on the ME coupling properties of the laminate composite. On the other hand, it is necessary to study its bending performance as the flexible ME transducer for better application for wearable magnetic sensors. In this paper, a series of flexible ME transducers based on nanocrystalline alloy (FeCuNbSiB)/poly (vinylidene fluoride) (PVDF) laminate composites for wearable magnetic sensors were fabricated. The effects of the composites size, geometry and structure on the ME coupling properties were investigated. Just as shown in Fig. 1, it is concluded that the ME voltage coefficient increases with decreasing transversal size aspect ratio (TAR) (from 3 to 1), reaching a maximum ME voltage coefficient of 203 V/cm Oe. The ME laminate composites with lowest longitudinal size aspect ratio (LAR) resulted in better ME voltage coefficient when compared with higher LAR. By investigating the ME coupling properties under different angles, it is also found that the optimal resonant ME voltage will decrease with the bending angle (θ) increases, getting the minimum of 11.56 V/cm Oe when θ=50°, which is shown in Fig. 2. The effects of thickness and fatigue properties for the ME coupling properties also were investigated. All these results provide an experimental basis for posterior research and practical application, which is very useful for science and advanced applications.

CW-10. Flat bandwidth expansion for spin-valve GMR magnetic field sensors.

Y. Chiang[1], X. Trinh[1] and *J. Jeng*[1]
1. Mechanical Engineering, National Kaohsiung University of Applied Sciences, Kaohsiung, Taiwan

The solid-state magnetic field sensors developed in recent years are transducers that convert magnetic fields under test into digital or analog voltage outputs. [1] The system consists of the front-end sensing element and the rear-end signal processing unit. The key performances of magnetic field sensor are demonstrated by its sensitivity, noise, linear range, and frequency bandwidth. The ultimate frequency response and noise behavior of the sensing system are determined by the driving method for the front-end sensing element. For quasi-static geomagnetic applications, flipping or modulation techniques is used to minimized the hysteresis for high accuracy measurement of DC field [2], but the available flat bandwidth is limited to less than one tenth of modulation frequency [3]. In contrast, a flat bandwidth over 30 kHz is observed for the DC-field-biased GMR sensor with a magnetic field feedback [4], which is ideal for high frequency applications, e.g. eddy-current sensing. However, the output under a DC-biased field is hysteretic and hence it is not suitable for DC measurement. For industry and high-end consumer applications, a magnetometer with a large bandwidth is necessary for mixed AC and DC measurement. A straight forward implementation of high bandwidth DC/AC magnetometer is to combine the DC sensor with and an AC induction coil [5]-[6]. However, the hybrid magnetometer of this kind has a feature size much larger than the solid-state sensor in it. In addition, the output levels for the two element sensors could be very different, inducing more complexity in signal processing. In this work, we explore the flat bandwidth expansion technique using two spin-valve GMR magnetic field sensors driven by different schemes, i.e. field modulation and DC-field-bias. Fig.1 shows the block diagram for the analog signal processing of the system. The low-frequency GMR sensor (LF sensor) is driven by AC magnetic modulation field to achieve high linearity and low hysteresis. A low-pass filter is used to extract the DC output induced by the nonlinear voltage-field relation of spin valve. In this way, the complexity of driving circuit with the inclusion of synchronous detection is avoided. The high-frequency GMR sensor (HF sensor) driven by a DC magnetic field bias has higher hysteresis in the low frequency range, but it exhibits high sensitivity and good linearity for high frequency field measurement. The LF sensor is suitable for detection of DC and low frequency magnetic field, while the HF sensor is capable of AC measurement at higher frequencies. The combined sensor output of the system has a wide bandwidth and is suitable for both DC and AC measurement. To combine the output of the two sensors, the output of HF sensor is high-pass (6 dB/oct) filtered at 100 Hz, and the output of LF sensor is low-pass (6 dB/oct) filtered at 100 Hz. The amplifier gains of the two outputs are fine tuned to achieve a uniform sensitivity, and the two outputs are combined with a summing amplifier. The observed outputs of LF and HF sensors as well as the combined signals are shown in Fig.2. It was found that the front-end sensitivities are 9.8 V/T for LF sensor and 251 V/T for HF sensor. The total sensitivity of the combined GMR sensing system is 2312 V/T with the total amplifier gains of 500 for the LF sensor and 20 for the HF sensor, supply voltage is 0.69 V for LF sensor and 2.61 V for HF sensor. The linearity error of the combined output signal is 2.2% within the ±4 μT range. The field noise spectral density is 65 nT/√Hz at 1 Hz. The output of summing amplifier is well consistent with theoretical values predicted by numeral calculations from the circuit model. The flat bandwidth of the combined output is expanded to the range from DC to above 10 kHz. The maximum deviation of normalized sensitivity is 1.7% at 100 Hz and the 3-dB flat bandwidth is 40 kHz. The phase lag of the combined output changes slowly to from 0° to -15° with an increasing frequency from 1 Hz to 1 kHz. The phase lag increases to -130° at 10 kHz and becomes random at frequencies above 100 kHz. Further improvement in the uniformity of frequency response is possible by optimizing the circuit parameters of low-pass and high-pass filters to fine tune their characteristic frequencies and gains. The observed frequency response of our system surpasses the existing GMR sensing systems reported by Tyler et al. [7], for which the 5% flat bandwidth is 530 Hz, and 10% flat bandwidth is 1.515 kHz. Our system exhibited a 5% flat bandwidth of 1.7 kHz and a 10% flat bandwidth of 8.3 kHz, while the response to quasi-static sweeping field at frequencies below 0.1 Hz shows negligible hysteresis. The broad bandwidth of our system makes it suitable for detecting the DC and AC magnetic fields in nondestructive evaluation [4]. It is also suitable for monitoring the environmental field in transient motion tracking with the software gyroscope [8] consisting of magnetic sensor and accelerometer. This work is supported by the Ministry of Science and Technology of Taiwan under Grant No. MOST MOST 105-2221-E-151-038.

The magnetoelectric sensor has the characteristics of high sensitivity, wide response frequency range, low power consumption and easy preparation. It has broad application prospects in the detection of weak magnetic field such as geomagnetic field, biological magnetic field etc. In recent years, the related research[1-4] shows that the output of the magnetoelectric composites vary with the angle of the measured magnetic field, in which the ratio of the maximum value to the minimum value of the output signal is denoted as K. When K is large, the magnetoelectric composites have high anisotropy. For example, Dong et al. [1] and our group [2] prepared magnetoelectric sensors with high anisotropy (100 ≤ K ≤1000), and found that K values are related to the shape anisotropy of piezoelectric materials and magnetostrictive materials respectively. It means that the magnetoelectric sensor is very sensitive to the magnetic field in a specific direction and is suitable for vector magnetic field measurement. In contrast, when K is small, the magnetoelectric composites are highly isotropic, which means that their outputs are less affected by the direction of the magnetic field, and are suitable for scalar magnetic field measurements. However, highly isotropic magnetoelectric sensors were seldom reported. For this reason, this paper studies a Terfenol-D / PZT highly isotropic magnetoelectric sensor based on ring-shaped composite structure. As shown in Figure 1 (a), we first prepared magnetoelectric composites using Terfenol-D and PZT-5H, both of which were annular in shape. The resonant frequency of the material is shown in Figure 1 (b). The sensor was placed in a solenoid with AC current, held by a foam, and fixed on a platform. In the case of the electromagnet to provide DC bias magnetic field, the spectrum analyzer measured the output signal of the magnetoelectric sensor. The frequency of the AC signal was changed continuously to record the output of the magnetoelectric composites, and the resonance frequency of the composites can be analyzed through the curve to be about 32 kHz. Fig. 1 (c) shows the relationship between the output of composites and the DC bias magnetic field, when the frequency of AC resonant magnetic field is 32 kHz, as well as the DC bias magnetic field Hdc is from 200 to 3360Oe. The result shows that the composites output increased first, then kept stable after. Next step, we measured the linearity and isotropy of the sample in a shield tube. Figure 2 (a) introduces the testing instruments, and the micro-sensor device was placed in the magnetic shield tube. Fig. 2 (b) show the linearity of the sensor. When the DC bias magnetic field is is about 280Oe by bias magnet, the output of the magnetoelectric sensor at the AC frequency of 32 kHz has a linear relationship with the amplitude of the AC signal, as well as the sensitivity is 24 mV / Oe, indicating that it has a good linear relationship. Finally, we analyzed this model with finite method, the finite element results show that the magnetoelectric isotropy could be influenced mainly by the shape of the magnetostrictive and piezoelectric material, and the position of the bias magnetic field. Then we measured the isotropic characteristics of the ring-shaped sensor. The result is shown in Figure 2 (c). We placed the sensor device in the shield tube and rotated the sensor 360 ° in steps of 30 ° to measure the change of the output signal. The isotropy ratio of the magnetoelectric sensor (K) was fitted with finite method, and the result shows that the result approximately is 13: 1. As can be seen from the figure, the test values were in agreement with the theoretical values with finite method. This is because both the Terfenol-D and PZT-5H materials are isotropic in shape, which greatly increases the isotropic effect of the magnetoelectric sensor.

I. INTRODUCTION Magnetoimpedance(MI) sensor utilizes permeability changes of the material through skin effect and ferromagnetic resonance when the sensor is applied to a magnetic field, and it has a higher sensitivity [1]. The sensors, which are composed of amorphous wires, are currently commercialized as compasses in mobile phones, and researches advance their sensitivity still continue for application of biomedical research [2] and nondestructive testing [3]. On the other hand, thin-film MI elements which has the compatibility with miniaturized integrated electronic devices such as driving and detecting circuits, contributes to the miniaturization of sensor device with higher spatial resolution. However, one problem of using thin-film elements is higher operating frequency. Typically, operating frequency is above 100 MHz to GHz range for elements with several μm thickness; this is unsuitable for general-purpose driving and detecting circuits, which normally operate below 20–30 MHz. During our investigations about thin-film MI elements, we found an interesting behavior that the frequency profile of impedance shows double peak depending on the applied bias field, that is, another peak appears at lower frequency region [4]. Then we analyzed this profile based on the domain wall equation and indicated the changes in impedance is attributed to the domain wall resonance (DWR) [5]. We also showed a potential of the phenomenon applied for developing a highly sensitive sensor operated at frequencies around the dozen megahertz region. In such cases, more detailed investigations about incident power is required because the behavior of impedance changes strongly depends on input high frequency power and this behavior is not still clear. Thus, in this study, we evaluated experimentally the impedance profile around frequency where the DWR occurs when the incident ac power modulated, and discussed about the sensitivity of impedance changes. II. EXPERIMENTAL PROCEDURE The thin-film element having 20-μm wide, 2-μm thick and 1-mm long was fabricated using an amorphous $Co_{85}Nb_{12}Zr_3$ film by photolithography and sputtering processes. The element was then annealed in vacuum by applying a field of 3 kOe at 400 °C and its easy axis is controlled parallel to the width direction. After field annealing, a Cu/Ti electrode with 2-μm thick, was fabricated. The impedance of fabricated element was measured by a network analyzer and a wafer probe. The incident ac power was changed from –20 to 5 dBm. During impedance measurements, a dc external magnetic field was applied to the element along the longitudinal direction by a Helmholtz coil. III. RESULTS AND DISCUSSION Fig. 1(a) shows an example of a frequency profile of impedance and inductance with/without DWR and it also includes the definition of parameters evaluated here; resonance frequency f_r, and changes in impedance peak ΔZ_p. When incident power is –10 dBm, the profile shows a peak for impedance and a rapid reduction of inductance due to DWR around 8.5 MHz, while the profile does not show DWR for –20 dBm (we applied magnetic field of 6.5 Oe to the element). Fig. 1 (b) shows the applied dc field dependence of f_r when the ac incident power altered. If the plotted data does not exist, which means we cannot observe DWR on the impedance profile. The values of f_r increase with increasing applied dc field and we confirmed ΔZ_p shows similar tendency to the changes in f_r. If the incident power is smaller, the field range where DWR occurs becomes smaller; e.g. the DWR appears from 7 to 8 Oe for –15 dBm while from 2 to 6 Oe for 5 dBm. On the other hand, the changing range of f_r and ΔZ_p has maximum point: in this case, f_r changes 55 MHz and ΔZ_p changes 14 Ω for –5 or –7 dBm. Then we investigated the impedance change against applied dc field and the sensitivity, defined as the maximum slope of the impedance profile, at a fixed frequency. Fig. 2 (a) shows the field dependence of impedance at 30 MHz when incident power changes. In the results of –20 dBm, we cannot observe DWR in this case, the impedance has a peak of 7.5 Ω at around 8.5 Oe. When incident power is –10 dBm, the peak value of impedance change becomes maximum (12 Ω at 8 Oe), then the peak intensity decreases with increasing incident power (See Fig. 2(b)). Also, the field intensity where the impedance has a peak shifts to lower field as the incident power increases (See Fig. 2(b)). When the incident power becomes –10 dBm, the sensitivity becomes maximum (38 Ω/Oe), which indicate DWR enhances the sensitivity of thin-film MI elements at the relatively lower frequency compared with the case without DWR (5.5 Ω/Oe for –20 dBm). IV. CONCLUSION The dependence of incident ac power on thin-film MI profile when the DWR occurs were investigated. If incident power is smaller, the profile did not show DWR, whereas larger incident power induces DWR, which brings abnormal impedance peak and rapid inductance reduction at relatively lower frequency region. Additionally, the DWR enhances the sensitivity of MI elements around the dozen megahertz region compared with the change without DWR.

CW-13. Influence of substrate material and geometry on giant magnetoimpedance of NiFe composite wires.

K. Roy[1] and *V. Srinivas*[1]

1. Department of Physics, Indian Institute of Technology Madras, Chennai, India

The giant magnetoimpedance (GMI) effect has been reported in soft magnetic materials at higher frequencies essentially due to the changes in skin effect as a consequence of applied external magnetic field [1]. The GMI element with zero-magnetostriction can be used to fabricate new sensitive, quick response and low power consumption micro-magnetic sensors [2]. Different geometries of GMI elements have been investigated to improve the sensitivity [3]. On the other hand, electroplated composite wires consisting of a highly conductive inner core and an outer soft magnetic shell have been predicted to exhibit GMI [1], which are suitable for the development of low magnetic field sensor. Further the soft magnetic properties which depend on microstructure of the film can be controlled by varying deposition parameters like additive(s) concentration in electrochemical bath. It was shown that deposition parameters have significant role in stabilizing the permalloy composition of NiFe thin films [4]. Main objective of the present investigation is two fold i.e, to study the MI response (i) of magnetic films deposited on different substrate material (Cu, Ag and Ni wires) (ii) when MI elements are connected in series and parallel geometry. The electrolytic compositions used are 0.36 M nickel sulphate, 0.05 M iron sulphate per litre and boric/citric acid concentration varied 10 to 60 g/lt. The NiFe films were deposited on ~100 mm diameter Cu (Cooper), Ni (Nickel) and Ag (Silver) wires and impedance was measured under dc magnetic field. The MI is defined as, $[Z(H_{ext})\text{-}Z(H_{max})]/Z(H_{max})$, where H_{ext} is the external magnetic field applied, H_{max} is the maximum applied magnetic field. Deposition was carried on all wires by optimizing the deposition parameters. The MI elements were deposited using identical deposition parameters and are connected in series and parallel geometry to study the cascading effect on MI. The composition and thickness of the films was determined by SEM. Subsequently MI as a function of applied field was measured at different frequencies and shown in Fig.1. Since the MI depends skin effect which in turn depends on the conductivity the MI characteristics are expected to be different. It is observed that the films deposited of Cu and Ag wires show a maximum MI of ~500% at field of 0 Oe (100 kHz) and 2.4 Oe (60 kHz) respectively. While a maximum MI of ~200% at field 2.4 Oe (200 k Hz) was observed for film deposited on Ni wire. Although Ni wire itself is a ferromagnetic sample the MI for Nickel is found to be negligibly small. From all the substrate variation studies, it is clear that the material of the substrate plays a major role not only on magnitude of MI but also frequency at which the maximum MI is observed. In the case of two wire series connection the maximum MI is 215%, while for four wire the maximum MI of 360% was observed at 4 Oe (500 kHz frequency). We have observed a significant change in magnitude of series combination. On the other hand in comparison to the single wire, the maximum MI frequency is shifted from 60 kHz to 500 kHz for both the double and four wire connections. Interestingly the H_k value is same for all the cases, which is expected since the films are deposited under identical conditions. These results suggest that the magnetic response is similar but the higher initial impedance could possibly be shifting the frequency at which the maximum MI is observed. This is important observation that emerges out of this study, which means a magnetic field sensor can be designed for suitable frequency range by choosing the series combination of MI elements. On the other hand two wire parallel combination the maximum MI is 300% at 4.8 Oe (90 k Hz) and for four wire the maximum MI of 120% observed at 2.4 Oe (200 k Hz). Here the MI value is decreased as the number of wires are increased. Also the maximum MI frequency is shifted from 60 kHz (single wire), 90 kHz(double wire) to 200 kHz(four wire). This is also a strong evidence of the fact that for high MI value the sample needs to have lower z, as well as highly soft magnetic in nature. These features can be understood on the basis of standard Maxwell equations and the Landau-Lifshitz-Gilbert equation [5]. A detailed experimental and numerical simulations will be presented in order to explain the observed changes MI with substrate material.

1. Shinshu University, Nagano, Japan; 2. Citizen Finedevice Co., Ltd., Kitasaku-gun, Japan

The Faraday-effect has been used for the measurement of magnetic field induced by electric current. Actually, an optical fiber sensor using the Faraday-effect has been developed as an alternative method of the current-transformer in the substation of the AC electric power system. However, in the optical fiber electric current sensor, it is difficult to minimize the sensor head because the optical fiber must be wound to a conductor wire. Recently, we proposed an optical magnetic field sensor with a small head [1] for the switching current measurement for the SiC/GaN power-devices, which consisted of a Faraday-element using a magnetic thin film. Such a magnetic thin film for the Faraday-element must have both higher transmittance for the light (transparency) and large Faraday-effect. Rare earth substituted yttrium iron garnet film (R:YIG) with high transmittance and large Faraday-effect has been widely studied, and a cerium substituted film (Ce:YIG) with high performance has recently been reported [2]. However, Ce:YIG film has a temperature-dependent magnetization owing to the low Curie temperature around or below 300 deg C. In this study, we focus on a granular film with ferromagnetic fine metal particles dispersed in an insulator matrix to obtain high transmittance and large Faraday-effect. Actually, N. Kobayashi *et al.* [3] reported a FeCo-AlF granular film with high transmittance. J. L. Dorman *et al.* [4] also reported a Fe-Al$_2$O$_3$ granular film with large Faraday rotation angle of 3000 to 4000 deg./cm at 1550 nm wavelength. In our study, to develop the Faraday-element for the optical magnetic field sensor, the granular film was fabricated by co-evaporation method using cobalt (Co) and magnesium fluoride (MgF$_2$). The evaporation rate ratio was kept to Co : MgF$_2$ = 1 : 2 (Co volume fraction of 0.33). The substrate- temperature during co-evaporation was R.T. to 450 deg C. The magnetic and magneto-optical properties of the film were characterized. The substrate-temperature dependences of the cobalt particle diameter and the extinction coefficient k in the Co-MgF$_2$ granular film deposited by co-evaporation are shown in Fig. 1. The Co particle diameter became large proportional to the substrate-temperature during the deposition. At low substrate-temperature during the deposition, average Co-granule diameter was about 3 nm and the granular film exhibited a superparamagnetism. On the other hand, not shown here in detail, at the substrate-temperature during the deposition of 350 deg C or above, the granular film exhibited a magnetization curve with a hysteresis as an evidence of the ferromagnetic behaviour. O. Kitakami *et al*. [5] reported a superparamagnetic critical diameter of hcp-Co, it was estimated to be about 7 nm, in our study, such the critical Co diameter was estimated to be about 4 nm. The cobalt particle size became large and the k of the film became low with increasing the substrate-temperature during the deposition. The minimum k of the film was 0.028 at the substrate-temperature of 450 deg C, which was much smaller than those of previous studies. Even in constant concentration of Co or MgF$_2$ in the film, the k changed by substrate-temperature during the deposition. We considered that the distance between the adjacent cobalt particles became wider when the cobalt particle became larger, and such a relationship between cobalt particle size and the distance between the adjacent particles was considered to be strongly related to the low k of the Co-MgF$_2$ granular film. Fig. 2 shows the magnetization curve of Co-MgF$_2$ granular film deposited at 350 deg C measured in the film plane and perpendicular to the film plane, and the Faraday-rotation angle versus applied magnetic field. From Fig. 2, the Co-MgF$_2$ granular film had the in-plane aligned magnetization, and the perpendicular magnetization process was considered to be due to the magnetization rotation by the perpendicular demagnetizing effect. Although not shown here, even at ambient temperature of 350 deg C, the decrease of saturation magnetization M_s of the Co-MgF$_2$ granular film deposited at 350 deg C was a little 10 %. Therefore, the Co-MgF$_2$ granular film was considered to have a Curie temperature much higher than 350 deg C. In Fig. 2, the Faraday-rotation loop was corresponding to the magnetization curve well. The Faraday-rotation angle was linearly proportional to the applied magnetic field within ±2 kOe. The upper limit of magnetic field 2 kOe of the linear relation was considered to be due to the perpendicular demagnetizing magnetic field H_d, where H_d was estimated to be about 4 kOe from the saturation magnetization M_s of 4 kG. Since the H_d was considered to be dependent only on the M_s with the curie temperature much higher than 350 deg C. Therefore, the Co-MgF$_2$ granular film will be useful for the Faraday-element of the optical magnetic field sensor used in high ambient temperature.

CW-15. Effect of Annealing Temperature on GMI in NiFe Thin Films.

L. Zhu[1], F. Jin[1], K. Dong[1], W. Mo[1] and J. Song[1]
1. China University of Geosciences, Wuhan, China, Wuhan, China

Soft magnetic amorphous films have the giant magneto-impedance (GMI) effect, which is of great significance to realize miniaturized and integrated GMI micro-magnetic sensor [1]. So it is the hotspot to improve the GMI effect and sensitivity of amorphous soft magnetic films nowadays. In this work, we studied the effects of different annealing temperatures on soft magnetic properties and GMI effect of NiFe films. We used the magnetron sputtering to prepare NiFe single layer thin films with a thickness of 80nm which were deposited onto a glass substrate. Then the films were annealed at different certain temperatures. The annealing temperatures were 200°C, 500°C and 600°C respectively. The magnetization curves at 200°C, 500°C and 600°C and XRD 2θ spectra at 500°C of the NiFe single layer film were shown in figure 1 (a) and (b). The in-plane easy magnetization direction was not obvious when the annealing temperatures was 200°C, while the annealing temperature reached 500-600°C, there were good in-plane easy magnetization directions. Annealing can effectively eliminate the films' magnetic anisotropy and optimize the soft magnetic properties of the film [2]. On the outcome of the analysis, a sample with a sandwiched multilayer structure defined as Ta/$(NiFe/Ag)_5$/Ag/$(NiFe/Ag)_5$/Ta had been prepared by magnetron sputtering. It had a total thickness of 5nm/$(80nm/2nm)_5$/200nm/$(80nm/2nm)_5$/5nm and a dimension of 1mm×10mm. The MI effect was measured in a network analyzer using a microstrip test-fixture. Figure 2 (a) and (b) showed the structural diagram and the sample of the multilayered film respectively. At present, the GMI curve test at room temperature has been completed, and the GMI curve test under the annealing conditions will continue.

CW-16. Effect of amorphous wire core diameter on the noise of an orthogonal fluxgate.

M. Butta[1], M. Janosek[1], B. Schutte[1], M. Vázquez[2], R. Perez del Real[2], E. Calle[2] and A. Jimenez[2]
1. Faculty of Electrical Engineering, Czech Technical University in Prague, Praha, Czechia; 2. Institute of Materials Science of Madrid (ICMM-CSIC), Madrid, Spain

Orthogonal fluxgates have been proved to provide low noise measurement of quasi-static magnetic field. Typically Co-based amorphous wires are used because they allow to reach noise as low as 2.5 pT/√Hz noise at 1 Hz for as-cast wires and 1 pT/√Hz noise for annealed wires [1]. So far, however, only one diameter has been used for such wires, namely 125 μm. This is due to the fact that commercially available magnetic wires manufactured by Unitika™ are available only in this diameter. In this paper we investigate the possibility to reduce the noise of an orthogonal fluxgate by increasing the diameter of the magnetic wires used as core of the sensor. We manufactured (Co0.94Fe0.06)72.5Si12.5B15 in-water solidified amorphous wires with diameter in a range from 80 μm to 220 μm by changing the diameter of the ejecting hole of the crucible where the alloy was melted [2]. For different holes diameter we adjusted the value of argon pressure inside the crucible and speed of the water wheel in order to obtain a continuos casting of the magnetic wire. We then analized the magnetic behaviour of the wire by measuring the hysteresis loop by means of VSM: the coercivity keeps between 80 A/m and 180 A/m for wires with diameter up to 190 μm, then it rises up to 4300 A/m for wires with diameter higher than 200 μm. This indicates that we can produce amorphous wires only with diameter up to 190 μm. For larger diameter the central part of the wire is nanocristalline. This is cause by limited cooling rate during casting (about 10^6 K/s) which does not allow to cool fast enough the inner portion of the wire making possible the development of crystals. The wires where then used as core for orthogonal fluxgate in fundamental mode [3]. The length of the wires was 8 cm, the pick-up coil was composed of 900 turns and it was 6 cm long (to avoid the effects of the terminations). The wire where excited by 50 mA dc current and 45 mA ac current. We characterized the noise for different values of excitation current frequency and we found out that is it slightly higher at resonance frequency, therefore for all wires we selected a frequency for excitation curret out of resonation. This lead us to different frequency for different wires, given that the resonance frequency depends on the wire's diameter. In order to obtain a fair comparison we selected a frequency (between 60 and 90 kHz) which returned the lowest achivable noise for every sensor. Fig. 1 shows the noise spectra of orthogonal fluxgates based on amorphous wires with 80 μm, 130 μm and 180 μm. As we can see the noise drops down from 12 pT/√Hz at 1 Hz to 2 pT/√Hz. Interestingly, this noise decrease is achieved despite the less favourable demagnetizing factor of the wires with high diameter (1.12×10^{-3} for 180 μm vs. 5×10^{-4} for 80 μm). Wires with larger diameter which contain a nanocrystalline core do not show any output signal, indicating they do not work as orthogonal fluxgate anymore. Therefore, we derive that the magnetic wires for orthogonal fluxgates have to be casted with the largest possible diameter, for this reduces the noise, despite less favourable demagnetizing factor; the upper limit of the maximum diameter the casting method allows to achieve fully amourphous wires.

Magnetic nanoparticles (MNPs) offer unique and important capabilities applicable to both fundamental research and technology based applications in biomedicine and the life sciences. In particular, their interaction with suitable static or alternating magnetic fields means that they can act as conduits for the remote application of mechanical forces to cells, as well as delivering local heating through the magnetic hyperthermia effect. In addition, their magnetic properties make it possible to not only track the particles *in vivo*, but also to probe their local environment using techniques such as magnetic particle imaging. However, in order to achieve their full potential, it is essential to understand how the cellular environment the magnetic nanoparticles occupy affects their behaviour and ultimately performance. MNPs exposed to alternating (AC) magnetic fields offer potential applications as hyperthermia mediators for cancer treatment [1,2], providing a complementary physical technique to therapies using pharmacological and immunological treatments. An important property of magnetic hyperthermia is that it produces a localised heating affect which can be used to induce apoptosis and necrosis of cancer cells. In fact, the ability to associate magnetic nanoparticles with individual cells, either by cellular uptake or by binding the nanoparticles to cell membranes, gives unrivalled potential for treating cancer on a cell by cell basis. An example of the uptake of iron oxide magnetic nanoparticles by breast cancer cells (MCF-7 cell line) is shown in the TEM image in Figure 1. Despite the exciting possibilities for cancer treatments offered by magnetic hyperthermia, there are still some significant challenges to overcome before this can become a viable therapy. Perhaps most significantly, recent experiments have shown a reduction in the MNP heating efficiency when the particles are located inside cells or tissues [3,4]. It has been suggested that the enhancement of nanoparticle aggregation and/or immobilization after interaction with cells could cause this effect, although a quantitative description is currently lacking. MNP aggregation can be caused following internalisation and subsequent sequestering of the MNPs into intracellular vesicles known as lysosomes [4,5], as can be clearly seen in Figure 1. In this talk I will describe the results of our recent experiments to use a combination of AC magnetic susceptibility [6,7] and AC magnetometry [8,9] to probe the in situ dynamic magnetic response of nanoparticles following their association with live cancer cells. Measurement of the AC hysteresis loop area provides a direct method for assessing the heating efficiency of the nanoparticles (known as the Specific Absorption Rate or SAR), without the heat dissipation complications associated with calorimetric methods [8]. Furthermore, the shape of the hysteresis loops provides crucial information on how the dynamic magnetic response of the nanoparticles is affected by their local biological environment. Complementary to this, AC susceptibility measurements probe the mobility and aggregation state of the particles, as well as their effective magnetic anisotropy. By combining these techniques, we were thus able to evaluate the behaviour of two different MNP core sizes following cell internalisation, and to compare this to experimental model systems where either the aggregation or the mobility of the particles was systematically varied. By fitting the AC susceptibility data with a computational model, we also obtained values for the effective magnetic anisotropy of the MNPs in their different environments. The SAR results shown in Figure 2, revealed that the heating efficiency was indeed reduced following cellular internalisation (by comparison with aqueous suspension), but that the effect was only significant for the larger (21 nm) particles. The origin of this reduction was found to be a corresponding decrease in the effective anisotropy of the particles, once they were associated with cells. Experiments on the model MNP systems revealed similar qualitative and quantitative trends to those seen in the cellular experiments, but caused predominately by increasing MNP aggregation rather than reducing nanoparticle mobility. The results discussed here are important for progress in magnetic hyperthermia research as they enhance our understanding of the dynamic magnetic response of MNPs in cells, which in turn defines their heating efficiency. The use of AC magnetic techniques to probe the MNP response in situ, also offers a method for assessing future MNP designs such that barriers to exploiting magnetic hyperthermia can ultimately be overcome.

DA-02. Design and Medical Applications of a Platform for Image-Guided Non-Invasive Brain Delivery of Magnetic Particles.

J. Benlloch[1] and *I. Weinberg*[1]
1. I3M, Valencia, Spain

The first successful clinical trial for shallow focussing of magnetic nanoparticles was performed in the mid 1990s to treat inoperable surface tumours [1]. Since then, much clinical progress has been achieved in the treatment of diseases with magnetic nanoparticles. In particular, a private company has obtained CE mark in 2014 for the therapy of some tumours, after treating 90 patients with brain tumors and about 80 patients with other tumors such as pancreatic, prostate or esophageal cancer [2]. The fluid containing magnetic particles is injected into a tumor and then it is heated through external application of alternating magnetic fields. Heating sensitizes tumor cells to radiotherapy and/or chemotherapy. However, injecting the fluid into a brain tumor, implies a considerable risk due to the potential functional damage in the brain areas traversed by the needle. Moreover, an optimally efficient hyperthermia or drug delivery system involves a perfect control on the particle delivery to achieve, for instance, an even distribution of the nanoparticles throughout the tumor. In order to reach that objective, a device that allows simultaneous visualization of the tumor and the magnetic nanoparticles is required. Therefore, a good question to ask is whether it is possible to deliver therapy to the right place through any biological tissue. In order to most efficiently deliver nanoparticles to specific foci in the brain and central nervous system, it would be helpful to have anatomic guidance at the time of administration and delivery. Magnetic particle imaging (MPI) does not allow simultaneous MRI guidance because the static field disrupts the ability to demagnetize the particles. We have built a low-profile electro-permanent MRI system [3] that can be quenched in milliseconds and then reconfigured to guide magnetic particles (Fig. 1). Particles can be designed and manufactured specifically to take advantage of the properties of this delivery system, for example with nano-engineered features that permit rotation of the particles during translation. A combination of custom magnetic pulses and particle shapes enables unprecedented capabilities: concentration and de-aggregation [4], rotation [5] and penetration through viscous materials [6]. This combined rotation and translation eliminates the corona formation that would otherwise hinder the motion of particles through biological tissues. We have shown (in rodents) that it is possible to administer the neuroparticles™ intra-nasally and then to guide them into and through the brain using magnetic gradients that can concentrate the particles (Fig. 2) [7]. Once in place, the particles can deliver drugs and nucleic acids as needed clinically. Using wearable electromagnets programmed securely in the field, it will be possible to stimulate the relevant brain foci mechanically to accomplish clinical missions (e.g. addiction therapy). Therefore, this platform is able to: Image with high spatial resolution [8] and in real time both the magnetic nanoparticles and the target in the human head. Move through tissue effectively. Traverse physiological barriers. Concentrate particles on target. Carry diverse payloads that are released in controlled fashion. Ablate target when needed. The platform could be used as a device to drive magnetic nanoparticles to a specific target and then perform a physical task, like treating refractory sinusitis or intracranial aneurisms. The platform could be also used as a drug delivery device through magnetic carriers. Potential indications of the use of the new Platform as a drug-device are the following: treat deep brain tumors, Parkinson disease, addiction therapy and severe depression treatment. The Platform might be used simply as diagnostic imaging device for head diseases.

DA-03. Magnetoelectric biomaterials for advanced tissue engineering applications.

S. Lanceros-Mendez[1], C. Ribeiro[2], S. Ribeiro[2], M. Fernandes[2], N. Castro[1] and V. Correia[2]
1. BCMaterials, Leioa, Spain; 2. Universidade do Minho, Braga, Portugal

Tissue engineering and regenerative medicine is a multidisciplinary research field that typically involves a biocompatible biomaterial, which can be combined with stem cells and different stimuli with the objective of repairing failing organs. In this context, it is increasingly recognized the need of active or smart scaffolds in order to properly regenerate specific tissues. Among the most relevant clues that active scaffolds can provide are electrical and electromechanical ones[1], as they are among the most relevant clues determining tissue functionality in tissues such as muscle and bone, among others. Thus, electroactive materials and, in particular, piezoelectric ones[1], demonstrate strong potential for novel tissue engineering strategies, in particular taking also into account the existence of these phenomena within some tissues, indicating their requirement also during tissue regeneration[1,2]. Piezoelectric materials can provide an electrical signal to the cells in response to a mechanical input[3], but also a mechanical excitation upon electrical input, being therefore suitable for both electrical and mechanical cell stimulation, being mechano-transduction other of the main clues determining cell differentiation and proliferation. In many situations the mechanical stimulation necessary for the electroactive response[2,3] cannot be provided by the human body and the electrical excitation of the piezoelectric material, necessary for the mechanical response, needs the use of wires and electrodes, which makes difficult the applicability of the materials. Those situations can be overcome by the use of magnetoelectric materials[4], that produce an electrical output upon magnetic stimulation and that can be also used to provide just mechanical stimulation in response to the magnetic field, due to the magnetostrictive effect. This talk will reports on magnetoelectric materials used for tissue engineering applications[4,5]. The most used materials and geometries[6] for tissue engineering strategies are reported together with the main achievements, challenges and future needs for research and actual therapies[4,5]. A compilation of the most relevant results and strategies will be provided as start point for novel research pathways in the most relevant and challenging open questions. Further, this novel approach has led to the need of novel bioreactor concepts to perform *in-vitro* studies in cell differentiation and proliferation. In this context, the main developed bioreactors will be also summarized as well as their adequacy to the developed magnetoelectric materials. It will be demonstrated that magnetoelectric cell stimulation is a novel, suitable and needed approach for tissue engineering allowing magnetic, mechanical and electrical stimuli. Currents circulating in excitable cells like neurons or nerve fibers may be measured by the radiated magnetic field. At the organ level, these magnetic fields can be detected by non-invasive experiments using highly sensitive magnetometers such as SQUIDS [1], atomic magnetometers [2] or mixed sensors [3], the latter using spin electronics. This technique, called cammed Magneto-Encephalography, allows measuring neuronal activity at a millisecond resolution and for collective response of population of typically 10 000 neurons and more. To understand the genesis of the signals obtained in brain areas, it is relevant to investigate the fields generated at the level of one or few cells. This requires small and sensitive field sensors, operating at physiological temperatures, which has long been out of reach from existing technologies. Spin electronics allow now developing small size and very sensitive magnetometers, reaching the sub-nanotesla field range on micron-size sensors. These devices operate from low temperature to hundreds of °C, so they can be used at physiological temperature. Furthermore, spin electronics sensors, based on thin film technology, can be deposited on silicon or glass substrates which can be shaped in needle-type devices to allow penetration in tissues with reduced damages. We have designed and fabricated magnetic sensors called magnetrodes, as a magnetic equivalent of electrodes, to probe locally the information transmission of excitable cells. These probes contain one or several GMR elements in embodiment compatible with recordings in contact with tissues or within tissues. Two types of sensors have been evaluated on living tissues; planar probes to investigate the Action Potential propagation in *in vitro* preparation of muscle cells, which have demonstrated the first local biomagnetic recordings with GMR sensors [4], and sharp probes for *in vivo* recordings of cortical activity. Here we present the first *in vivo* experiments performed, which have paved a new way to a local description of electrical activity, without direct contact to the cell and which allow accessing not only the amplitude of the activity but also its direction of propagation, at any depth within the tissues. Magnetrodes have demonstrated their ability to detect neuronal signals such as Evoked Response Fields, which correspond to electrical Local Field Potentials in response to an external stimulus [5] as well as Action Potential, which are related to the activity of a single neuron.

DB-01. Organic Ligand Induced Ferromagnetism in Ni doped ZnO films.

s. Nallusamy[1] and G. Nammalvar[1]
1. Physics, National Institute of Technology, Tiruchirappalli, India

Diluted Magnetic Semiconductors (DMS) are one of the most prominent classes of materials in spintronics with certain interesting properties such as magnetic, magneto-optical, magneto-electronic and semiconducting behavior for memory device applications. ZnO based DMS have been paid great attention owing to their plausible magnetic and optical properties. There are numerous reports available on the improved optical and magnetic properties of ZnO upon doping transition metal (TM) ions like Mn^{2+}, Co^{2+} and Cu^{2+} [1-3]. However, many of these reports lack the device fabrication process even though the magnetic properties of the ZnO material was found enhanced. One way to improve the ferromagnetic behavior of ZnO is to use dopants of appropriate magnetic nature such as Ni, Fe and further surface functionalization using organic ligands[4-6]. Here, we present Amine functionalized (3, 5, & 7 mol. %) Ni doped ZnO thin films grown by RF magnetron sputtering. The Ni doped ZnO targets of 3,5 & 7 mol.% were prepared by mixing appropriate amount of NiO powder with ZnO powder. These pellets were used for the thin film deposition on Si (100) substrate by RF Magnetron sputtering. Before deposition, 10^{-6}mbar vacuum was achieved from rotary and diffusion pumps. The RF power of 120 W & Ar and O_2 pressures, 0.015 mbar and 0.02 mbar, were maintained during the deposition process. The optimized substrate temperature, 450°C and sputtering time of 40 minutes w maintained during the depositions of all the thin films. The deposited film has been subsequently functionalized with Amine by the spin coating technique. Using micro pipette, Amine was spread over on the grown film. After an adsorption time of 60 seconds, the spin coater was ramped to 3000 rpm at 500 rpm intervals. The above process was repeated for 10 cycles to achieve a uniform coverage of organic molecules on the grown Ni doped ZnO films. After completion of the process, the films were annealed in air at 80 °C for 5 min. Fig.(1a) shows the schematic diagram of the entire process. The structural properties were analyzed by XRD (Rigaka Ultima III) using Cu-kα. The defect level and vacancies present in the Ni doped ZnO thin films were identified by Photoluminescence measurement (Perkin elmer Ls55). The presence of chemical bond and functionalization of Amine (N) molecule has been examined by X-ray photoelectron spectroscopy using Al K_{α} radiation. The surface morphology and elemental composition were investigated using the SEM attached with EDX. The magnetic properties of the films were analyzed by VSM at room temperature. The hexagonal wurtzite structure was confirmed by X-ray diffraction analysis. The grain size was found to decrease from 44.35 to 23.10 nm at various Ni doping concentration. The PL emission intensity at 2.8 eV reveals the presence of Oxygen vacancies in Ni^{2+} doped ZnO films which in turn originates the ferromagnetism. The green emission further blue shifted to 3 eV upon Amine capping. The magnetic saturation of 5 mol.% of Ni^{2+} doped ZnO films measured as 12.09 emu/cm^3 and 22.20 emu/cm^3 for Amine functionalized Ni doped ZnO thin films. This clearly shows the enhancement of ferromagnetism due to functionalization. The functionalization of Amine was confirmed the appearance of Zn-N bond observed in the XPS spectrum reveals the formation of surface layer between Zn and N atom. Fig(1b) shows the Magnetization (M) - Magnetic field (H) hysteresis loop of Amine functionalized and unfunctionalized (3,5 & 7 mol%) Ni doped ZnO thin film samples measured at room temperature. It was noticed that the saturation magnetization values are increases up to 5 mol% Ni doped ZnO films and then decreases. The higher stauration magnetisation might be due to the exchange interaction between oxygen vacancies and doped Ni ions in the Ni doped ZnO films. The decrease of Saturation Magnetization for 7 mol% is due to the compensation effect of oxygen vacancies combined with the increase of antiferromagnetic interaction between the Ni ions due to the shortening of distance between ionic distance in the lattice[7,8]. Upon Amine functionalisation on these Ni doped ZnO films shows enhanced ferromagnetism. In particular, Amine functionalized 5 mol% Ni doped ZnO films exhibit maximum enhanced Saturation Magnetization. The enhancement of ferromagnetism in amine functionalized Ni doped ZnO films is attributed to the lowering electronegativity value of N atoms than that of O atom. Also, there is an expansion of the Zn-O bond nearest to the N atom is due to the charge redistribution caused by the ligands. As the Zn atom transfers part of its charge to the N atom, the charge transfer to the neighboring atom decreases, thus weakening the Zn-O bond while simultaneously creating a hole in the O 2p orbital. The accompanying changes in the Zn-O bond, there is a hybridization between the Zn s orbitals with N p orbitals. The resulting unpaired P electrons in O, N sites lead to the enhance the magnetic moments and make the system more magnetic[9,10]. The enhanced ferromagnetism is well justified by the difference in XRD, PL, and XPS results of unfunctionalized and functionalized Ni doped ZnO films. The ligand induced magnetic materials are much useful in magnetic sensor and biomedicine applications.

We demonstrate that electrospray deposition enables the preparation of monolayers of intact Fe_4H single molecule magnets on graphene/Ir(111) [1]. Topographic information obtained by using scanning tunneling microscopy confirms the realization of high-quality 2D assembly on the graphene/Ir(111) substrate. From the magnetic field dependence of the x-ray magnetic circular dichroism signal, we infer that the magnetic easy axis of each Fe_4H molecule is oriented perpendicular to the sample surface with the value of the uniaxial anisotropy being unaffected upon the deposition on graphene. Furthermore, we observe inelastic features in scanning tunneling spectroscopy, due to spin-flip excitations from the magnetic ground state, giving access to the intramolecular exchange coupling J_1 on the single-molecule level, which is unprecedentedly close to the bulk value. Our findings suggest that Fe_4H molecules undergo only negligible interaction with the graphene/Ir(111) substrate, resulting in a two-dimensional array of molecular magnets that retain their bulk magnetic properties.

Spin injection in molecule-metal heterojunctions is dominated by interfacial effects. [1] At the interface between semi-conducting molecular films and metal or semi-conducting substrates, hybrid states emerge which can then be occupied through charge transfer across an interfacial potential. Where the conduction bands of the substrate are spin split, such as in ferromagnetic or half-metallic metals, hybrid interface states can also be spin polarised leading to emergent magnetism in surface molecules. [2, 3, 4] Over the last decade, there has been a concerted effort to understand these interfacial effects and their potential impact on molecular spintronics. However, a persistent challenge in molecular spintronics is how to utilise these interfacial effects as a toolbox to develop multifunctional devices which can compete with conventional spintronics. [5] One method for controlling interfacial effects is to utilise the coupling of ionic and charge current in a manner similar to a memristor. When the electrode material in a molecular heterojunction is a metal oxide such as a manganate, it has been observed that the diffusion of oxygen ions into the molecular film has a profound effect on spin injection and transport characteristics. [6] By controlling the flow of oxygen ions between a molecular semi-conductor and a metal oxide electrode, it is possible to reliably switch interfacial effects on and off in a two terminal device. Here we present such a multifunctional device based on a MnO_2/C_{60}/ferromagnet heterojunction. The interfacial properties of this system are dominated by the exohedral bonding of oxygen to C_{60} which produces half-metallic surface states and a strongly rectifying contact barrier. During transport across this device, spin polarised charges become trapped in surface states due to the spin filtering action of this half-metallic interface causing charge and spin to accumulate in highly stable interfacial trap states. Where interfacial polarisation is stabilised by a magnetic electrode, spin polarised charge can be stored over timescales in excess of 30 minutes as measured by X-ray Magnetic Circular Dichroism (XMCD). The capacitance of these heterojunctions is also shown to follow the magnetisation of the ferromagnetic electrode, being maximised when the electrode is saturated and minimised when it is demagnetised. Because the half-metallic surface states are dependent on interfacial chemistry, diffusion of oxygen into the molecular film quenches these behaviours by screening the interfacial potential and switching the character of the C60 from n-type to p-type through the formation of a mid-gap acceptor band. Because C60 can repeatably absorb and desorb exohedral oxygen without destruction of the cage, the interfacial effects can be switched on and off through bias cycling. [7] This system also exhibits photovoltaic effects due to the p-n junction formed at the interface. The photovoltaic properties can also be controlled through bias cycling wherein the interfacial potential is quenched by the formation of the mid-gap acceptor band. It has not yet been established whether the spin-filtering interface means that the photovoltaic effect is dependent on the polarisation of incident light or the magnetisation of the ferromagnetic electrode though it is expected that there should also be a spin dependence in the open circuit voltage. The MnO_2/C_{60} system provides unprecendented multifunctionality which is applicable to molecular spintronics. In a single two terminal device, it is possible to realise spin dependent charge trapping and spin filtering, photovoltaic effects and a strongly rectifying barrier all of which can be reliably switched on and off through voltage cycling.

Lett. 7, 2310 – 2315, 2016. [5] M Cinchetti et al, Nat. Mat. 16, 507-515, 2017. [6] H Xie et al, Appl. Phys. Lett. 108, 011603, 2016. [7] T Arai et al. Solid State Comm. 84, 8, 1992.

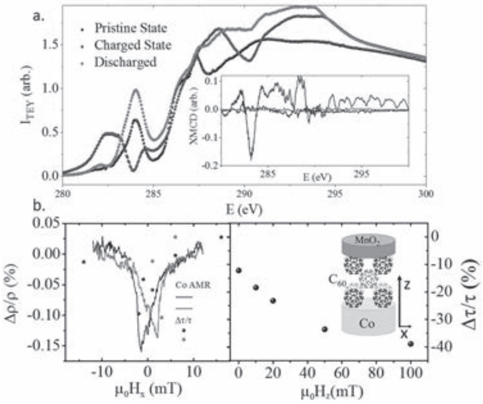

Fig. 1. a. XAS and XMCD measured in a heterojunction of $Co/C_{60}/MnO_2$. XAS is measured in TEY mode and primarily measures the upper three monolayers of the C_{60} film closest to the MnO_2. After applying a bias, the K-edge is significantly altered with the LUMO supressed and a peak emerging 1eV lower. This state is predicted by density functional theory and occurs due to the accumulation of interfacial charge. This state shows a spin polarisation observable in XMCD which is stable over timescales of 30 minutes. b. Measurements of the decay time constant for the open circuit voltage (VOC) after the interface is charged by a pulse of light from a XeHg lamp. The solid lines show AMR in the cobalt electrode and the points show the percent change in time constant. The decay of VOC is fastest around the coercivity. When a field is applied out of plane, larger out of plane field leads to faster decay.

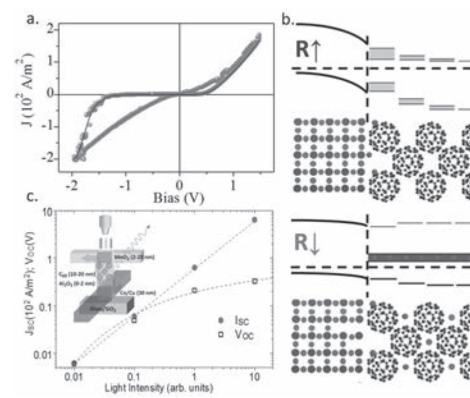

Fig. 2. a. IV characteristic of a $Co/C_{60}/MnO_2$ heterojunction. The MnO_2/C_{60} interface creates a strongly rectifying barrier making the IV asymmetric. At high negative bias (<-1.5 V) the junction breaks down as oxygen begins to diffuse into the molecular film forming a mid-gap acceptor band, b. The accetor band compensates donor transport, reducing mobility and increasing resistivity. However, because it also quenches the interfacial barrier it leads to an apparent drop in resistance and symmetric IV. Above the breakdown voltage, the resistivity of C60 oxide is higher than the as deposited film as expected. c. When in the asymmetric state, the interfacial potential leads makes the device a high ideality (>2) low efficiency (<0.1 %) photovoltaic.

Magnetic nanoparticles with high magnetization and high surface-to-volume ratio provide attractive platform for magnetic separation in wastewater treatment, analytical chemistry, catalysis, and sorting of cells in medical research. The separation of analytes from dilute samples poses a crucial step in chemical analysis of organic pollutants such as steroid compounds. Magnetic nanoparticles with suitable surface modifications offer an excellent sorbent for this purpose. Importantly, zinc-doped ferrimagnetic systems of magnetite/maghemite exhibit higher magnetization than their undoped counterparts, and they can be prepared by the thermal decomposition method as fine particles with almost bulk-like magnetic properties [1]. Moreover, such products can be easily transformed to carbon-coated nanoparticles, whose surface might be efficient for adsorption of organic compounds. Zinc-doped iron oxide nanoparticles were synthesized by thermal decomposition of zinc acetylacetonate and iron(III) acetylacetonate in octadecene [2], and the as-prepared particles were stabilized by addition of surfactants, namely oleic acid and oleylamine. The nanoparticles with surfactants were thermally treated at 500 °C under argon flow to achieve carbon-coated particles (ZF@C). In addition, the original particles were thoroughly purified, whereby magnetic cores (ZF) with only a residual organic component were obtained. The analysis of ZF and ZF@C samples by XRD revealed only a single phase of the spinel structure (*Fd*-3*m*). The Rietveld refinement evidenced that lattice parameter a and the mean size of crystallites d_{XRD} remained unchanged after the carbonization of surfactants since almost the same values of a = 8.4026(5) Å and 8.4039(5) Å and d_{XRD} = 22 nm and 21 nm were found for ZF and ZF@C, respectively. Further, XRF analysis of ZF cores was used to determine the Zn:Fe ratio. The actual oxygen stoichiometry was inferred from the Mössbauer spectra, and the composition of magnetic cores was refined to $(Fe^{3+}_{0.81}Zn^{2+}_{0.19})_T[Fe^{3+}_{1.19}Fe^{2+}_{0.63}Zn^{2+}_{0.18}]_O O_4$ for ZF and $(Fe^{3+}_{0.72}Zn^{2+}_{0.28})_T[Fe^{3+}_{1.40}Fe^{2+}_{0.45}Zn^{2+}_{0.09}Ø_{0.06}]_O O_4$ for ZF@C, where Ø denotes the vacancy. Interestingly, zinc ions migrated preferably to tetrahedral sites during the thermal treatment of particles. Finally, TGA measurements were performed in an inert atmosphere and in air on the particles stabilised by surfactants to simulate the process of carbonization, and the content of carbon in the ZF@C product was estimated to ≈5% wt. The TEM inspection of ZF showed predominantly spheroidal shape of particles and rather narrow size distribution with the mean size of 15 nm and s_d = 2 nm. Practically identical size of particles was found for the ZF@C sample, whose HRTEM analysis demonstrated high crystallinity of the cores, presence of a thin amorphous surface layer of carbon nature, and formation of particle clusters. Magnetic behaviour of the samples was probed by SQUID magnetometry; selected properties are demonstrated in Fig. 1. Hysteresis loops evidenced high magnetization for the ZF@C particles as well as for the comparative ZF sample (Fig. 1a). The loops show coercivity ≈0.25 kOe at 5 K and almost negligible coercivity at 300 K. The investigation of the blocking behaviour by the ZFC/FC susceptibility measurements revealed that the ZF@C sample was almost completely in the superparamagnetic state at 300 K (Fig. 1b). However, the carbonization shifts the ZFC/FC bifurcation to higher temperature, which hinders the onset of full superparamagnetic relaxation. This finding might be explained in relation to stronger dipolar interactions among magnetic cores in the ZF@C sample with only a thin carbon layer compared to the initial particles where a residual layer of bulky surfactants may persist. Finally, the performance of ZF@C nanoparticles in separation of organic pollutants was tested. First, methylene blue was selected as a model compound to determine the adsorption isotherm. Aqueous solutions of methylene blue of different concentrations were incubated with ZF@C particles (0.5 mg mL^{-1}), and the decrease of the dye concentration in the supernatant was analysed spectrophotometrically (see Fig. 2). The adsorption isotherm was fitted by the Langmuir model for a monomolecular layer of a sorbate on a homogeneous sorbent [3]. Second, the separation of ß-estradiol and the reusability of the sorbent were studied by repeated application of ZF@C particles (5 mg) into 1 L of the steroid solution (0.27 mg L^{-1}), followed by magnetic separation and spectrophotometric determination of ß-estradiol eluted from the sorbent (see inset of Fig. 2). High performance and reusability of the ZF@C nanoparticles suggest their prospective applications in separation of steroid and other organic pollutants.

DB-05. Singlet ground state in the spin-1/2 weakly coupled dimer compound $NH_4[(V_2O_3)_2(4,4'\text{-bpy})_2(H_2PO_4)(PO_4)_2].0.5H_2O$.

A. Unnikrishnan[1], V. Kumar[4], P. Anjana[2], A. Thirumurugan[2], J. Sichelschmidt[3], A. Mahajan[4] and R. Nath[1]
1. School of Physics, Indian Institute of Science Education and Research, Thiruvananthapuram, India; 2. School of Chemistry, Indian Institute of Science Education and Research, Thiruvananthapuram, India; 3. Max Planck Institute for Chemical Physics of Solids, Dresden, Germany; 4. Department of Physics, Indian Institute of Technology Bombay, Mumbai, India

We present the synthesis and a detailed investigation of structural and magnetic properties of polycrystalline $NH_4[(V_2O_3)_2(4,4'\text{-bpy})_2(H_2PO_4)(PO_4)_2]$. $0.5H_2O$ by means of x-ray diffraction, magnetic susceptibility, electron spin resonance, and ^{31}P nuclear magnetic resonance measurements. Temperature dependent magnetic susceptibility could be described well using a weakly coupled spin-1/2 dimer model with an excitation gap Δ/k_B = 26.1 K between the singlet ground state and triplet excited states and a weak inter-dimer exchange coupling J'/k_B = 4.6 K. A gapped chain model also described the data well with a gap of about 20 K. The ESR intensity as a function of temperature traces the bulk susceptibility nicely. The isotropic Lande g-factor is estimated to be about g = 1.97, at room temperature. We are able to resolve the ^{31}P NMR signal as coming from two inequivalent P-sites in the crystal structure. The hyperfine coupling constant between ^{31}P nucleus and V^{4+} spins is calculated to be $A_{hf}(1)$ = 2963 Oe/ μ_B and $A_{hf}(2)$ = 1466 Oe/μ_B for the P(1) and P(2) sites, respectively. Our NMR shift and spin-lattice relaxation rate for both the ^{31}P sites show an activated behaviour at low temperatures further confirming the singlet ground state. The estimated value of the spin gap from the NMR data measured in an applied field of H = 9.394 T is consistent with the gap obtained from the magnetic susceptibility analysis using the dimer model. Because of a relatively small spin gap, $NH_4[(V_2O_3)_2(4,4'\text{-bpy})_2(H_2PO_4)(PO_4)_2]$. $0.5H_2O$ is a promising compound for further experimental studies under high magnetic fields.

DB-06. Spinterface induced magnetic properties in Fe or Co thin films.

S. Mallik[1], S. Mattauch[2], M.K. Dalai[3], T. Brückel[2] and *S. Bedanta*[1]
1. Physics, National Institute of Science Education and Research (NISER), Bhubaneswar, India; 2. Jülich Centre for Neutron Science (JCNS), Munich, Germany; 3. CSIR–National Physical Laboratory, New Delhi, India

Study of spinterface between organic semiconductor (OSC) and ferromagnetic (FM) layers has drawn significant research interest in recent years because of their potential in spintronic applications [1,2]. Different aspects of organic spintronics such as magnetoresistance, induced interface moment etc. have been studied extensively in the last decade [2,3]. Among various available OSCs, Buckminsterfullerene (C_{60}) has drawn immense research interest in organic spintronics because it exhibits the following properties viz. low spin-orbit coupling, large spin diffusion length at room temperature, thermal and mechanical resilience, absence of hyperfine interaction etc.[4, 5]. An induced moment of 1.2 μ_B per cage of C_{60} and suppression of ferromagnetic moment of Co up to 21% have been observed for Co/C_{60} multilayers by X-ray magnetic circular dichroism (XMCD) and polarized neutron reflectivity (PNR) measurements [6]. Similarly, the hybrid interface between Fe and C_{60} leads to magnetic moments of the C_{60} to $\mu_S = -0.21$ and -0.27 μ_B per molecule where it was aligned antiparallel on Fe(001) substrate and Fe on W(001) substrate, respectively [7]. We have studied the magnetic interface in bilayers and trilayers of FM/C_{60} and FM/C_{60}/FM samples where FM is either Fe or Co. These samples are prepared on both MgO (001) and Si (100) substrates using DC magnetron sputtering and thermal evaporation for FM and C_{60}, respectively. The thicknesses of the FM and the C_{60} layers were varied between 5 nm to 15 nm and 15 nm to 40 nm, respectively. Investigation of structural interfaces has been performed by secondary ion mass spectroscopy (SIMS). Structural characterization by SIMS revealed a few angstrom of inter-diffusion between all the layers. PNR was performed on the samples at MARIA reflectometer in Heinz Maier-Leibnitz Zentrum, Germany. The PNR fits for MgO(001)/Fe(15 nm)/C_{60}(40 nm)/Au(6 nm) sample along the cubic hard axis ($\phi = 45°$) (Figure 1(a)) indicates spin-polarized charge transfer at the interface between Fe and C_{60} layer. It has been observed that ~ 1.9 nm of C_{60} layers exhibit a magnetic moment of 3 μ_B per cage [8] probably due to the sp hybridization between Fe and C_{60} molecules [6, 7]. The layer structure of the sample obtained from the PNR fit is shown in figure 1(b). However, in case of the PNR fits for the sample with similar structure but prepared on Si (100) substrate exhibits a decrease in induced magnetic moment of C_{60} cage by 34% due to the presence of strain in the Fe layer arising from the lattice mismatch between Si and Fe. The thickness of the magnetic C_{60} layer is also reduced in this sample. The induced magnetic moment in C_{60} gets increased for the samples having lower thicknesses of the Fe layers (5 nm and 10 nm). PNR fits for similar samples with Co as the FM layer also exhibits hybridized interface with a decrease in the Co magnetic moment near the interface. The hysteresis loops along with the domain images were measured for all the samples at room temperature by a magneto optic Kerr effect (MOKE) based microscope in longitudinal mode by varying the angle (ϕ) between the easy axis and the applied field direction at an interval of 10°. For the samples prepared on MgO substrates, we have observed a uniaxial anisotropy superimposed on the cubic anisotropy due to the oblique deposition geometry and the epitaxial growth of Fe on MgO (001) substrate, respectively [9]. However, due to the large lattice mismatch between Fe and Si (100), Fe grows in polycrystalline nature. Therefore, samples prepared on Si (100) substrate exhibit only uniaxial anisotropy due to the oblique deposition geometry. For the control sample prepared without C_{60} layer i.e. MgO(001)/Fe(15 nm)/Au(6 nm), the magnetization reversal occurs either via two 90° or 180° domain wall motions combined with partial rotation depending on ϕ [9]. However, for MgO(001)/Fe(15 nm)/C_{60}(40 nm)/Au(6 nm), a significant change in the magnetization reversal process as well as in the domain structures has been observed in comparison to the control sample due to the presence of C_{60} layer on top of the Fe layer. Similarly, a significant change in the domain size and structure have been observed between the samples prepared on Si (100) substrates. Understanding the spinterface induced magnetization reversal mechanism and domain structures will have a significant impact on the fundamental physics as well as various device engineering.

DB-07. Evaluation of Local Anisotropy of Magnetic Response from Non-oriented Electrical Steel by Magnetic Barkhausen Noise.

Y. He[2], M. Mehdi[1,2], E. J. Hilinski[3], A. Edrisy[1], *S. Mukundan*[4], A. Mollaeian[4] and N. C. Kar[4]
1. Mechanical, Automotive, and Materials Engineering, University of Windsor, Windsor, ON, Canada; 2. CanmetMATERIALS, Hamilton, ON, Canada; 3. Tempel Steel Co, Chicago, IL, United States; 4. Electrical and computer engineering, University of Windsor, Windsor, ON, Canada

Abstract Non-oriented electrical steels are indispensable materials for use in electric motors as magnetic cores. It is desired that the magnetic properties of the steel sheets be optimal and uniform in all the directions in the sheet plane. Thus, knowing the magnetic properties of the steel sheets in all the directions is crucial for the design of the electric motors. However, the magnetic properties of non-oriented electrical steels are usually measured by standard Epstein frame method, which normally only gives the overall magnetic properties in the rolling and transverse directions, and the magnetic properties in other directions are usually not known. In this research, magnetic Barkhausen noise (MBN) technique is utilized to characterize the local magnetic response of the processed non-oriented electrical steel. By rotating the MBN sensor to all the directions in the sheet plane, the local magnetic responses are obtained. The measured MBN is then directly compared to the crystallographic texture (texture factor) measured in the same direction. In this way, the local magnetic response of the steel sheet can be correlated to the crystallographic texture. It was found that magnetic Barkhausen noise technique was able to detect the difference in magnetic response induced by magnetocrystalline anisotropy if the effect of the residual stress can be eliminated. This would provide a potential technique for the characterization of magnetic properties of non-oriented electrical steel. *I. Introduction and Methodology* Non-oriented electrical steel sheets used in electric motors are usually produced from cast ingots through a series of thermomechanical processing steps such as hot rolling, cold rolling, and annealing. The thin steel sheets are then punched and stacked to form the magnetic core, which is subsequently wound with wires around the radial teeth. To maximize the magnetic flux density and reduce the core loss, it is desired that the easy axes (<100> for iron) be aligned to the magnetization directions (i.e. along all the teeth in the magnetic core) [1]. This requires that the magnetic properties in all the directions of the rolled sheet be optimal and uniform. However, during thermomechanical processing, anisotropy in magnetic properties is inevitably induced, while the magnetic properties of non-oriented electrical steels are usually measured in the rolling and transverse directions only [2]. For the better design of electric motors, the magnetic properties of the steel sheets in all the directions should be known. In this paper, a relatively new technique, i.e. magnetic Barkhausen noise analysis, is utilized to characterize the local magnetic response of electrical steel sheet in all the directions of the sheet plane. The measured magnetic Barkhausen noise is then correlated to the crystallographic texture, which is one of the factors that affect the anisotropy of the material. *II. Material and Experimental procedure* The material used in this study is a non-oriented electrical steel containing 0.9 wt% Si. The steel was cast, hot rolled, annealed and cold rolled to sheets of 0.5 mm in thickness [3]. The thin sheets were then annealed at different temperatures to produce microstructures with various fractions of recrystallization. The textures of the steel sheets were measured by electron backscatter diffraction and the texture factor at all the directions was calculated based on the orientation distribution functions. The magnetic Barkhausen noise was measured in various angles (0°-360°) to the rolling direction, and the root mean square values of the MBN are directly compared to the texture factor in the same directions. *III. Results and discussion* The angular magnetic Barkhausen noise shows apparent anisotropy in various angles from the rolling direction, indicating differences in the magnetic response of the material and in magnetic properties. For samples after complete recrystallization, the angular MBN results correspond well with the texture factors measured in the same directions, while for partially recrystallized samples, the correspondence between the MBN and the texture factor is disrupted because of the existence of residual stress in the microstructure. *IV. Conclusion* Using MBN, it is able to characterize the local anisotropy of magnetic response of non-oriented electrical steel. By directly comparing the angular MBN results to the measured texture, it is able to explain the correspondence between the MBN signal and the easy magnetization axes of the steel. This would provide a potential method for the characterization of directional magnetic properties for magnetic cores.

Superelasticity is the shape memory property that has been most explored for commercial use. Its application is guided by the ability of SMAs to sustain large elastic strains at certain temperatures during use. The storage of large amount of energy when stress is applied accompanied by constant unloading of this stress is the basis for applications employing this property [1]. Applications of superelastic alloys includes guide wires, catheters, and stents to be used, for instance, in minimally invasive surgery such as endovascular peripheral surgery or neurosurgery. There is a strong demand to improve the maneuverability, reliability, and safety of these devices as well as to improve advantages over the NiTi alloy system through increase in superelastic properties [2]. Thus, Fe-based shape memory alloys have been developed since they offer relatively cheap alloying constituents and ease of fabrication and facilities for conventional steel making can be employed. These novel, intelligent, high-performance shape memory materials are expected to possess multifunctionality, fast response, smaller size, and reliability for application as integrated multifunctional sensing-actuating systems. Recently a FeNiCoAlTaB SMAs, which exhibits remarkable tensile superelastic strains higher than 13% at room temperature in the polycrystalline state and strengths of >1GPa, was reported by Tanaka et. al. [3]. In the attempt to reduce the steps involved in the thermo-mechanical processing of this materials, a cost effective technique, rapid quenching from the melt, has been reported by our group for the fabrication of these magnetic superelastic materials as wire-shaped materials [4]. We have reported up to 2% superelasticity in wire-shaped $Fe_{40.95}Ni_{28}Co_{17}Al_{11.5}Ta_{2.5}B_{0.05}$ materials with the diameter of about 200 micrometers which have been subjected to successive cold-drawing down to 50 micrometers and and ageing by thermal annealing at 800°C for one hour. In this work we report 5% superelasticity in rapidly quenched $Fe_{43.5}Ni_{28}Co_{17}Al_{11.5}$ microwires cold drawn 50 μm in diameter and subsequently annealed at 800°C for one hour. $Fe_{43.5}Ni_{28}Co_{17}Al_{11.5}$ microwires with the diameter of about 200 micrometers have been prepared by in rotating water quenching technique and subsequently subjected to successive cold-drawing down to 50 micrometers (aprox. 93% reduction of diameter) followed by annealing at 800°C for one hour. Scanning electron microscopy (SEM, Transmission Electron Microscopy (TEM), thermomagnetic, and magnetic measurements have been performed to assess the structural and magnetic differences between the cold-drawn as-cast samples and samples annealed at 800°C for one hour. The magnetic measurements have been performed using the PPMS and VSM. The SEM investigations revealed an amorphous-like structure in the as-cast state for 200μm which transforms into a polycrystalline structure with some elongated grains after cold-drawing, the grains increasing in number and size (up to micrometers) after subsequent annealing at 800°C for 1h. Thermomagnetic curve of as-cast microwire, presented in Figure 1, measured at low fields of 20 Oe present a maximum at 325°C which is abruptly decreasing until 370°C (Curie temperature of austenite phase). Within this temperature range the martensitic transformation takes place and it is also accompanied by a relaxation of the stresses induced during cold drawing, fact which is accordance with the results of the measurements of resistivity vs. temperature. When cooling the curve does not follow the same path, showing irreversible transformation. An increase in magnetization can be observed. In the case of annealed microwires, a more definite curie temperature has been observed indicating that the stresses have been released through annealing and the martensitic transformation took place. Superelastic tensile stresses (Figure 2) of up 5 % have been achieved in the annealed FeNiCoAl cold-drawn microwires. Potential uses of superelastic alloys also include miniature stents, catheters or guide wires in minimally invasive medicine due to their small dimensions.

The discovery of three-dimensional (3D) topological insulators (TIs) has triggered research activities for the physical properties of this new state of matter[1], and exploring its applications to spintronics and optoelectronics[2]. The most remarkable property of TIs is their topologically protected surfaces states characterized by a tight correlation between spin orientation and momentum, known as spin-momentum locking. The resulting spin texture has been mapped by spin- and angle-resolved photoemission spectroscopy (SR-ARPES)[3]. When the topological surface states (TSS) are hexagonally deformed (Fig. 1a), the spin texture acquires a momentum-dependent out-of-plane component[4]. This hexagonally warped helical spin texture, depicted in Fig. 1b, has been observed in various TI materials by SR-ARPES[5]. In addition to the optical methods, electrical detection of the spin-polarized TSS has been achieved with the use of ferromagnetic contacts as spin detectors[6]. However, only the in-plane spin component could be detected by this method. In this work, we report the observation of a new magneto-resistance effect in a single layer of nonmagnetic 3D TI Bi_2Se_3, which scales linearly with the applied electric current and magnetic field: we thus name it "bilinear magneto-electric resistance" (BMER)[7]. In contrast with other magneto-resistance effects in TIs, the BMER effect originates from a nonlinear spin current J_s (E^2) induced by the variation of electron distribution at the second order in the applied electric field E, δf_2, which, contrary to the electron distribution at the first order in E (δf_1), has equal signs for surface states of opposite momenta and spins. The nonlinear spin current is partially converted to a nonlinear charge current by the external magnetic field, giving rise to the BMER effect. Making use of the BMER effect, we demonstrate that a mapping between momentum-dependent spin textures and the angular dependence of the BMER can be established (Fig. 2), which enables transport measurements of the 3D spin texture in the TSS with hexagonal warping.

DC-02. Ultra-low-power spin-orbit-torque switching using the colossal spin Hall effect in BiSb topological insulator.

K.H. Nguyen[1], Y. Ueda[1] and N. Pham[1,2]
1. Electronic and Electrical Engineering, Tokyo Institute of Technology, Tokyo, Japan; 2. Center for Spintronics Research Network (CSRN), The University of Tokyo, Tokyo, Japan

Spin-orbit-torque (SOT) switching using the spin Hall effect (SHE) in heavy metals and topological insulators (TIs) has great potential for ultra-low power magnetoresistive random-access memory (MRAM). To be competitive with conventional spin-transfer-torque (STT) switching, a pure spin current source with large spin Hall angle ($\theta_{SH} > 1$) and high electrical conductivity ($\sigma > 10^5\ \Omega^{-1}m^{-1}$) is required. While heavy metals (such as Pt, Ta, and W) have high $\sigma > 10^5\ \Omega^{-1}m^{-1}$, their spin Hall effect is not strong enough ($\theta_{SH} \sim 0.08$-0.4) [1-4] for practical SOT-MRAM. In contrast, TI have been shown to have large $\theta_{SH} > 1$ at room temperature [5], but their $\sigma \sim 10^4\ \Omega^{-1}m^{-1}$ is low and thus not compatible to realistic SOT-MRAM. There is no spin Hall material so far that can satisfy both conditions simultaneously. Here, we demonstrate such a pure spin current source: BiSb narrow-gap topological thin films with $\sigma \sim 2.5\times10^5\ \Omega^{-1}m^{-1}$, $\theta_{SH} \sim 52$, and spin Hall conductivity $\sigma_{SH} \sim 1.3\times10^7\ (h/4\pi e)\ \Omega^{-1}m^{-1}$ at room temperature. We show that BiSb thin films can generate a colossal spin-orbit field of 2770 Oe/(MA/cm^2). In term of σ_{SH}, BiSb outperforms the nearest competitor (Pt) by a factor of 30, and other TIs by a factor of 100. Therefore, BiSb is the best candidate for the pure spin current source in ultra-low power SOT-MRAM [6]. To demonstrate SOT switching with ultra-low current density using the colossal spin Hall effect of BiSb, we prepare a 100 μm × 50 μm Hall bar of a $Bi_{0.9}Sb_{0.1}$ (5nm) / $Mn_{0.45}Ga_{0.55}$ (3nm) bi-layer. Figure 1(a) and 1(b) demonstrate the SOT switching of the MnGa layer when applying 100 ms pulse currents to the Hall bar and an in-plane H_{ext} = + 3.5 kOe and -3.5 kOe, respectively. We observed clear switching at an average critical current density of $J = 1.5\times10^6$ A/cm^2 ($J_{BiSb} = 1.1\times10^6$ A/cm^2). Here, the critical current density is defined at which the Hall resistance changes sign. Furthermore, the switching direction is reversed when the in-plane H_{ext} direction is reversed, consistent with the behavior of SOT switching. The observed critical current density is much smaller than those of Ta (5 nm) / MnGa (3 nm) ($J = 1.1\times10^8$ A/cm^2) [7], IrMn (4 nm) / MnGa (3 nm) ($J = 1.5\times10^8$ A/cm^2) [8], and Pt (2 nm) / MnGa (2.5 nm) ($J = 5.0\times10^7$ A/cm^2) [9]. Note that this low critical current density was observed even though the MnGa ferromagnet used in our bi-layer has higher perpendicular anisotropy energy $H_K^{eff} \approx 50$ kOe by one order of magnitude than those used in previous room-temperature SOT switching experiments in Bi_2Se_3 / CoTb [10] and Bi_xSe_{1-x} / CoFeB [11], double-checking the colossal spin Hall effect of BiSb. We estimate that the critical switching current for a BiSb-based SOT-MRAM with size of 37 nm and a 5 nm-thick BiSb layer as the spin current source was estimated only 2.2 μA, which is one order of magnitude smaller than that of STT-MRAM at the same size fabricated by the industries [12]. Therefore, the switching power can be reduced by at least one order of magnitude. Furthermore, since SOT-MRAM can be switched one order of magnitude faster than STT-MRAM, the switching energy can be reduced by at least two orders of magnitude. That means BiSb-based SOT-MRAM can be very competitive to even static random-access memory, and is the suitable ultra-low-power memory for internet-of-thing applications.

DC-03. Role of surface states in the generation of the colossal spin Hall effect in BiSb topological insulator.

K. Yao[1], T. Shirokura[1] and N. Pham[1,2]
1. Electrical&Electronic Engineering course, Tokyo Institute of Technology, Tokyo, Japan; 2. Center for Spintronics Research Network, The University of Tokyo, Tokyo, Japan

Spin-transfer-torque (STT) magnetoresistive random access memory (MRAM) is a non-volatile memory technology that is gaining steam in various applications with no idling power consumption, un-limited endurance, and fast read/write time. However, STT-MRAM still has some fundamental problems, such as large writing current as well as considerable asymmetry between the read and write current. Recently, spin-orbit-torque (SOT) switching using the spin Hall effect (SHE) in heavy metals [1,2] and topological insulators (TIs) [3,4] has attracted much attention as an alternative writing method for MRAM. SOT-MRAM can overcome the problems of STT-MRAM thanks to separated writing and reading path. For practical SOT-MRAM, a spin current source with large spin Hall angle θ_{SH} (>1) and sufficiently large electrical conductivity σ ($>10^5\Omega^{-1}m^{-1}$) is required to achieve efficient spin current generation. Heavy metals, such as Pt, Ta, and W have large σ, but their reported values of θ_{SH} are smaller than 1. Recently, giant SHE with θ_{SH} larger than 1 has been observed in several TIs [5,6], which are exotic materials with insulating bulk states and spin-momentum locking surface states. Since TIs are essentially insulators, σ of many of TIs is limited to $10^4\Omega^{-1}m^{-1}$, almost one order of of magnitude smaller than that of ferromagnets used in MRAM. Recently, we have shown that BiSb can have both giant SHE and σ. BiSb is a TI with very small band gap [7][8], thus it has much larger σ (σ~$2.5\times10^5\Omega^{-1}m^{-1}$) than other TIs [9]. Furthermore, colossal SHE with θ_{SH} ~ 52 has been observed in MnGa/BiSb(012) bi-layer at room temperature, and ultra-low current magnetization switching of MnGa using SHE of BiSb(012) has been demonstrated [10]. In this work, to explore the role of the surface states as well as the surface orientation in the generation of SHE, we have systematically investigated the spin Hall angle of BiSb as a function of temperature. Figure 1(a) shows the conduction model of BiSb, where carriers are transported through two surface states with conductivity σ_S, spin Hall angle θ_S and total thickness t_S, and bulk states with conductivity σ_B, spin Hall angle θ_B and total thickness t. The ratio between the surface conductance and the total conductance $\Gamma = \sigma_S t_S / (\sigma_S t_S + \sigma_B t)$ can be deduced from the temperature dependence of the conductivity of a single BiSb layer [11]. From the temperature dependence of Γ and θ_{SH}, we can deduce the role of the surface states in the generation of θ_{SH}. We have prepared a 50 nm-thick $Bi_{0.6}Sb_{0.4}$(001) / 4.7 nm-thick MnAs bi-layer on GaAs(111)A substrates by molecular beam epitaxy method. The sample was patterned into a 50 μm width Hall bar structure by photolithography and Ar ion milling. To evaluate θ_{SH}, we used the in-plane magnetization rotation technique [12]. Figure 1(b) shows our measurement setup, with I the applied dc current along the x axis, σ the unit vector of the spin polarization direction of the injected spin current, H_{ext} the in-plane rotating magnetic field, H_T the transverse field-like effective magnetic field, H_{SO} the perpendicular damping-like effective magnetic field, m the magnetization of MnAs, θ the angle between I and H_{ext}, and ϕ the angle between I and m. In our case, $H_T << H_{ext}$, thus $\phi = \theta$ and H_{SO} is proportional to cosθ. By measuring the Hall resistance R_H as a function of θ under various current density and temperature, we can deduce H_{SO} and θ_{SH}. Figure 1(c) shows representative $R_H(\theta)$ curves measured at 8 K with an applied current of +5mA (left) and – 5 mA (right). Blue circles and red solid lines correspond to measured data and fitting curves, respectively. Clear difference between them can be seen, reflecting the effect of H_{SO}. Figure 2(a) shows the temperature dependence of θ_{SH} and Γ. We observe that θ_{SH} increases much faster than Γ. At room temperature, θ_{SH} is 3 but becomes as large as 166 at 8 K. In Figure 2(b), we plot the nominal sheet spin Hall angle of the whole layer $q_{SH} = \theta_{SH}/t$, and the sheet spin Hall angle of the surface states $q_S = \theta_S/t_S$ as functions of temperature. We observed almost similar trend of q_{SH} and q_S, indicating the dominance of the surface state spin Hall effect in the generation of θ_{SH} in BiSb. The maximum q_S of BiSb(001) is $3.3nm^{-1}$ at 8K, which is smaller than that (q_S = $5.2nm^{-1}$) of BiSb(012) at room temperature. This indicates that the surface orientation is critical for observation of colossal SHE at room temperature.

DC-04. High spin-orbit torque efficiency of *in-situ* fabricated Bi_2Se_3/Fe heterostructures.

D. Zhu[1], Y. Wang[1], S. Shi[1], K. Teo[1], Y. Wu[1] and H. Yang[1]
1. Department of Electrical and Computer Engineering, National University of Singapore, Singapore

Due to the spin-momentum-locked topological surface states (TSS), three dimensional topological insulators (3D-TI) have attracted much attention for realizing highly efficient charge-spin interconversion and current induced magnetization switching in the adjacent ferromagnet (FM) layer [1-6]. Especially, extensive efforts have been devoted to evaluate the spin-orbit torque (SOT) efficiency in TI/FM heterostructures by using different techniques such as spin torque ferromagnetic resonance (ST-FMR) [1-3], second harmonic magnetometry [4], and spin pumping [5]. However, a large variation of the SOT efficiency values has been reported, even in the same TI material Bi_2Se_3. The different quality of the interface between Bi_2Se_3 and FM layers might be one important reason for the reported discrepancy of SOT efficiency in the Bi_2Se_3 due to the *ex-situ* deposition of the FM layer on top of TI or the involvement of capping/decapping processes for the Se protection layer. In this study, we employ an *in-situ* film growth of Bi_2Se_3/Fe heterostructures in a MBE system. We investigate the SOT efficiency of the Bi_2Se_3/Fe heterostructures by the ST-FMR technique. From conventional analysis of the ST-FMR spectra [2, 3, 7], the effective SOT efficiency $\theta_{||}$ has been obtained at different temperatures, as shown in Fig. 1. The $\theta_{||}$ is ~0.7 at 300 K, and it increases remarkably with decreasing the temperature and reaches ~5.1 at 15 K. Moreover, an *interface* SOT efficiency $\lambda_{TSS}= J_S/J_{C\text{-}TSS}$ is evaluated to extract the TSS originated SOT efficiency, where J_S is the spin current density (A/cm^2) with in-plane spin polarization at the Bi_2Se_3/Fe interface, and $J_{C\text{-}TSS}$ (A/cm) is the surface charge current density flowing in the TSS. The λ_{TSS} is determined to be ~1.53 nm^{-1} at 20 K. Both the $\theta_{||}$ of ~5.1 and λ_{TSS} of ~1.53 nm^{-1} are significantly enhanced as compared with those obtained from traditional *ex-situ* film deposition methods in Bi_2Se_3/FM heterostructures by ST-FMR measurements. The higher SOT efficiency we have obtained is attributed to the high quality interface and thus the enhanced interface spin transparency due to the *in-situ* fabrication and the low kinetic energy of Fe flux in the sample deposition process. Our *in-situ* deposition can reduce the contamination, degradation, and interdiffusion of the interface between the Bi_2Se_3 and Fe. Our results reveal that the interface can play an important role in the SOTs in TI/FM structures, and the interface engineering may serve as an effective pathway for exploring highly efficient TI based spintronic devices.

DC-05. Spin and charge conversion in topological surface states and oxide interface states.

W. Han[1]
1. International Center for Quantum Materials, Peking University, Beijing, China

Spin and charge conversion has attracted a lot of interest in the field of spintronics. Edelstein effect refers to spin current conversion from charge current flowing in inversion asymmetric two-dimensional electron gases (2DEGs) with large Rashba spin orbit coupling. In this talk, I will present the spin and charge conversion using the topological surface states and Rashba-split 2DEG. In the first one [1], I will describe our experimental results that demonstrate the spin injection and the inverse Edelstein effect in the spin-momentum locked surface states of a topological Kondo insulator, SmB_6 (Figure 1). I will also discuss the spin pumping efficiency between the topological surface states and a ferrimagnetic insulator due to interfacial s-d exchange interaction. In the second part of my talk, I will discuss the gate-tunable spin and charge conversion (Figure 2) at room temperature of the Rashba-split 2DEG between $SrTiO_3$ and $LaAlO_3$ via the inverse Edelstein effect [2]. These results are important for the generation and manipulation of the pure spin current for future spintronics applications.

We report the observation of spin-to-charge current conversion in strained mercury telluride at room temperature, using spin pumping experiments. The conversion rates are found to be very high, with inverse Edelstein lengths up to 2.0 +/- 0.5 nm. The influence of the HgTe layer thickness on the conversion efficiency has been studied, as well as the role of a HgCdTe barrier inserted in-between the HgTe and NiFe layers. These measurements, associated to the temperature dependence of the resistivity, allow ascribing these high conversion rates to the spin momentum locking property of HgTe surface states [1], promising electronic states for spintronics. Spintronics devices need efficient ways to transform charge current into spin current or to make the opposite conversion to detect spin current. Classical spintronics generally uses magnetic materials and exchange interaction. Such manipulation can also be achieved by harnessing the Spin Orbit Coupling (SOC) in non-magnetic materials. For instance, the Spin Hall Effect permits to convert charge currents into spin currents in the bulk of heavy metals, such as Pt or Ta [2]. Yet a more efficient conversion can be obtained in two dimensional electron gas (2DEG) at surfaces and interfaces such as Rashba Interfaces [3] and newly discovered topological insulator materials. The main interest of topological insulators lies in their surface states, which possess a linear Dirac-like dispersion, and a spin momentum locking as seen on figure 1. A flow of electric current in the 2DEG would cause a perpendicular spin accumulation. This effect is known as the Edelstein Effect [4], while the reverse spin-to charge-conversion effect is known as the Inverse Edelstein Effect (IEE). Recent results suggest that surfaces of topological insulators as Bi_2Se_3 [5] or strained α-Sn [6] have a strong potential for spintronics, both for the generation or detection of spin currents through direct or inverse Edelstein effects. Among these newly discovered class of material strained HgTe is a promising one. Gap opening and Topological insulator properties can be induced in HgTe by applying a tensile strain that can be achieved by epitaxy of HgTe on a substrate with a larger lattice constant, such as CdTe [7]. Moreover large mobility and mean free path has been reported. The spin to charge current conversion was studied in strained HgTe thin films by ferromagnetic resonance spin pumping in cavity as described on figure 2. The spin to charge current conversion rate, the inverse Edelstein length [8], was measured to be up to 2 nm, one to two orders of magnitude larger than in Bi-based topological insulators [9]. Such high conversion rate can be related to the large value of the mobility [10] and mean free path of the surface states of strained HgTe and the lower bulk to surface conductivity ratio at room temperature compared to Bi_2Se_3. Moreover the non-conventional thickness dependence of the conversion rate allows ascribing this conversion to the topological surface states.

DD-01. Neuromorphic computing with spintronic devices.

J. Grollier[1]
1. Unité Mixte CNRS/Thales, Palaiseau, France

Today, neural networks are everywhere: they are the virtual assistants in our smartphones, they are powering our search engines and they are the key to big data classification. They can even beat humans at image recognition or at strategy games such as Go. However neural networks are still running as software on our current computers, consuming tens of kilowatts and working rather slowly. In comparison, the brain from which they are inspired, operates with 20 W and can realize incredibly complex tasks in fractions of seconds. Building chips more closely inspired from the brain architecture is the path to cognitive computing at low energy cost. Applications of such chips span from embedded automatic pattern recognition for big data management, going through unmanned vehicle control to bio-medical prosthesis. The challenge of fabricating brain-inspired hardware relies in the ultra-high density networks that have to be built, out of complex processing units interlinked by tunable connections providing memory. Magnetic nanodevices can be a key technology in this context thanks to their ability to provide massive access to memory, their multiple and tunable functionalities, their non-linear dynamics and compatibility with CMOS [1]. In this talk I will give an overview of recent advances in the field of hardware brain-inspired computing. I will show how magnetic nanodevices can be used for brain-inspired computing, and discuss the working principle of neuromorphic models that can be implemented in Spintronics. Finally, I will show our first results of cognitive pattern recognition with magnetic oscillators [2,3].

Non-volatility of spintronic devices opens up possibility of implementation of Artificial Neural Networks (ANN) in hardware and thereby take advantage of the parallel architecture of the system similar to human brain [1,2,3]. Spin orbit torque driven domain wall based devices that act as synapse have been shown to be much more energy efficient than CMOS devices that implement neural networks [2,4]. Here, we have considered the role of defects in ferromagnetic layer and thereby proposed a spin orbit torque driven skyrmionic device, which consumes even lower energy compared to domain wall based device for synaptic behavior. We perform micromagnetic simulations on mumax3 [5] to demonstrate motion of Neel skyrmion and transverse Neel domain wall in a ferromagnet layer of thickness 1 nm, driven by spin orbit torque from current flowing through layer of heavy metal (Pt, spin Hall angle = 0.07) underneath [6,8,9]. We observe (as shown in Fig. 1a) that in the presence of triangular notch defects of 6 nm depth and modified anisotropy 1.2 MJ/m^3 (the magnet has uniform perpendicular anisotropy of 0.8 MJ/m^3 elsewhere) on the two edges of the magnet at a separation of 60 nm each, domain wall is pinned up to a current density of 24 MA/cm^2 through the heavy metal. But a skyrmion is depinned by current density as low as 1 MA/cm^2 though its velocity at such small current density is also very small [6,7]. Based on this result, we propose a skyrmionic device as shown in Fig. 1b, which can act as a synapse. A Magnetic Tunnel Junction (MTJ) structure is present at the right end of the device. Based on magnitude and duration of current pulse through heavy metal layer (applied between terminal T3 and T1) certain number of skyrmions moves to the region of the ferromagnet below the MTJ. Hence Tunneling Magneto-Resistance of MTJ measured between terminal T2 and T1 is a function of the current between T3 and T1 and corresponds to the weight of the synapse, which can be controlled by the current and stored subsequently since skyrmions won't move once current pulse is removed just like domain walls (Fig. 1b). The resistance vs current behavior of the skyrmionic synapse (Fig. 1c), obtained through micromagnetic simulations, shows that in the presence of defects a very small range of current (3.5 μA to 6.5 μA) can modulate the resistance from its lowest to highest value, corresponding to weight of synapse varying from -1 to 1. On the other hand a much larger range of current (-300 μA to 380 μA) is needed to do the same for domain wall based synapse proposed in Ref. 4 if defects are present. Next we solve the standard digit recognition problem (Fig. 2b) by simulating a feedforward neural network with backpropagation algorithm [10] (Fig. 2a) using the domain wall device (Ref. 4) or skyrmion based device (Fig. 1b) as synapses. A three layer feedforward network is trained to identify digits 0-4 across 10 computer generated variations for each digit, that mimic variations due to different handwriting. 35,000 iterations are needed to train the network and total number of synapses is 425. Error generated at the output layer after every iteration needs to be used to change the weights of all the synapses for subsequent iteration through the back-propagation algorithm. This is implemented by passing currents proportional to the generated error through the heavy metal layer of the synaptic devices (between terminal T3 and T1) and move the domain wall/ skyrmion to change the resistance of the MTJ (between T2 and T1) and thus change the weight value of the synapse.The energy dissipation due to this current flow in the heavy metal layer is called the "write" energy consumption, which is the most dominant energy contribution in the system. Fig. 2c is our key result which compares the total "write" energy consumption to train the network with synaptic devices being of the following four types: i. domain wall without defect (write current pulse width: 1 ns) ii. Skyrmion without defect (write pulse width: 15 ns) iii. Domain wall with defect (write pulse width: 0.5 ns) iv. Skyrmion with defect (write pulse width: 550 ns). We see that in the absence of defect, domain wall synapses consume less energy than skyrmion based synapses because domain wall moves faster than skyrmion for a given current density (Fig. 1a). But in presence of defects, since domain wall is pinned till current density of ~24 MA/cm^2 while skyrmions do not get pinned at current density even much smaller than that, if we "write" the skyrmion synapses with current pulses of very long duration (≥ 500 ns) and very small magnitude (3-6 μA) the skyrmion synapse based network can be trained at 2 orders of magnitude lower energy consumption than domain wall synapse based network. Thus in this paper we propose and simulate a skyrmion based synaptic device and show it to be much more energy efficient than domain wall based device. It will be particularly suitable for solving problems where time is not a major constraint.

Recently it has been demonstrated that binary neural network (BNNs) can achieve satisfying accuracy on various databases with the significant reduction of computation and memory resources [1], which provides a promising way for on-chip implementation of deep neural networks (DNNs). To storage synaptic weights, the SRAM is traditionally utilized in the CMOS based ASIC designs for hardware acceleration implementation of DNNs. However, it has been proved to be extremely area- and power-inefficiency due to its large cell area (>200F^2) and volatility, respectively. To overcome these issues, the emerging non-volatile spin transfer torque magnetoresistive RAM (STT-MRAM) with small cell area (<10F^2) recently has been proposed to implement synaptic weights instead of SRAM [2]. Moreover, STT-MRAM has been demonstrated at Gb chip-level by industry [3]. In this paper, a single-layer binary perceptron (BP) is proposed for image recognition, which can be implemented via the pseudo-crossbar array of 1T-1MTJ (STT-MRAM cell) as shown in Fig. 1(a). With the learning rule in [1], such BP was trained in an off-line manner on a set of N=30 patterns, including three stylized letters ('z', 'v', 'n') as shown in Fig. 1(b) [4], which also was used for testing. To classify these three stylized letters, we design a winner-takes-all (WTA) circuit as shown in Fig. 1(c), which is used as the peripheral inference circuit of proposed BP. Based on a physics-based STT-MTJ compact model and a commercial CMOS 40 nm design kit, the functionality of the proposed BP and WTA circuit have been demonstrated as shown in Fig. 2(a). Additionally, we also investigate the impact of TMR and device variations on the recognition rate as shown in Fig. 2(b) and Fig. 2(c), respectively. In summary, a STT-MRAM based binary synaptic array with a WTA circuit has been proposed for image recognition, which provides a promising solution for hardware implementation of BNNs on-chip.

Neuromorphic signal processing is one of the most promising post-von Neumann computational paradigms. Neuromorphic circuits mimic the brain functionality using artificial "neurons" and "synapses" and provide superior performance for cognitive tasks like, e.g., image or speech recognition. Currently, several commercial neuromorphic circuits built using conventional CMOS technology are available. However, the CMOS-based elements are better suited for digital logic operations than for analog nonlinear processing necessary for neuromorphic computing. Therefore, an intensive search for alternative neuromorphic elements is performed by many research groups worldwide. In particular, promising results demonstrating potential of spintronic spin-torque oscillators for neuromorphic computing have been recently reported [1]. In this work, we show that antiferromagnetic (AFM) spin Hall oscillators (SHO) [2, 3] can serve as ultrafast and energy efficient neuromorphic "neurons". The AFM neurons can operate at frequencies around 100 GHz, can be coupled in complex synchronized networks, can perform complex logical operations, and can have small power consumption about 1 μW per oscillator. The sketch of an AFM-based SHO is shown in Fig. 1(a). Similarly to ferromagnetic SHOs, the AFM oscillator is based on a bi-layer consisting of an active layer (AFM) and a heavy metal (e.g., Pt) layer which serves as a spin Hall polarizer. In the considered oscillator, the AFM material should have a bi-axial type of anisotropy (e.g., NiO) with the hard axis lying in the film plane [3]. In this geometry, the bias DC current creates a constant torque on the AFM sublattice magnetizations. When this spin-torque exceeds the restoring torque created by the in-plane AFM anisotropy (supercritical regime), the AFM magnetizations start to rotate with frequency proportional to the DC current [3]. The neuromorphic operation of the AFM SHO is achieved in the subcritical regime, when the DC bias current below the threshold current. Although the subcritical DC spin-torque is not sufficient to overcome the anisotropy energy barrier, it rotates the AFM magnetizations close to the direction of the maximum of the anisotropy energy (see Fig. 1(c)). In this state the AFM SHO is extremely sensitive to weak input signals, which can move the magnetizations over the energy barrier. Then, the AFM magnetizations will make one full rotation until they again stop near the energy maximum. During this rotation, the AFM generates an output spike due to the spin-pumping effect. It is important to note, that this AFM rotation is governed by the intrinsic ultra-fast AFM dynamics, and, therefore, the output spike is ultra-short (about 4 ps for NiO-based AFM oscillator), rather intense, and its characteristics are independent of the characteristics of the input signal. The output spike of the AFM SHO can be used to initiate other AFM-based neurons. Our simulations show, that the amplitude of the output spike and the coupling strength provided by a common Pt layer are sufficient to initiate a second AFM-based neuron, thus providing possibility for a multi-stage neuromorphic processing without any intermediate amplifiers. An example of such simulations is shown in Fig. 1(b), which shows the dynamics of 2 mutually coupled AFM SHOs. The first oscillator ("input", upper panel) was driven by an externally set sequence of pulses. The second oscillator ("output", lower panel) received input only from the 1st oscillator, and, in response, produced a completely synchronized sequence of spikes. By changing the amplitude of the DC bias current, it is possible to change the sensitivity of the AFM neuron, and to realize various logical gates (i.e., AND, OR, and MAJ) using just one AFM element. Inversion of the sign of the input signal (which can be done using the control "synapse" part of a neuromorphic circuit) further increases the set of possible operations performed by a single AFM neuron, and allows one to create rather sophisticated logical circuits with just a few elements. In particular, we demonstrate that a full adder can be realized with only 3 AFM oscillators. By employing two-way mutual coupling between the AFM oscillators, it is possible to go beyond standard logical functions, and create, for example, controllable memory loops. The simplest loop consists of 2 mutually coupled AFM neurons. When an input "write" signal is applied to the 1st neuron, it will initiate the 2nd one, which, in turn, will again initiate the 1st neuron, resulting in continuous generation of the spike sequence, which can be controllably terminated by external "erase" signal (see simulation results in Fig. 2). Finally, our estimations show that the minimal energy consumption of an AFM neuron, determined by the ohmic losses in the Pt layer, can be as low as 1 μW, and can be further reduced if more efficient spin Hall materials are used. Thus, the proposed AFM-based spin Hall oscillators look very promising candidates for the practical realization of ultra-fast and energy efficient artificial neurons in the future neuromorphic circuits.

DD-05. Domain wall based Mackey-Glass oscillator for neuromorphic applications.

J. Williame[1] and J. Kim[1]
1. Centre de Nanosciences et de Nanotechnologies, CNRS, Université Paris-Sud, Université Paris-Saclay, Orsay, France

Delayed feedback in dynamical systems, whereby the output signal of a system is sent back into its input with amplification and delay, can stabilize a system or, on the contrary, result in a variety of nonlinear behaviors [1]. One example of delayed feedback loop to stabilize a system are the phase lockings loops used to enhances the spectral properties of an oscillator [2]. You can also use time delayed feedback loops to control the chaos in some systems. On the other hand we can use such loops to increase the complexity and destabilize a system. As such one important consequence of delayed feedback is the possibility of inducing chaotic dynamics, even in low-dimensional systems. From a mathematical perspective, the delayed feedback expands the phase space of the dynamical system, which means that phenomena such as chaos can appear. We then can use chaos for various applications like chaos computing, chaos multiplexing for encryption, random number generation or neuromorphic applications like reservoir computing. In traditional reservoir computing we use a reservoir of many interconnected units called neurons to mimic the human brain and perform tasks like pattern recognition. The main problems to implement such reservoir is the large number of required neurons and connections. This is where the time delayed feedback loops come in. Indeed, it was demonstrated that we can use only one non-linear neuron with such loop to mimic an entire reservoir. A good canditate for such neuron is the Mackey-Glass oscillator [4], which is described by a first-order delay-differential equation and can exhibit a variety of different dynamical states, including limit-cycle and aperiodic states, and complex transients. Indeed, such a dynamical system has recently been implemented in an optoelectronic circuit to perform reservoir computing [3]. This optoelectronic circuit is very efficient and can perform spoken word recognition up to one million word per second but is not easy to implement in our everyday devices like smartphones and laptops. This is due to the intrinsically big optic part of this system which is very hard to scale down. Our approach to solve this problem is to use an already micro or nanoscale device as our non linear neuron. And because we know that a Mackey-Glass oscillator system can perform the pattern recognition we are looking for it makes sense to look for a device behaving like a Mackey-Glass. We then decided to use the oscillations of a pinned domain wall [5] as we believed it could exhibit a Mackey-Glass like behavior. In this work we simulated such domain wall with the opensource micromagnetic simulations software Mumax3 [6]. In the first part of our work we present the device we simulated and we demonstrate that its behavior is indeed very close to a Mackey-Glass oscillator. The system is a permalloy racetrack with an inverted notch on one side of the track in order to pin the domain wall. Thanks to the asymmetry the domain wall is strongly pinned to the notch side of the racetrack but can move relatively easily along the other side. We then have a diagonal wall anchored to the notch and with a slope changing with the injected current along the racetrack. In order to make the time delayed feedback loop we have to get an output. We assume the racetrack to be along the x axis and in the xy plane. The output we chose to use for the feedback is the average value of the magnetization along the y axis in the region just after the inverted notch, ie the area where our diagonal wall is, which is a value that could be measured experimentally with a proper device design. With the proper parameters for the racetrack dimensions and for the feedback loop we show that our device can have a transfer function very close to the one of a Mackey-Glass oscillator as shown in the first figure. In the second part of our work we explore the different dynamics our device can exhibit with a large array of feedback parameters. With the feedback we can modulate the amplitude of the wall oscillations or stop them. We can also induces near chaos oscillations which is interesting for pattern recognition since reservoir computing works better with neurons in a state at the edge of chaos. A example of this behavior is shown in the second figure. In this second part we will also see if our device is able to perform neuromorphic tasks like spoken digit recognition or chaotic number series prediction.

The most notable difference between neuromorphic system and conventional information processing system is their use of memory structures. Von Neumann architecture (conventional information processing system) have one (or more) central processing unit (CPU) which is separated from the main memory. Therefore, bottleneck of von Neumann architecture is given by memory-related constraints such as latency and bandwidth. The brain-inspired computing offers an attractive solution for implementing an alternative non von Neumann computing because biological (or bio-inspired, neuromorphic) system has a colocalized memory and computation. The synapses of (artificial) neural network act as memory storage and nonlinear operator at the same time for parallel computation. Restricted Boltzmann machines (RBMs) is a generative stochastic energy-based model of artificial neural network [1]. It has been introduced as bi-directionally connected networks of stochastic processing units as shown in following figure. The RBM has only connections between the layer of hidden (or latent) and visible (or observable) variables but not between two variables of the same layer. Spin-transfer torque magnetic random access memory (STT-MRAM) is one of the most promising nonvolatile memories with low power consumption. The binary information (high resistance or low resistance) is recorded in the magnetic state of nanomagnets via spin current. Magnetization reversal (switching) of STT-MRAM is a probabilistic process due to thermal fluctuations and the switching probability of STT-MRAM can be changed by applying an electric field because energy barrier of STT-MRAM can be modulated using an electric field [2]. In this work, we numerically demonstrated RBM composed of STT-MRAMs. By virtue of stochastic binary states and non-linearity of STT-MRAM, it is possible to build RBM without additional random number generator which cannot be easily achieved. We believe that our work is helpful to develop artificial neural network using emerging technology and would open the way for unexplored applications of STT-MTJs in robust, low power, cognitive-type systems.

DE-01. Role of thermal activation in the electrical switching of antiferromagnetic Mn_2Au and CuMnAs.

T. Matalla-Wagner[1], D. Graulich[1], M. Rath[1] and *M. Meinert*[1]
1. Faculty of Physics, Bielefeld University, Bielefeld, Germany

Electrical manipulation of antiferromagnets with specific symmetries offers the prospect of creating novel, antiferromagnetic spintronic devices [1]. Such devices aim to make use of the insensitivity to external magnetic fields and the ultrafast dynamics at the picosecond timescale intrinsic to antiferromagnets. The possibility to electrically switch antiferromagnets was first predicted for Mn_2Au [2] and then experimentally observed in tetragonal CuMnAs [3]. We report on the electrical switching of magnetron-sputtered films of Mn_2Au and CuMnAs. The switching in Mn_2Au is observed in simple Hall-cross structures with a parallel pulsing scheme, see Fig. 1. An exponential dependenc of the switching amplitude on the current density is observed and a saturating behaviour with pulse widths approaching 1ms is seen. We analyze the switching with a macroscopic stochastic switching model and propose an analytical expression for the critical curent density required to switch the Néel vector in the presence of thermal activation. Furthermore, an expression for the switching amplitude is derived in the linear response regime. A kinetic Monte Carlo technique is applied to simulate the switching and quantitative agreement between experiments and model calculations is obtained, see Fig. 2. It is found that the switching is thermally assisted by the Joule heating of the current pulses, which facilitates the switching of Mn2Au. The model analysis shows that the electrically set magnetization state of Mn_2Au is long-term stable at room temperature ($\Delta = E_B / k_BT = 64$), paving the way for practical applications in memory devices [4]. We estimate the spin-orbit torque efficiency as 0.4 ... 1.05 mT / (10^{11} A/m^2), in reasonable agreement with the prediction by Zelezny et al. [2]. In the case of CuMnAs, we find a notable dependence of the switching amplitude per pulse on the temperature, with a pronounced peak around 260K. This is similar to usually observed distributions of the blocking temperature in exchange-coupled antiferromagnet / ferromagnet systems, which are related to the grain size distribution in the antiferromagnets [5]. The switching is observed even in films with rather poor crystalline quality and does not seem to rely on excellent crystal quality. Similar switching behaviour as compared to Mn_2Au is observed, however at much smaller current densities and in agreement with the previously reported switching in epitaxial CuMnAs [3].

The spin current transport has been extensively studied in the conductive materials, in which spin current is carried by the itinerant electrons. It has been recently shown that spin current can pass through or even be amplified with a layer of the antiferromagnetic (AF) insulator NiO inserted between a ferromagnet (FM) and a heavy metal [1-5]. In this case, there is no itinerant electron in the NiO layer due to its insulating nature. It has been suggested that the spin current is conducted through NiO via the thermally excited AF magnons [2,4,6]. Thus it is of importance to experimentally prove the spin transmission thru the NiO layer. Furthermore, a highly efficient SOT driven magnetization switching at room temperature has been recently demonstrated in topological insulators (TIs)/FM bilayer [7,8], in which the switching efficiency is about two orders of magnitude larger than that in heavy metals. However, current shunting is an unavoidable issue in the TI/FM bilayer due to the higher resistance of TI than FM layer. To solve this issue, we propose to insert an AF insulator NiO between the TI and FM layers, by which we can confine the flow of charge current within only TI layer, and the spin currents generated in TI can still be transmitted through the NiO layer and reach the FM layer. In this study, we show that the spin current is carried thru a moderately thick NiO layer by using spin-torque ferromagnetic resonance (ST-FMR) measurements in the Bi_2Se_3 (8 nm)/NiO (t_{NiO} = 0–17.5 nm)/NiFe (6 nm) structures at room temperature as shown in Fig. 1(a). The SOT efficiency ($\theta_{\|}$) as a function of NiO thickness is plotted in Fig. 1(b). It is observed that $\theta_{\|}$ abrupt decreases from ~0.9 to ~0.18 with only a 2-nm NiO insertion layer. As t_{NiO} increases above 10 nm, an enhancement of SOT efficiency to ~0.5 ($t_{NiO} \geq 14$ nm) is observed. Our results reveals that the AF magnons may carry the spin currents in thicker NiO layers. In addition, we achieve the SOT-induced magnetization switching, imaged by a magneto-optic Kerr effect (MOKE) microscope, in the Bi_2Se_3/NiO/NiFe heterostructures with t_{NiO} up to 17.5 nm at room temperature by injecting a pulsed dc current. We find J_C in the thicker NiO region ($t_{NiO} \geq 12$ nm) is about 2 times larger than that in the region of $t_{NiO} \leq 2$ nm. Further, no full magnetization switching can be achieved as 2 nm < t_{NiO} < 12 nm. This is in line with the results in Fig. 1(b). Moreover, we find that the switching efficiency (η) for $t_{NiO} \geq 12$ nm is ~6 times higher than that for $t_{NiO} \leq 2$ nm. Here, η is defined as $M_s t\alpha(H_c + M_{eff}/2)/J_C$, where M_s, t, α, H_c and M_{eff} are the saturation magnetization, thickness, damping constant, coercivity field and effective magnetization of NiFe layer, respectively. We have successfully demonstrated SOT induced magnetization switching in Bi_2Se_3/NiO/NiFe by utlilizing the spin transport in an AF insulator, which might pave the way for high performance TI based magnetic devices.

Metallic antiferromagnets are taking an increasingly critical role in research of spintronics due to their high conductivity, strong exchange bias and large spin-orbit torques (SOT). Zhang *et al* have shown that the spin Hall angle (SHA), which is believed to be positively related to SOT, of alloys of Mn is comparable to Pt [1]. Among other antiferromagnetic alloys, IrMn is an appealing medium to study SOT in metallic antiferromagnets because of its well-defined crystallographic phases and the correspondingly unique magnetic configurations. In 2016, Zhang *et al* demonstrated that the SHA of $L1_2$-$IrMn_3$ can be as large as 0.35 [2]. Moreover, IrMn could be a promising material for applications of spintronics. Tapping on the merits of exchange bias and SOT in IrMn, Oh *et al* observed field-free switching in a bilayer structure of IrMn/CoFeB, taking a big step towards low-energy spintronics [3]. Currently the mechanisms of SOT in IrMn are yet well understood. In addition, there exists a gap between empirically observed SOT and theoretical frameworks. Past reports were frequently based on polycrystalline IrMn thin films but the models relate to the long-range structural or magnetic orders of IrMn. Keep these in mind, this work will demonstrate that the SHA of epitaxially deposited $L1_0$-IrMn shows an unprecedented high value of 0.7, in sharp contrast to its polycrystalline counterpart. Thin film stacks of IrMn(25)/Permalloy(Py)(20)/SiO_2(2), from left to right, were deposited using DC magnetron sputtering. Numbers in the brackets indicate thickness in nanometers. The layer of IrMn was deposited at high temperature while Py and SiO_2 were deposited at room temperature. The films was subject to X-ray diffraction (XRD) measurement to characterize the crystallographic structure of IrMn. The thin film stack was then patterned to micro bars with a combination of photolithography and ion-beam etching. The patterned device was subject to spin-torque ferromagnetic resonance (STFMR) measurement: a microwave was applied along the long axis of the micro bar and an external magnetic field was swept parallel to the sample plane at 45 degrees with the microwave. Using methods presented in ref. [4], the measured rectifying voltage was fitted against external field to extract the SHA. Fig. 1 shows the two-theta scan of the epitaxially deposited $L1_0$-IrMn. The $L1_0$ phase was further verified using reciprocal lattice space mapping. Fig. 2 (a) shows the typical STFMR measurement results and the quality of fitting. The collected data points are well fitted with symmetric and anti-symmetric components clearly separated. Fig. 2 (b) shows the calculated SHA for $L1_0$-IrMn, which is approximately around 0.7 over the microwave frequency range of 8-12 GHz. The error bars reflect the spread of 5 devices on the same sample.

DE-04. Spin-Hall and Anisotropic Magnetoresistance effects in Layered Structures with Ferrimagnetic Co-Gd alloys.

T. Seki[1], W. Zhou[1], T. Kubota[1] and K. Takanashi[1]
1. Tohoku University, Sendai, Japan

Introduction: Antiferromagnetic spintronics is an emerging research field and has attracted much attention because of the unique properties of antiferromagnets: zero net magnetization and small magnetic susceptibility that enable us to develop the ultrahigh density magnetic memory devices. Also antiferromagnets exhibit the high speed magnetization dynamics compared with those for ferromagnets used in the conventional spintronic devices. Recent studies demonstrated that the flow of spin angular momentum, *i.e.* spin current (J_s) was generated from the antiferromagnet and J_s also interacts with the magnetic moments of antiferromagnet [Ref. 1]. However, the detailed mechanism of the interaction between J_s and the antiferromagnetic structure has not fully been understood yet. We consider that the ferrimagnetic Co-Gd amorphous alloys, in which the Co and Gd moments (m^{Co} and m^{Gd}) are coupled antiferromagnetically, are a promising system for the systematic investigation of the interaction between J_s and the antiferromagnetic structure. Since the net magnetic moment of Co-Gd (m^{Co-Gd}) is given by $| m^{Co} - m^{Gd} |$, which of m^{Co} or m^{Gd} is dominant for m^{Co-Gd} strongly depends on the composition of Co-Gd. In addition, the compensated ferrimagnet is obtained at the Co-Gd composition showing $m^{Co} = m^{Gd}$. The ferrimagnetic structure at the compensation point is similar to an antiferromagnetic structure from the viewpoint of zero net magnetization. Recently, several studies reported the interaction between J_s and local spins of Co-Gd or Gd-Fe-Co near the compensation points [Ref. 2,3]. In this study, we investigated the composition dependence of spin-Hall magnetoresistance (SMR) for the in-plane magnetized $Co_{100-x}Gd_x$ amorphous alloys sandwiched by the Cr and Pt layers. In addition to the SMR, we also measured the composition dependence of anisotropic magnetoresistance (AMR) of the Cr / $Co_{100-x}Gd_x$ / Pt layers, and we found the different composition dependences of SMR and AMR. Experimental Results: Thin films were deposited on a thermally oxidized Si substrate using a magnetron sputtering system. First, a 4 nm-thick Cr buffer was deposited on the Si-O substrate. Then, Co and Gd were co-deposited to form $Co_{100-x}Gd_x$ layers with a thickness of 30 nm. Finally, a 4nm-thick Pt layer was deposited. All the layers were deposited at room temperature. By tuning the sputtering powers of Co and Gd targets, the Gd concentration was widely varied from $x = 0$ to $x = 45$. Except $x = 0$ corresponding to the pure Co, all the Co-Gd layers were amorphous alloys. The top Pt layer serves as not only the capping layer to prevent the Co-Gd from oxidation, but also the layer generating transverse J_s from the charge current (J_c) via the spin-Hall effect owing to its large spin-orbit coupling. Magnetic properties were measured using a superconducting quantum interference device magnetometer and a longitudinal magneto-optical Kerr effect (L-MOKE) equipment with a laser wavelength of 680 nm. The *M-H* curves showed the magnetization (M) was changed with x. As x was increased from 12 to 37, the local minimum of M appeared at $x = 25$. In contrast to the M - H curves, the L-MOKE loops showed the gradual decrease in the magnitude of Kerr rotation angle with x. A remarkable point observed in the L-MOKE loops was that the sign of Kerr rotation angle reversed at $x = 25$. In other words, the discontinuous change in the Kerr rotation angle versus x was observed at $x = 25$. These experimental facts indicate that the compensation point (composition) of the present Co-Gd exists around x = 25. The composition dependence of AMR showed the sign change from positive to negative as x was increased, and zero AMR was observed near the compensation composition. It is well known that the pure Co shows the positive AMR while the pure Gd showed the negative AMR. Our experimental result suggests that both *d*-electrons of Co and Gd contribute the magnitude of AMR. We consider that the AMR disappears when the positive AMR from Co and the negative AMR from Gd cancel each other. On the other hand, the non-zero SMR was obtained even when the AMR became almost zero. Our experimental results clearly indicate the different scattering mechanisms for AMR and SMR. In contrast to the AMR effect based on the *s-d* scattering in the bulk, SMR depends on other parameters such as spin mixing conductance at the interface that do not play an important role for the AMR effect. That is a possible reason for the different composition dependences between SMR and AMR. Consequently, our experimental results and findings using the ferrimagnetic Co-Gd alloys are useful and important to reveal the underlying physics of SMR and AMR.

DE-05. Spin-orbit torque in antiferromagnets.

C. Song[1], X. Zhou[1], X. Chen[1], P. Zhang[1], G. Shi[1] and F. Pan[1]
1. Department of Materials Science and Engineering, Tsinghua University, Beijing, China

Antiferromagnets with zero net magnetic moment, strong anti-interference and ultrafast switching speed have potential competitiveness in high-density information storage [1,2]. Electrical switching of antiferromagnets is at the heart of device application [3]. We will present our recent progress in the current-driven magnetization switching through spin-orbit torque (SOT) in three antiferromagnetic systems, including Mn_2Au, and [Co/Pd]/Ru/[Co/Pd] synthetic antiferromagnets (SAF). Body centered tetragonal antiferromagnet Mn_2Au with opposite spin sub-lattices is a unique metallic material for Néel-order spin-orbit torque (SOT) switching. The SOT switching in quasi-epitaxial (103), (101) and (204) Mn_2Au films prepared by a simple magnetron sputtering method will be discussed. We demonstrate current induced antiferromagnetic moment switching in all the prepared Mn_2Au films by a short current pulse at room temperature, whereas different orientated films exhibit distinguished switching characters. A direction-independent reversible switching is attained in Mn_2Au (103) films due to negligible magnetocrystalline anisotropy energy, while for Mn_2Au (101) and (204) films, the switching is invertible with the current applied along the in-plane easy axis and its vertical axis, but becomes attenuated seriously during initially switching circles when the current is applied along hard axis, because of the existence of magnetocrystalline anisotropy energy [4]. SAF were proposed to replace ferromagnets in magnetic memory devices to reduce the stray field, increase the storage density and improve the thermal stability. We will discuss the SOT in a perpendicularly magnetized Pt/[Co/Pd]/Ru/[Co/Pd] SAF structure, which exhibits completely compensated magnetization and a high exchange coupling field of 2200 Oe. The magnetizations of two Co/Pd layers can be switched by spin-orbit torque between two antiparallel states simultaneously. The magnetization switching can be read out due to much stronger spin-orbit coupling at bottom Pt/[Co/Pd] interface compared to its upper counterpart without Pt. Both experimental and theoretical analyses unravel that the torque efficiency of antiferromagnetic coupled stacks is significantly higher than the ferromagnetic counterpart, which conquers the exchange coupling field, leading to the critical switching current of SAF comparable to the ferromagnetic coupled one [5,6]. Besides the fundamental significance, the efficient switching of antiferromagnets by current would advance magnetic memory devices with high density, high speed and low power consumption.

Department of Mathematical and Computer Science, Physical Sciences and Earth Sciences, University of Messina, Messina, Italy

In the last decades, the research in spintronics has mainly concentrated on ferromagnetic materials, which respond to the different kinds of spin-transfer torques with gigahertz-frequency dynamics [1-3]. A jump to higher-frequency devices, working in the range of terahertz, is promised by the use of antiferromagnets (AFM) [4-6]. AFM materials will, probably, be in the research spotlight in the near future. In order to study their behavior, however, a new theoretical approach is needed, which, for instance, has to account for the strong internal exchange field in AFMs, for the absence of macroscopic magnetization, and possibility to operate without an external bias field. When it comes to modeling, AFMs are generally studied by considering the magnetizations M_1 and M_2 of the two sublattices. Dynamics of M_1 and M_2 is ruled by two coupled Landau-Lifshitz-Gilbert equations [6]. In this work, we model micromagnetically an antiferromagnetic spin-Hall oscillator (ASHO). This device consists of an AFM layer coupled to a layer of a heavy metal, as sketched in Fig. 1, where a coordinate system *x-y-z* is also shown. The AFM layer is square-shaped, with dimensions 40x40 nm^2, whereas the dimension along *z*, namely its thickness *d*, varies from 1 to 5 nm. The heavy metal is designed with 4 terminals that can be used to apply a charge current, and/or to read the device resistance [7]. According to the well-known spin-Hall effect, when a current is applied (in our case in the plane *x-y*), it creates a spin polarization in the heavy metal. The consequent spin current, flowing along the *z* direction, creates a spin accumulation at the interface with the AFM, and, therefore, a torque on the AFM. The direction of the spin-Hall polarization p is perpendicular to the plane of the charge and spin currents, namely, if the charge current is applied along the axis *x* and the spin current is along the axis *z*, the spin polarization is along the axis *y* [2,7]. The spin-Hall-driven torque, therefore, acts on the magnetizations M_1 and M_2 of the two AFM sublattices in the same direction, thus allowing dynamics with a non-zero net magnetization. We investigate this dynamics, solving the equations of motion for the two sublattices by means of a custom-developed micromagnetic code. The following parameters are used in our simulations: saturation magnetization M_S=350x10^3 A/m, spin-Hall angle θ_{SH}=0.10. The exchange constant *A* is a variable parameter in our simulations, and assumes the values of 0.5, 1.0 and 1.5x10^{11} J/m. Similarly, the Gilbert damping constant α is set equal to 0.01, 0.05 and 0.1. The AFM is assumed to have the in-plane anisotropy along the *x* direction, the corresponding constant is K_u=10^5 J/m^3, and simulations start from the equilibrium AFM configuration of M_1 and M_2 along the easy axis, shown in Fig. 1. Last, but not least, the current is applied differently at the terminals, in order to modify the direction of the spin-Hall polarization with respect to the easy axis *x*. We consider three cases: (i) current at the terminals A-A' along *x* direction (p along *y*), (ii) current at the terminals B-B' along -*y* direction (p along *x* axis), and (iii) current at both A-A' and B-B' with equal intensity (p is directed 45° w.r.t. to x and y axes). By means of this configuration, it is, therefore, possible to manage the direction of the spin-Hall polarization with respect to the AFM easy axis, simply by tuning the two currents at the two couples of terminals. The above described systematic study has provided important data on the behavior of an AFM under the action of the spin-Hall effect. Dynamics of magnetization is excited above a certain threshold current. However, the same dynamics is turned off at the lower values of the driving current, highlighting a clear hysteretic behavior of the excitation. The values of the threshold currents and the width of the hysteresis region depend on different parameters. For instance, the threshold current increases with the increase of the AFM thickness, or the damping, or the exchange constant. When the polarization is moved from the axis *y* to the AFM easy axis, the threshold current slightly increases, and to get the excitation of dynamics we need to include a small thermal field. Above the threshold, the magnetizations of the two AFM sublattices show a precession around the spin-polarization direction, as shown in the inset of Fig. 2. The net magnetization is, mainly, given by the sum of the components of M_1 and M_2 along the spin polarization p, whereas the other two components give almost zero contribution when the sum of M_1 and M_2 is evaluated. The frequency of the net magnetization dynamics shows a blue-shift with the increase of the applied current (see the example in Fig. 2). The values of the generated frequency are from hundreds of GHz up to several THz, as expected. The hysteretic excitation, the blue-shift of the frequency, the order of threshold current, and of output frequencies confirm the predictions of the previous analytical studies [6], and confirm the validity of our numerical approach.

Spintronic nano-oscillators [1, 2] are now considered as promising nano-scale AC signal sources for the future energy-efficient electronics. However, nowadays such sources mainly utilize ferromagnetic materials (FM), and, therefore, their operation frequencies are limited to the interval of 1–50 GHz [1, 2], which is not sufficiently high for many practical applications. To substantially increase the frequency of the spintronic AC signal sources one could use antiferromagnets (AFMs), where characteristic operation frequencies, typically, lie in the terahertz range (0.1–10 THz) [3-5]. The theoretically proposed AFM-based nano-oscillators can operate in the absence of a bias dc magnetic field, and can be driven by a dc electric current [6-8]. However, the problem of a practical development of AFM-based AC signal generators, and, in particular, the problem of a power extraction from such AFM generators, has not been solved yet. In [7] an AFM-based spin Hall oscillator (SHO), where the power of the generated AC signal is extracted through the inverse spin-Hall effect (ISHE), has been proposed. The other power extraction mechanism, based on the reception of the magneto-dipolar radiation from a current-driven canted AFM attached to the high-Q resonator has been analyzed in [8]. Both these methods of the THz-frequency signal extraction have some disadvantages: for an SHO utilizing ISHE the AFM material must be bi-anisotopic with a weak perpendicular anisotropy [7], while in the case of a canted AFM embedded in a resonator, the device has a large size (~ 10 μm) defined by the wavelength of the generated signal [8]. In this paper we consider an alternative mechanism of the THz-frequency signal extraction from an AFM-based SHO, where the signal power is collected through the AC variation of the tunneling anisotropic magnetoresistance (TAMR) in an AFM tunnel junction (ATJ), the electrical switching of which has been experimentally observed in the recent works [9, 10]. We consider an AFM SHO based on an IrMn/Pt bilayer structure, where the driving dc current I_{drive} flowing in the Pt layer forces a flow of a spin current I_{SH} into the AFM layer. This spin current excites the rotation of magnetizations of the IrMn AFM sublattices through the spin-Hall effect (SHE) [5], which gives rise to the AC variations of the TAMR [10]. Thus the junction resistance changes in time as $R(t) = R_0 + \Delta R \sin(\omega t)$ (Fig. 1). At the same time, the simultaneously supplied bias dc current I_{dc}, traversing the junction cross-section, results in the generation of the AC voltage of the magnitude $U_{ac} = I_{dc}\Delta R$ across the whole structure. Thus, when such a dc biased ATJ is connected through a bias tee to a load, having the resistance of $R_L = 50\ \Omega$, the AC voltage generated in the ATJ excites an AC current in the load, allows one to extract an AC power P_L of the excited signal from the load. Our theoretical model of the proposed AC source based on an ATJ is very simple. We consider an ATJ as a circuit consisting of an AC voltage source (generating AC voltage of the magnitude U_{ac}) with the internal resistance R_0 shunted by a capacitor of the capacitance C. This equivalent circuit is connected through an ideal bias tee to a resistive load of the resistance R_L. Using Kirchhoff's laws, we found the following expressions for the powers: $P_{dc} = I_{dc}^2 R_0$ is the dc power injected in the ATJ, $P_L = (R_L U_{ac}^2)/[2(R_L + R_0)^2 + R_L^2\beta^2)]$ is the power emitted in the load, where $\beta = \omega R_0 C$. Then, the efficiency of the AC power extraction can be estimated as $\zeta = P_L/P_{dc}$. The frequency dependences of the P_L and ζ, calculated for a junction having experimental parameters (resistance-area product, tunnel magneto-resistance ratio, etc.) taken from [10], are shown in Fig. 2. They demonstrate that both these characteristics are decreasing with the increase of the generated frequency. The calculations also demonstrated, that the output power P_L, injected into the load in the frequency range 0.1 – 1 THz, is comparable to, or may even exceed, the power extracted via ISHE and magneto-dipole emission mechanism, while the efficiency of the power extraction mechanism via AC TAMR variations is about 1%, which may be sufficient for some practical applications. Also, it should be noted, that a substantial advantage of the proposed AFM-based AC signal source with signal extraction through TAMR lies in the simplicity and reliability of its experimental realization at micro- and nano-scale. In conclusion, we proposed a method of the AC signal extraction from an ATJ-based SHO based on TAMR, which can be easily experimentally realized at micro- and nano-scale, and can provide an output AC power of the order of $P_L \sim 10\ \mu W$ and an efficiency of about 1%.

DE-08. Injection-locking of a nonlinear sub-THz antiferromagnetic spin-Hall oscillator.

R. Khymyn[1], V.S. Tiberkevich[2], A.N. Slavin[2] and J. Åkerman[1,3]

We demonstrate theoretically that a spin-Hall oscillator (SHO) based on a thin layer of an antiferromagnetic (AFM) material can be effectively phase-locked to a driving ac electrical signal at both the fundamental frequency, and the frequencies of higher harmonics. The latter phenomenon is a direct consequence of the strongly nonlinear dynamics of the AFM SHO. The nano-oscillators based on the spin transfer torque (STNO) and spin-Hall (SHO) effects are of a considerable interest for modern spintronics as tunable generators of microwave signals. For practical applications, a critically important property is the ability of oscillators to synchronize to the external driving signal and with each other. The STNOs and SHOs have hitherto been based on ferromagnetic materials, and their generation and synchronization properties, are relatively well-known. Recently, however, it was proposed to use AFM materials as active layers of SHOs, because the strong internal exchange field in AFMs allows one to achieve generation frequencies belonging to the THz range [1-4]. In an AFM-based SHO, the spin current created by the spin-Hall effect (SHE) in adjacent current-driven heavy metal layer induces a torque on the Neel vector l of the AFM. If the spin polarization of the current p is *perpendicular* to the equilibrium orientation of the Neel vector l_0, the Neel vector starts to rotate in the plane perpendicular to p [1,3]. The extraction of the ac signal caused by this rotation using the inverse SHE (ISHE) is, however, nontrivial, because it requires that the rotation of the Neel vector is non-uniform in time. Several approaches were proposed to solve this problem [2-4], for instance, it was shown in Ref. [3], that the non-uniform rotation of the Neel vector could be achieved in AFM materials with bi-axial type of anisotropy (e.g., NiO). The generation of the ac signal starts when the spin transfer torque caused by the SHE overcomes the energy barrier caused by the anisotropy-induced potential. This competition determines the critical (threshold) value of the electric current density j_{th} in the adjacent layer of a heavy metal [3]. At low values of the supercriticality $\xi = j_{dc} - j_{th}$ the AFM dynamics is strongly *nonlinear*, which is reflected in the nonlinear dependence of the generation frequency $f(j_{dc})$ on the applied current j_{dc} (see dashed line on Fig. 1). This makes our AFM SHO a fundamentally nonlinear oscillator. The injection-locking of an AFM SHO to an external ac signal in the *linear* region of $f(j_{dc})$ dependence has been studied in Ref. [5] for the case when dc and ac spin currents acting on the AFM layer have orthogonal polarization. In the current work, we are focused on the *nonlinear* dynamics of the oscillator, and we are interested in the case when both dc and ac components of the spin current have the same polarization (i.e., when the ac component of the electrical current with the carrier frequency f_{ac} is directly mixed with the dc current, $j(t) = j_{dc} + j_{ac}\sin(2\pi f_{ac} t)$), which is much easier to realize experimentally. To investigate the synchronization properties of an AFM SHO we solve a set of two coupled Landau-Lifshitz equations for each magnetization sublattice of the AFM with the parameters typical for the nickel oxide. The generation frequency of an SHO driven by the ac with f_{ac}=0.3 THz as a function of j_{dc} is shown on Fig. 1 by a solid line. As one can see from the comparison with the free-running SHO (j_{ac}=0, dashed line in Fig. 1), this dependence exhibits a series of flat plateaus, which correspond to the injection-locking to the external signal. The plateaus are observable when the frequency of the free-running SHO is close to integer divisors of the frequency of the driving signal - f/f_{ac}=1,1/2,1/3... We also observe a narrow synchronization regions for other rational numbers, e.g. 2/3, 4/5. Therefore, the nonlinear AFM SHO can be effectively synchronized not only at the fundamental frequency, but also at the frequencies of higher harmonics. We investigated the maximum detuning frequency of the injection-locked SHO, i.e. the synchronization bandwidth, for the fundamental frequency, and for the second harmonic. The corresponding plots for f_{ac}=0.3 THz are shown in Fig. 2. Both synchronization bandwidths are approximately linear functions of the amplitude of the driving ac signal j_{ac}, and can reach values of several GHz for reasonable current amplitudes j_{ac}. Unexpectedly, it turned out, that the synchronization bandwith for the second harmonic is *higher* than for the fundamental frequency, which can be explained by a strongly nonlinear behavior of the AFM SHO in the region of small generation frequencies f. These results show, that an AFM SHOs operating in the nonlinear regime can be efficiently phase-locked to an external current, and can be used for the detection and frequency conversion of sub-THz external signals.

DF-01. Thermally induced magnetisation switching: basic physics and potential for a new storage technology.

R.F. Evans[1], T. Ostler[3], O. Chubykalo-Fesenko[2] and *R.W. Chantrell*[1]

Ultrafast magnetisation processes are generally observed as a response of the magnetisation to a femtosecond laser pulse. This pump-probe technique uses a high power pump pulse to excite the system with a low power (probe) beam split off and used, after a time delay, to measure the magnetic state via MOKE. Since the pioneering demonstration of ultrafast demagnetization in Ni [1], the field has produced a series of remarkable discoveries, including that of magnetization reversal driven by circularly polarized light [2] giving rise to the intriguing concept of all-optical magnetic recording on the picosecond timescale. We have investigated the physics of this phenomenon using an atomistic model as described by Evans et.al. [3]. This approach models the dynamic response at the atomic scale using Langevin Dynamics, with the interatomic exchange based on the Heisenberg form. It was shown [4] that all-optical reversal was achieved due to the elevated temperatures achieved in the pulsed laser process, which accessed the so-called 'linear' reversal mechanism capable of switching on the sub-picosecond timescale. Linear reversal is a high-temperature phenomenon where reversal proceeds via magnetisation collapse to a highly non-uniform state and is not accessible to conventional micromagnetic models. Linear reversal is important in the ultrafast processes because it accesses the longitudinal relaxation time of a few hundred fs around 2 orders of magnitude faster than conventional precessional switching. We will firstly outline the physics of these processes, leading to the discovery of Thermally Induced Magnetisation Switching (TIMS) [5] in ferrimagnets, in which magnetization switching occurs in the absence of an externally applied field. This effect is shown to arise from the excitation of a 2-magnon bound state, which is responsible for the transfer of angular momentum between sublattices. This gives rise to a transient ferromagnetic-like state which drives magnetization reversal. The basic requirements for TIMS are antiferromagnetically coupled sublattices or layers, with differential relaxation times. Formation of the transient ferromagnetic-like state and the subsequent thermally induced switching can be interpreted as arising from a large effective field due to the strong inter-sublattice exchange. In terms of recording technology this field has considerable significance since it has been shown [6] that basic thermodynamic considerations lead to the requirement of fields larger than those accessible to conventional inductive switching in order to avoid errors due to thermally induced back switching. The implications of TIMS for future magnetic storage devices is considerable, in terms of the reduction in complexity of write transducers, increased data rate and power reduction. Until recently, such magnetisation switching could only be triggered by ultrafast laser pulses. Arguably, a recent paper [7] has brought the technology closer by demonstrating TIMS using ultrafast (non-polarised) current pulses, potentially accessible to CMOS technology. The results suggest that relatively slow current pulses are required, which will be discussed in terms of the atomistic model approach. We will finally consider potential recording densities and the materials required for their realisation.

DF-02. Micromagnetics at Finite Temperature.

D. Wei[1]
1. School of Materials Science and Engineering, Tsinghua University, Beijing, China

Micromagnetics include two main parts: "magnetization curve theory" and "domain theory" [1]. In 1935, the Landau-Lifshitz equations were brought up to analyze the domain wall motion [2]. Since the early works by Brown Jr. in 1960s, micromagnetics had considerable progress in 1980s, including the utilization of the Landau-Lifshitz-Gilbert (LLG) equations to calculate the thin film's magnetization curve [3], and the establishment of the Finite-Difference-Method Fast-Fourier-Transform (FDM-FFT) micromagnetics to highly speed up the computation of the most time consuming magnetostatic interactions among total number N micromagnetic cells [4]. Recent developments of computational magnetism require the ability to calculate the magnetics at finite temperature [5], to calculate domains at large scales, i.e. three-dimensional micromagnetics at finite temperature are the target for the development of computational magnetics. In 2016, the author and collaborators developed a new micromagnetic method based on the Hybrid Monte Carlo (HMC) algorithm, which can calculate M-H loops and domains at finite temperature below Curie point [6], after two years' testing in explaining experiments, and in the characteristics of computational costs, it is found that the simulations using the HMC micromagnetics method can explain M-H loops and domains from 0K to the Curie temperature, even with superparamagnetic properties calculated. It costs roughly $O(N)$ computational time with a faster convergence time than the conventional Landau-Lifshitz equations. The Hybrid Monte Carlo method is a numerical simulation method used extensively in lattice field theory community which is capable of generating a Boltzmann-like distribution of the form $e^{-S[\Phi]}$, where Φ denotes the collection of all degrees of freedom of the system and $S[\Phi]$ is known as the Euclidean action (energy) of the system. The way to perform this simulation is to mimic what Nature does for the molecules in the air. For our purpose, the field variables Φ are just all magnetization vectors $\{M_i\}$ for various micromagnetic cells and the action $S[\Phi]$ is replaced by $F[\{M_i\}]$--the Landau magnetic free energy divided by k_BT. In the micromagnetic simulation, the ferromagnetic material is discretized into a regular mesh, similar as the FDM-FFT method. The Hamiltonian for the HMC algorithm is given by Eq. (2) in Ref. [6], where V_c is the volume of a micromagnetic cell, M_i is the magnetization vector in the ith cell and Π_i is the corresponding conjugate momentum, two of which forming a conjugate pair similar to that of coordinate and momentum in mechanics. The equation of motion for the system is Hamilton equations Eq. (3) in Ref. [6] for the magnetization vector M_i and the corresponding conjugate momentum Π_i. The whole simulation time is divided into trajectories. In each trajectory, this set of Hamilton equations will be utilized to generate the configurations of $\{M_i\}$ versus Monte Carlo time τ according to Eq. (2); at the end of the trajectory, a Monte-Carlo judgment is performed (if the total energy is lower than that at the beginning of the trajectory, the new configuration is accepted, if the total energy is higher than that at the beginning of the trajectory, the new configuration is accepted with a probability $e^{-\Delta E/kT}$), finally at a certain temperature T the equilibrated distribution $e^{-F[\{Mi\}]/kT}$ can be achieved. The expression for the effective field H^i_{eff}, as we will see below, is quite similar to the effective field in traditional micromagnetic models using LL equations, except for terms related to the newly added constraint potential to confine the magnitude of M_i near a sphere $|M_i|$=Ms(T). The magnetic free energy is Eq. (4)-(9) in Ref. [6], where the anisotropy energy and the constraint potential form a double-well potential that usually appears in the Landau's second-order phase transition theory, with $\{M_i\}$ as the order parameter. For a $(40nm)^3$ magnetic cube with 8*8*8 micromagnetic cells, the simulation result is unchanged at a chosen K for λ=bK in the shaded area, as seen in Fig.1. HMC micromagnetic method can also be utilized to study non-equilibrium problems such as time-dependent coercivity. If we compare the simulated $M_i(t)$ versus the Sharrock's law, we can determine that a trajectory ($\tau=10^{-3}$) in the HMC algorithm roughly equals to t=1 ns in the real time scale [7]. We cooperate with NIMS Japan [8] to study the M-H loops of FePt-C media at different temperature. It is found that the power η for $K(T)/K(0)=[Ms(T)/Ms(0)]^{\eta}$ has correlation to the alloys, in FePt-C media η is around 2.5, the calculated magnetization loops at temperatures 300K, 400K, 500K, 600K agree well with the experimental results; at 700K, no experimental M-H loops are measured because the magnetic signal is so weak comparing with the noise, but using HMC micromagnetics, the superparamagnetic properties can be simulated. This confirms the validity of the HMC micromagnetic method in the polycrystalline thin film.

Heat assisted magnetic recording (HAMR) is a new technology which uses temporary near field laser heating of the media during write to increase hard disk drive storage density. By using plasmonic antenna embedded in the write head, an extremely high thermal gradient is created in the recording media (up to 10K/nm). State of the art HAMR media consists of grains of $L1_0$-FePt exhibiting high perpendicular anisotropy separated by 1 to 2 nm thick carbon segregant. Next to the plasmonic antenna, the difference of temperature between two nanosized FePt grains in the media can reach 80K across the 2 nm thick grain boundary. This represents a gigantic local thermal gradient of 40K/nm across a carbon tunnel barrier. In the field of spincaloritronics, much weaker thermal gradient of ~1K/nm was shown to cause a thermal spin-transfer torque capable of inducing magnetization switching in a magnetic tunnel junction. Considering on one hand that two neighboring grains separated by an insulating grain boundary in a HAMR medium can be viewed as a magnetic tunnel junction and on the other hand that the thermal gradients in HAMR are one to two orders of magnitude larger than those used in conventional spincaloritronics, one may expect a strong impact from these thermal spin-transfer torques on magnetization switching dynamics in HAMR recording. This issue has been overlooked in the previous investigations on the development of HAMR technology. This study combines theory, experiments aiming at determining the polarization of tunneling electrons across the media grain boundaries and micromagnetic simulations of recording process taking into account these thermal gradients. It is shown that the thermal in-plane torque can have a detrimental impact on the recording performances by favoring antiparallel magnetic alignment between neighboring grains during the media cooling. Implications on media design are discussed in order to overcome the influence of these thermal torques. Suggestions of spincaloritronics experiments taking advantage of these huge thermal gradients produced by plasmonic antenna will also be given.

Written-in transition jitter is the dominant source of media noise in Heat Assisted Magnetic Recording (HAMR) systems. The down-track thermal gradient observed in the media is believed to be one of the key contributors to transition quality. In general, this gradient is defined as the change in temperature in the downtrack direction in the vicinity of the write position. This write position, and consequently the thermal gradient, is determined by media properties such as anisotropy field and Curie temperature, as well as the magnitude of the applied magnetic field from the head. The thermal gradient also depends on the near field transducer (NFT): its geometry, its material properties, and its interaction with the media and heat sink. Recently, a reliable estimation of the down-track thermal gradient has been obtained via the laser current modulation [1],[2],[3] method. In this method, the laser current is modulated during the recording of a single tone pattern. By changing the laser power, the size of the thermal spot changes thereby changing the location of the transition. This minor shift in position is related to the change of temperature near the transition, namely the thermal gradient. By measuring the shift in transition position and knowing the amplitude of the laser power modulation, the thermal gradient can be calculated. This study elucidates the effect of recording conditions, such as relative head to media velocity, on this measurement by comparing single tone patterns captured from a drive and a spin-stand to micromagnetically modeled patterns. Dynamic recording system models have had much success in predicting phenomena observed at spin-stand and drive [4] via common performance metrics such as transition and remanence SNR. However, this is the first effort to use a laser current modulation method in a micromagnetic model in order to directly compare to thermal gradient measured experimentally. Figure 1 compares measured and modeled downtrack thermal gradient as a function of relative head to media velocity under different laser power and writer current conditions. At spin-stand, the thermal gradient is characterized using the side band ratio (SBR) method described in reference [1]. A single tone pattern is recorded with laser power modulation. This modulation produces a phase modulation of the signal, resulting in sidebands in the signal frequency spectrum. The transition displacement, and by association the thermal gradient, can be calculated from the amplitude of these sidebands. Measurements are captured at zero skew, a radius of 23 mm and an active clearance of 1 nm. Simulated data is obtained using a micromagnetic model that employs the renormalized Landau Liftshitz Gilbert equation [5] to represent high temperature magnetization dynamics. The media and magnetic writer/NFT configurations used are consistent with the designs used in the experiment. The peak spot temperature in the model is chosen such that the track widths obtained are similar to those measured. In the model, like in the measurement, a single tone pattern is recorded with modulated peak laser temperature. The change in phase of the signal due to this modulation is extracted using a Hilbert transform. The shift in the transition is calculated from phase jump at the location of the laser temperature step .This shift was then used to calculate the thermal gradient. In the data set shown in figure 1(a), the laser power is kept constant at each head velocity and writer current condition. This means that the track width, and therefore the signal, will change with changing velocity. As the velocity increases there is less time for grains to switch, meaning that writing occurs at a higher temperature than when the velocity is low. The thermal gradient decreases near the peak temperature of the hot spot, accounting for the decrease observed in both the spin-stand and the model. Figure 1(b) shows measurement and modeling results where the track width is kept constant at each head velocity and writer current condition by varying the laser power. As velocity increases, the maximum thermal spot temperature must be increased to compensate for the decreased time grains experience the effect of the heat spot. Since the write temperature increases with velocity to maintain the track width, and the maximum thermal spot temperature increases at each velocity condition, the effective thermal gradient at the write point tends to remain constant. The spin-stand data also shows increasing thermal gradient with increasing write current. This is a reasonable observation, given that increasing the write current produces an increasing applied magnetic field, as long as the write pole is far away from saturation. This in turn results in a lower write temperature and a higher thermal gradient, since the gradient is higher further away from the peak temperature. Given that the model accurately describes the effects of recording conditions such as laser power, writer fields and head to media velocities on thermal gradient, the effect of skew and thermal spot properties can be explored in depth.

DF-05. Understanding of Different Noises in HAMR.

Y. Jiao[1] and R.H. Victora[1]
1. Electrical and Computer Engineering, University of Minnesota, Minneapolis, MN, United States

I. INTRODUCTION AND METHODS As Perpendicular Magnetic Recording (PMR) technology reaches its areal density limit, the commercial introduction of Heat-Assisted Magnetic Recording (HAMR) [1], considered to be the most promising candidate to push areal density forward to 4 Tb/in^2, becomes more imminent. However, as the areal density increases, concerns about noise become more important. In Seagate's recent presentation [2], remanence noise appears to be a very important factor for HAMR's jitter, unlike the case of PMR. In this work, we try to understand the different contributions to noise in HAMR, especially the remanence noise and transition noise. Then we discuss how they will affect the performance of HAMR. II. NOISE DEFINATION AND CALCULATION Separation of the different types of noise from the playback signal can be a difficult and arbitrary task. When bit length is large and uniform (tone), a simple division based on distance to the transition can suffice. Seagate has introduced a technique [3] that splits the noise into transition and remanence components for a more realistic bit length and pseudo-random bit sequence. It is based on the general understanding that transition noise always exists around the transition region, while remanence noise exists all over the media and should be independent of the patterns recorded on the media. However, when bit length is small, it is a challenge to apply this method because it is difficult to unambiguously define a transition region so as to get an appropriate window function. Instead, we propose principle components analysis (PCA) [4], which is a statistical method based on signal variances, with these two assumptions: 1. δSignal > δNoise_rem > δNoise_trans. δSignal means the standard deviation of original signals without any noise; δNoise_rem means the standard deviation of remanence noise and δNoise_trans means standard deviation of transition noise. It is obvious that signals have the largest fluctuations, so the first components in the new coordinate system should describe signals, and then comes the remanence noise, and finally transition noise. This is because the standard deviation of transition noise is non-zero only near the transition region. 2. All three parts in the playback signals should comply with linear superposition, which means that they can be added directly together. Here, we show simulated [5] data for eight repetitions of the recorded signal on different media samples for a minimum bit length of 25.5 nm with 20-m/s head-moving velocity and 5.5-nm grain pitch. We use Singular Value Decomposition (SVD) to determine eight principal components of the playback signals. The sorted eigenvalues are shown in Figure 1. It is found that the first eigenvalue is much larger than the other seven after doing PCA, which means the signals have the largest variance in playback signals. Then we choose the first R principal components (columns) of the left singular matrix to reconstruct signals. Figure 2 shows the reproduced signals after we did PCA with different values of R. In Figure 2(a), we show only signal components with little noise when R = 1. When R = 4 (Figure 2(b)), we can see larger fluctuations among the reproduced signals, especially in the vicinity of peaks and valleys. These fluctuations are considered to be remanence noise. When R = 8 (Figure 2(c)), all eight components were counted to reproduce playback signals and these signals are exactly the same as our original playback signals.

DG-01. Design and analysis of an integrated electromagnetic energy harvester from water flow.

T. Wang[1], Y. Zhang[1] and S. Zhu[1]
1. Zhejiang University, Zhoushan, China

1. Introduction Energy harvesting is an attractive technique for a wide variety of wireless network sensors and nodes, which have strong demand for being battery free. Hydrokinetic energy is a remarkable energy source which comes in two forms, vertical in waves and horizontal in currents and tides. This work focuses on harvesting the kinetic energy from water flow with relatively low velocity in oceans or rivers for remote sensors and robots. A direct idea is the miniaturization of conventional blade water turbine and electrical generator. However, this energy harvester usually has large volume because the independent turbine and generator are required to be coupled coaxially or by using gearbox. Moreover, the relatively high viscous drag on the blades at low Reynolds numbers may deteriorate the generation performance. In this work, an electromagnetic energy harvester is designed and analyzed by using Tesla disk turbines which have the advantages of easy manufacture, low noise, and no blades. In addition, axial-flux permanent magnet generation technique is applied to make the machine compact. 2. Schematic Figure 1 presents the schematic diagrams of the cylindrical electromagnetic energy harvester on radial and axial cross sections respectively. The turbine rotor mainly consists of a series of disks installed with uniform gaps on a shaft which is supported by a pair of bearings. Permanent magnets with alternative axial magnetization direction are mounted on the end surfaces of the turbine rotor, and coils are fixed in the end caps correspondingly. The permanent magnets and the coils form a miniature axial-flux permanent magnet generator. A ring cover with symmetrical grooves is fixed on the outer of the energy harvester so as to convert water flow with random direction to the direction almost tangential to the disks. The physical process of flow energy harvesting is illustrated as follows. When the electromagnetic energy harvester is located in regions with horizontal water flow, an amount of water will flow into the gaps between disks through the grooves of the ring cover. Then viscous drag force will be generated to drive the turbine rotor as well as the attached permanent magnets to rotate according to Newton viscous law, which results in periodic variation of the flux through the coils. Based on electromagnetic induction theory, electromotive forces will be induced in the coils and current will be generated when the coils are connected with electrical loads. 3. Analytical model In the ironless axial-flux permanent magnet generator, the magnetic field is mainly produced by a series of cubical permanent magnets distributed axial symmetrically. Therefore, the flux density in three-dimensional coordinate can be derived as a function of position based on Coulombian model and rotation transformation. Then the flux through a coil turn can be calculated by integrating the flux density over the corresponding area, and the total flux through the coil can be obtained as a sum of the flux through every turn at the specific location. According to the law of electromagnetic induction, the induced electromotive force can be derived by calculating the derivative of the coil flux with respect to time. Assuming a resistive load is connected, the output voltage and power can also be expressed. 4. Prototype and test A prototype is fabricated by using plastic material and 3D printing technique with precision of 0.1 mm. It has diameter of 6.5 cm, height of 4.6 cm, and approximate weight of 140 g. In the turbine rotor, there are 8 disks with diameter of 5.2 cm and thickness of 0.15 cm, and the adjacent disks are separated by sleeves with thickness of 0.15 cm. The number of rectangular NdFeB permanent magnets on each end surface is 12 and the dimension is 1.0 cm × 0.5 cm × 0.3 cm. The coils are wound by using copper wires with diameter of 0.1 mm, and the turn number per coil is about 200. There are total 8 grooves set in the ring cover. An experimental setup is developed to test the prototype and verify the analytical model. No-load experiments show that the prototype can operate at flow velocity down to 0.61 m/s and induce peak-to-peak electromotive force of 2.64~11.92 V at flow velocity of 0.61~1.87 m/s. Figure 2 presents the comparison between the measured waveform and the analytical waveform of the induced electromotive force at the rotating speed of about 500 rpm. It can be observed that the two waveforms are in good accordance. Loaded experiments show that the output electrical power is 23.1 mW at flow velocity of 1.87 m/s when the load resistance is approximately equal to the coil resistance. 5. Conclusion In conclusion, an integrated electromagnetic energy harvester is designed and analyzed for remote sensors and robots in oceans or rivers. The compact structure is beneficial to integrate with remote wireless electronic devices such as autonomous oceanographic sampling networks. Experimental results validate the effectiveness of the analytical model and the harvesting capability of the energy harvester for water flow with relatively low velocity.

DG-02. Investigation of a Novel Dual-PM Partitioned-primary Hybrid-excited Flux-switching Linear Machine.

Z. Zeng[1] and *Q. Lu*[1]
1. College of Electrical Engineering, Zhejiang University, Hangzhou, China

Introduction: Hybrid-excited flux-switching linear machine (HEFSLM) has become a research hotspot due to the merits of high thrust force density, wide operation area, robust secondary, etc. Recently, several topologies have been proposed [1], [2], but all these structures accommodate excitation winding, armature winding and PMs on the primary, which makes the primary crowded. Consequently, both flux-adjusting ratio and thrust force density may be confined. In order to solve the aforementioned contradiction, this paper proposes a novel dual-PM partitioned-primary HEFSLM (PP-HEFSLM) featuring dual-PM and dual-primary structure, thus excitation windings and armature windings are separately amounted in corresponding slot areas [3-5]. Since these two kind slots are increased simultaneously, both thrust force performance and speed-adjusting area can be improved effectively. Topology and Optimization: Fig. 1(a) shows the topology of conventional 6-slot/11-pole (6s/11p) E-core HEFSLM. Fig. 1(b) shows the topology of the proposed 6s/7p dual-PM PP-HEFSLM. Apparently, the former HEFSLM makes the excitation windings, armature windings and PMs located in the single-primary, thus the areas of excitation slots and armature slots are limited. However, to latter HEFSLM, the primary is partitioned into two separated parts with excitation slots aligned to PM I. PM I is sandwiched between two U-shaped steel lamination, while PM II is inset in the excitation teeth. The magnetization direction of PM I and PM II are parallel and perpendicular to moving direction respectively. Moreover, to make armature flux-linkage caused by PM I and PM II have same polarity, the magnetization direction of two adjacent PM II and their middle PM I should be clockwise or anti-clockwise. The operation principle of the proposed HEFSLM is similar to the E-core HEFSLM, that is to say, based on flux-switching mechanism. Along with a secondary-pitch movement, the armature coil flux changes an electrical circle, so brushless AC operation is suitable for the proposed machine. Its feasible slot/pole combinations can be 6s/4p, 6s/5p, 6s/7p and 6s/8p, among which 6s/5p and 6s/7p structures exhibit larger winding coefficient. To E-core counterpart, the corresponding values are 6s/11p and 6s/13p. Therefore, these two HEFSLMs with their own two suitable slot/pole combinations are globally optimized for maximal average thrust force based on genetic algorithm under fixed armature copper loss 30 W, maximal excitation current density 15 A/mm^2, and identical volume for an unbiased comparison. It is found that 6s/7p and 6s/11p are the optimal slot/pole combinations for PP-HEFSLM and E-core HEFSLM, respectively. Comparative Investigation: For the globally optimized 6s/7p PP-HEFSLM and 6s/11p E-core HEFSLM, the electromagnetic performances are comparatively investigated. The PP-HEFSLM exhibits 13.27% larger fundamental back-EMF amplitude and smaller harmonics as shown in Fig. 1(c), and *d*-axis flux-linkage of PP-HEFSLM can be adjusted from 75.38% to 116.66%, while it is only 91.64% to 112.35% for E-core one as shown in Fig.1(d). Apparently, PP-HEFSLM greatly improves both back-EMF waveform and flux-adjusting capability. The thrust force performances and loss curves are shown in Fig.2 (a)-(d). As it can be seen, the PP-HEFSLM exhibits relatively big average thrust force especially at heavy load, while E-core one seems to be more easily saturated. At zero *d*-axis current control method, it also exhibits bigger average thrust force and maximal average thrust force, which indicates its reluctance force can be negligible. In addition, due to double-sided PM structure, its normal force is very low compared with that of E-core structure, which greatly simplifies installment and simultaneously avoids uneven airgap caused by big normal force. Along with the increasing of velocity, the losses of both structures drastically increase due to the increased electrical frequency, but this phenomenon is more evident for E-core structure and the loss is also larger at same velocity because of larger secondary pole number. Conclusion: This paper proposes a novel dual-PM PP-HEFSLM. Its optimal slot/pole combination is investigated, and then the electromagnetic performances are calculated. By comparing with corresponding optimal E-core structure, the results show the proposed machine exhibits better thrust force performance, wider flux-adjusting range, greatly reduced normal force and smaller loss. Detailed descriptions will be given in the full paper.

DG-03. A novel two-degree-of-freedom electromagnetic vibration energy harvester: design, modeling and experiments.

Z. Wang[1], S. Wu[1], T. Yao[2], D. Lv[1] and H. Zhang[1]
1. State Key Laboratory of Reliability and Intelligence of Electrical Equipment, Hebei University of Technology, Tianjin Municipality, China; 2. School of Mechanical Engineering, Hebei University of Technology, Tianjin Municipality, China

1. Introduction With the rapid development of Internet of Things(IoT) technology, a large number of microprocessors, sensors and other small power electronic devices are widely used, inexhaustible vibration energy often exist in the working environment of these electronic devices. If the vibration energy is collected, the power supply problem of these electronic devices can be solved. Green vibration energy harvesting technology can not only greatly reduce the battery consumption, but also help to extend the working time of electronic devices. This technology has received much attention over the past few years. The traditional single-degree-of-freedom vibration energy harvester has low electromechanical conversion efficiency which hinders the engineering application of this technology. A novel vibration energy harvester that has linear motion part and rotary motion part is proposed to improve the electromechanical conversion efficiency. The harvester can be modelled as a two-degree-of-freedom (TDOF) mechanical system containing linear springs and rigid pendulum. The system response can be calculated based on the derived model for a given excitation. The maximum electromechanical conversion can be obtained by parametric resonance analysis. The output electromotive force (EMF) can be calculated by Faraday Law, and the magnetic field is solved by Finite Element Method and the TDOF model. A prototype is fabricated accordingly, and is tested on the vehicle running on the urban road. 2. Mathematical analysis The proposed vibration energy harvester is shown in Figure 1. The device mainly consists of a shell, two springs, two wheels, a pendulum and coils. The wheels move left and right under the vibration excitation applied on the shell, and then the mover swings accordingly. The flux of the coils varies with the relative motion between the coils and the permanent magnets inside the mover. The EMF can be generated in the coils. And part of the vibration energy can be conversed into electrical energy by supplying power to load. The Lagrange theorem is applied to analyze the proposed model with given displacement excitation. If the mass of pendulum is omitted, the system kinetic energy can be expressed by the mass of all parts and the length of the pendulum. Potential energy depends on the stiffness of the spring and the location of the mover. Further more, the system TDOF motion differential equation is deduced. 3. Simulation and Test The vibration energy harvester, contain 4 cylindrical permanent magnets and 8 coils with 300 turns each, are simulated in the follow. In general, our test results show that the vibration frequency focus on about 20Hz on the condition of the vehicle is running on the urban road. Therefore, $X(t)=10\sin(40\pi t)$ mm is set as the vibration excitation. The wheels' displacement x (Figure.2(a)) and the swing angle of pendulum θ (Figure.2(b)) can be calculated. Figure.2(a) shows the maximum x is about 35mm, which is nearly 3.5 times greater than that of the X. That means the proposed harvester can amplify the vibration. Figure.2(b) shows the maximum θ is up to 60 degrees. The output EMF (Figure.2(c)) can be calculated on the basis of θ and magnetic field distribution which analyzed by finite element method. As shown in Figure.2(c), the peak-to-peak value and the effective value of the output EMF are 13.02V and 3.59V, respectively. The average output power is 344.65mW under impedance matching conditions. The prototype is designed and fabricated on the basis of simulation analysis. The coils are made of copper enameled wire coil. And permanent magnets are NdFeB with grade N35. The prototype is tested in the vehicle running on the urban road. This work was supported in part by the National Natural Science Foundation of China under Grant No. 51107030 and 51775166, in part by the Hebei Province Foundation for Recruiting Returned Scholars under Grant No. CL201708

DG-04. A planar translational permanent magnet generator for an inertial wave energy converter.

M. Trapanese[1]
1. DEIM, Palermo University, Palermo, Italy

Amongst renewable energy sources, sea wave energy is definitely the less developed. Wave energy converter technology is still at an immature stage. This is probably caused by two reasons: i) the strong technical novelties that are required to extract the energy that is contained in a highly and stochastically variable motion; ii) the difficulty to find a suitable electrical system able to convert the energy contained in the motion of the sea into electrical energy. Several approaches to harvest sea wave energy have been proposed; almost all of them introduce a mechanical conversion device between the waves and the electromagnetic generator. This stage converts the mechanical energy contained in the motion modes of the converter placed on the waves (heave, sway, surge, yaw, pitch and roll) into a more usable mechanical energy; it may be a hydraulic coupling device or a mechanical gear and, in any case, introduces additional losses, weakness in the reliability of the system and additional maintenance requirements. In order to solve these issues a generator directly coupled to the sea waves entirely contained in a vessel has been proposed. These systems are known as Inertial Wave Energy Converter and up to know they have been designed to exploit only one motion mode of the wave converter. The most proposed solutions are linear generators for heave motion in point absorber technology and rotating generator coupled to a fly wheel for rolling motion mode. This paper presents a permanent magnet planar translational generator able to exploit more motion modes of the mechanical converter coupled to the waves. Linear electrical generator has been recently studied for the exploitation of sea wave energy [1-2] but, to our best knowledge, no planar translational generator has been proposed. In this paper in order to maximize the energy extraction all the motion modes of the waves have been considered and included in the mathematical model of the system. The principle of operation of the generator can be summarized as follows: the moving part (translator) of the generator is driven from the sea waves and induces and emf on the winding mounted on the armature. The movement of the translator is two dimensional and therefore all the movement modes of the wave, but heave motion, can be exploited. The mathematical model includes the dynamic equations of the moving part of the generator and the electric equations of the windings. The coupling parameters (inductances, fluxes etc.) have been determined by a FEM analysis (which includes a careful analysis of the boundary conditions, because of the fact that the machine is working in a conductive medium). The design has been optimized by including in the mathematical model used for the optimization the following aspects: 1. the dynamic and stochastic features of the waves; 2. a dynamic model of the mechanical system; 3. a parametric circuit model of the magnetic circuit as well as of the electric windings; 4. A circuit model of the power electronics converter used to connect the generator to the utility. The main innovation of the optimisation approach proposed is that the speed of the machine is neither supposed known nor supposed fixed, but the stochastic features of the imposed movement are the factors that mostly influence the optimisation process. The optimization has been performed by finding the maximum of an objective function that has been built on the basis of the mathematical model developed. The variables of the function were related to the magnetic circuit of the converter, the parameters to the stochastic features of the waves as well as to the characteristics of the hydraulic system and of the power electronics converter. The results show several maxima that indicate several possible alternative designs. In order to verify the results, a reconfigurable machine has been built and tested in laboratory. The tests have verified the value of the emf, of the magnetic induction as well as of the power production in several configuration of the machine. In a scaled down version of the machine, it has been possible to generate almost 10 watt and to reach an output voltage of 25 V peak to peak. These values were in agreement with the design values within an error of 15%.

DG-05. Ultra small and thin energy-harvesting device based on electromagnetic induction.

K. Morii[1] and S. Koganezawa[2]
1. Kansai University Graduate School, Suita-shi, Japan; 2. Kansai University, Suita-shi, Japan

1. Introduction Energy harvesting devices (EHDs), which generate a small amount of electric power from energy sources in the environment, are expected to be power sources for Internet-of-Things (IoT) devices or wearable electronic devices to realize a high-grade sensor-network society. Many EHDs suitable for various applications have been reported so far and are being developed. In this study, we propose a novel EHD with an extremely small and thin structure. A potential application of the proposed EHD is its installation in the soles of shoes to generate electric power by the repeated loading and unloading of weight during walking to drive health-monitoring sensors. Such an application requires the EHD to be small and lightweight. We applied electromagnetic induction to the proposed EHD, although electromagnetic-induction based devices are generally considered difficult to be miniaturized. To our knowledge, the smallest electromagnetic EHD for application to shoes has a volume of 8.8 cm^3 and thickness of 16 mm [1]; these dimensions are too large to allow embedding in a shoe sole. However, electromagnetic induction generates much lower voltage than power generators based on piezoelectric transducers and electrostatic induction, which are often used for small structures. Therefore, an electromagnetic generator can easily be used with an integrated circuit and electronic components, which are small but need to take into account electro-static discharge susceptibility. Based on this idea, we have developed a small electromagnetic generator with sufficient power generation capacity. 2. Design We set the target EHD design to a 4-cm^2 footprint and 7.5-mm thickness; these dimensions render the device extremely small and thin compared to those in previous studies [1]–[3]. Because recent low-power wireless sensors can be driven with 100-μW power, we set the target power generation amount to >100 μW. The prototype of the designed EHD is shown in Figure 1. Figure 2 illustrates the design with some parts transparentized for a better understanding of the structure. The device consists of a base, covers, eight coils with iron cores, four springs, moving parts, and yokes. The moving part receives the input force in the z direction, and two neodymium magnets and yokes are fixed to the moving parts. Note that the maximum energy product of each magnet is approximately 320 kJ/m^3, and its dimensions are 7 mm × 1 mm × 1.3 mm. The moving part is supported by four springs, whose total spring constant is 6864 N/m. Each coil is wound around a 1-mm-diameter iron core, and the number of turns of each coil is 206. Eight coils are connected in series, thus the impedance of the EHD is 16 Ω at 500 Hz. The footprint of the EHD is 20 mm × 20 mm. The height to the top of the cover is 5 mm, and that of the moving part is 7.5 mm. There is a 2.5-mm difference in height between the cover and moving part, and this difference determines the range of movement of the magnets. The volume of the device is 2.4 cm^3. Figure 2 (b) depicts a cross-section of the EHD, which facilitates an understanding of the power generation mechanism. When a force in the z direction is applied to the upper surface of the moving part, the moving part is pushed down toward the base. The magnets mounted on the moving part pass over the iron cores of the coils with a small gap of approximately 0.1 mm. Consequently, the magnetic flux density going through the iron cores varies corresponding to the distance between the magnet and cores (i.e., the permeance of the magnetic circuit). Once the force is released, the moving part returns to its initial position by the restoring force of the springs supporting the moving part. The magnets pass over the iron cores again. Thus, when the force is exerted or released, electric power is generated. To obtain a large power generation, the variation of magnetic flux density due to the reciprocating motion should be as large as possible. Because the minimum air gap between the magnet and the yoke is very narrow (approximately 0.1 mm), the maximum magnetic flux density achieved is 1.0 T. In contrast, when the moving part is at either the top or bottom position, the magnets are the farthest from the iron cores, and the magnetic flux density is only 0.27 T. Therefore, the variation of the magnetic flux density during a stroke of the moving part is 0.73 T. Such a large variation is an advantageous feature of the proposed structure and the source of the large power generation. 3. Experimental result We measured the power generation amount by applying an impact force to the moving parts. An external resistor of 16 Ω was connected in series with the coils of the EHD. Then, an impact force was applied to the top of the moving part, and the voltage generated between both ends of the external resister was measured. The power generation amount was defined as the energy consumption in the external resistor. The impact acceleration was measured using a small acceleration sensor. When a half-sine impact pulse with a maximum force and duration of 161 N and 2 ms, respectively, was applied, the generated voltage was 2.1 V, and the power generation amount was calculated as 119 μJ (49.6 μJ/cm3). Assuming that such input repeats at 1 Hz during walking, the power generation performance is 119 μW. Therefore, the performance of proposed EHD exceeded the target power generation amount required to drive a low-power wireless sensor.

DG-06. Performance Analysis of a Novel Fall-Back Transverse-Flux Permanent-Magnet Generator with Outer Rotor Design Suitable for Direct-Coupling Wind Turbine.

M.A. Patel[1] and S.C. Vora[1]
1. Department of Electrical Engineering, Institute of Technology, Nirma University, Ahmedabad, India

A fall-back transverse-flux permanent magnet generator (FB-TFPMG) with inner rotor design preferred for wind power applications, employs half the number of PMs (as against conventional TFPMG), elliptical shaped stator core and toroidal shaped coil. In this manuscript, a novel concept of FB-TFPMG with outer rotor design, suitable for direct coupling to wind turbine, is explored with a possibility to improve the power to volume ratio in comparison with the inner rotor FB-TFPMG. In the proposed configuration, the blades of the wind turbine are directly fastened to the drum to perceive the direct coupling between the wind turbine and the outer rotor FB-TFPM generator. This leads to immediate benefit of lower weight and better cooling. The dynamic performance of a novel concept of the proposed topology is analysed using 3-D finite element tool and the results are compared with the inner rotor FB-TFPMG. With expeditious penetration of wind power generator technologies and remarkable wind power generation capacity installed worldwide, numerous concepts of wind generator have been proposed and assembled. In [1]-[2], possible future wind generation systems and topologies are reviewed. A conventional transverse-flux permanent-magnet generator (TFPMG) with U-shaped stator core [3]-[4] is chosen as the best generator among all direct-drive PM generators because of its higher power density and simple coil design. The main drawbacks of conventional TFPMG has a complex design, an uneven magnetic flux distribution and high flux leakage due to multi-dimensional magnetic flux pattern. An iron bridge is employed between adjacent stator cores, as a solution to prevent the excessive leakage flux [5]-[6]. An improvement to the concept of conventional transverse-flux permanent-magnet generator, with a fall-back rotor is presented in [7]. A fall-back transverse-flux permanent-magnet generator (FB-TFPMG) with *inner* rotor design reduces the number of PMs to half, possess elliptical shaped stator cores and toroidal shaped coil in comparison to conventional TFPMG. Fall-back path of the rotor offers several advantages, importantly it avoids the losses in inactive magnets and the reduction in overall cost of the generator. Various outer rotor configurations of permanent magnet generators are deliberated in the literature i.e. radial flux, axial flux, transverse flux design, claw pole type and superconducting generators [8]-[10]. Transverse flux PM generator with outer rotor designs are compared in [11]-[12]. In this paper, a novel concept of FB-TFPMG is extended with outer rotor design, suitable for direct-coupling of wind turbine. This design is explored with a possibility to improve the performance and power to volume ratio in comparison with the inner rotor FB-TFPMG. The detailed cut section of the one phase of a novel FB-TFPM generator with outer rotor design is depicted in Fig. 1. The FB-TFPMG is basically a multi-phase configuration with circumferential toroidal shaped coil per phase in the stator. It possesses half of the total magnets with outer rotor for benefits of the availability of the space in it and possibility to modify the PM rotor pole position for better performance. It comprises of inner stator core assembly, which is mounted on the fixed shaft. Soft magnetic composite material is used for stator structure with even number of U-shaped magnetic circuits (cores) placed circumferentially inside a rotor core assembly. Rotor possesses number of magnetic pole pairs (NdFeB) exactly equal to the number of stator cores. The rotor back is made of mild steel. PM fluxes of all N-poles add up in the stator core in one direction and as the rotor travels one PM pole angle, all fall-back part (S-poles) add up their fluxes in the stator core in the reverse direction. As the rotor travels, the magnets and fall-back part of the rotor change their polarities and hence alternating emf is induced in the toroidal shaped coil. PM flux paths are bi-directional in the stator and three-dimensional in the rotor. The results of a novel outer rotor FB-TFPMG are focused on the most important parameters such as electromagnetic field analysis and induced emf under no-load condition and on-load condition. The induced emf plots under no-load and on-load condition are shown in Fig. 2 and are in good agreement with the inner rotor FB-TFPMG. Outer rotor design with 10.27% reduction in volume gives the equivalent output power as compared with the inner rotor design.

I. INTRODUCTION Microgeneration wind turbines often have starting problems due to cogging torque. Since small turbines for urban use are often located near or on top of buildings, they are subjected to a lower level the wind speed and to a more turbulent wind. The wind turbine presented in this digest is rated at only 1 kW; to increase the wind speed through the turbine, a diffuser is proposed. This can increase the speed in about 30% and improve the power coefficient C_w by about 70 %. The rotor is integrated into the turbine by fixing the turbine blade tips to an outer rotor ring which avoids shading by a centre rotor hub [1]. This ensures that the turbine reaches rated speed in less time and with greater regularity, i.e. it improves the starting. The turbine micro generator has an induced volts-per-phase of 94 V at 450 rpm. It is formed from a rotor with 100 surface mounted magnetic poles with no back iron, and an ironless three-phase stator. The inner diameter of the rotor is 1500 mm and determined by the length of the blades. The outer diameter of the rotor is 1546 mm. Each magnetic pole measures 30×40×5 mm (w× l × h). The outer diameter of the micro generator is 1554 mm. The pole pitch is very small due to the pole pair number and the diameters of the rotor. Therefore, the permanent magnets poles do not need to be arc shaped and rectangular shapes can be employed. Fig. 1 presents a view of the wind turbine with the electrical generator, the blades, and the diffuser. II. ANALYSIS OF THE MICROGENERATOR In the machine design process, experimental data can help determine the magnitude of the magnetic induction produced by the NdFeB permanent magnets [2]. To perform the design of the machine and understand the distribution of the internal magnetic flux, it is proposed an analytical model based on the magnetic scalar potential applied to a coreless configuration. In the analytical model, the magnetic field equations allow one to preview the behaviour of the magnetic flux density in terms of its distribution (Fig. 2). Values for the induced voltage across the windings can also be obtained. The formulation of the magnetic scalar potential assumes that all regions are free from current. The analytical model employs rectangular coordinates because the pole pitch arc is very short compared to the large diameter of the machine. Hence, the machine is considered linear. The magnetic circuit of the machine is divided in boundaries, each one with appropriate conditions for the field. These boundaries define the permanent magnets, the inner air volume where the blades are located, and the outer air volume where the armature windings are placed. In the air-gaps, the Laplacian of the magnetic scalar potential is null (Laplace's equation) [3]. The permanent magnet may be characterized by a fixed magnetization, so that the respective Poisson's equation equals the divergence of the magnetization vector. By means of the magnetic potential equation of each region, and by the imposed magnetic field boundary conditions, it is possible to obtain the equations for the magnetic flux density vectors in all regions. The magnetic flux-per-pole when the micro generator is running is obtained by integration of the normal component of the magnetic flux density vector over a pole pitch. The induced voltage-per-phase in the windings is computed using the normal component of the magnetic flux density vector. Fig. 2 presents a graph of the induced voltage-per-phase as a function of the wind turbine speed. The analytical model results are compared to numerical analysis calculations for validation and good correlation is found. The non-sinusoidal wave in Fig. 2 is the first step to study the magnitude of the voltage under load. In this project, the AWG 12 wire employed offers a very low resistance calculated in 0.48Ω per phase. With a line current density of 2.29 kA/m and a current density of $1.08\text{x}10^6 \text{A/m}^2$ in the armature conductors, the magnetic field produced in the winding is too weak to distort or reduce the permanent magnets field. The inductance in the absence of ferromagnetic material and proportional to a seven-turn coil is also low and computed to be 100 μH. It results in a very good regulation for the machine with losses of 20 W at rated power output. III Conclusions This digest outlines a method for predicting the magnetic field produced by a permanent-magnet coreless machine. Compared to machines with a substantial back iron, the proposed machine has lower magnetic induction in the windings and no cogging torque. Using magnetic scalar potential, it is possible to determine the magnitude of the magnetic field as a function of the tangential distance along the pole pitch and the coil span. It allows an approach in terms of rectangular coordinates. The analytical method provides means to optimize the machine without complex and time consuming numerical methods, which can speed up the design process and allow automated design. The induced voltage calculation achieves good agreement with numerical analysis in a 2D arrangement with a mean percentage error of 2.73 %, as seen with the aid of Fig. 2. Likewise, the armature reactance has good agreement, and that will also be presented in more details by the full paper. This work, therefore, makes a good contribution to the rapid and automated design of these small turbines.

DG-08. Multiple-Objective-Based Optimal Energy Distribution for Wireless Power Transfer.

Z. Zhang[1], H. Pang[1], R. Tong[1], W. Ai[1], *S. Chang*[1] and J. Wang[1]
1. School of Electrical and Information Engineering, Tianjin University, Tianjin, China

I. Introduction Along with the increasing popularity of smart home, multi-coupling wireless power transfer (WPT) technique has shown significant potentials for portable electric-driven appliances. Accordingly, there existing growing diversity of charging requirements from various household appliances like mobile phones, iPad or laptop, for examples quick charging, the State of Charge (SoC), etc., therefore, the multi-coupling WPT system needs to deal with various charging requests simultaneously. Besides, the security of the wirelessly transmitted energy attracts attentions from researchers as well, especially for multiple WPT receivers coupling with the identical transmitting coil. Previously proposed energy encryption scheme utilized the characteristic of frequency sensitivity to encrypt the transmission channel [1]. Consequently, the key point of delivering the maximum power is to ensure the impedance matching, especially adjusting the resonant capacitor of primary unit while the frequency is regulated randomly. As aforementioned, this paper proposes an optimal-distribution and maximum-power based system which can distribute the limited transmitted power to different receivers simultaneously based on the proposed multi-coupling energy distribution scheme utilizing a novel control algorithm, meanwhile the proposed system is able to compensate the change of capacitance voltage due to the change of resonant frequency on account of various standard of charging equipment. More importantly, the proposed compensation which can extend the range of resonant frequency significantly only need one capacitor with a brand new current injection topology named capacitance buffer rather than the traditional capacitor array, so the system can continuously adjust the impedance to the resonate state to maintain the maximum output power. II. Proposed Optimal Energy Distribution Fig. 1 depicts the prototype of proposed optimal energy distribution based WPT system. Fig.2 shows four different working conditions regarding to this system. Fig. 2 (a) represents the average energy distribution where the RMS voltage of load 1 and load 2 are 1.89V and 1.93V, respectively, it means the energy is divided into two equivalent part. Fig. 2 (b) stands for the situation that load 1 is at the high priority through the proposed energy distribution algorithm so it need to be charged quickly, meanwhile load 2 is at the bottom of the charging list which is likely to receive the less quotient energy since the majority of transmitted energy is received by load 1, where the RMS voltage of load 1 and load 2 are 2.67V and 0.141V, respectively. Both these two situations are operating at the resonant state thus the inductance voltage and the capacitance voltage equal the same, which is 78.3V and 79.2V in Fig. 2 (a) with 117.6V and 118.9V in Fig. 2 (b). Fig. 2 (c) and Fig. 2 (d) both operate at the average energy distribution mechanism. Fig. 2 (c) shows the operating frequency is adjusted to the random frequency of 22kHz, however, the compensation capacitor is still 81.22nF which is the value of resonant state at 20kHz. In such a case, the inductance voltage and the capacitance voltage are 50.0V and 36.1V, respectively. So the difference between inductance voltage and capacitance voltage equals 14V which means the primary circuit works at the non-resonant state due to the frequency deviation and the excitation current will decrease dramatically as well. Besides, the RMS voltage of load 1 and load 2 are 0.779V and 0.766V, respectively, which drop to an extremely low level compared to the situation in Fig. 2 (a). Fig.2 (d) shows the same situation in Fig. 2 (c) but with the capacitance buffer utilizing the current injection topology where the RMS voltage of load 1 and load 2 are 1.67V and 1.62V, respectively, it means the transmitted power reverts to the resonant level in Fig.2 (a) and the inductance voltage and the capacitance voltage are 71.9V and 72.4V, respectively. It illustrates the ideal functionality of the proposed capacitance buffer to fine tune the compensation impedance so as to maintain the maximum power. III. Conclusion This paper has proposed an optimal-distribution and maximum-power based WPT system. It means that the wirelessly-transmitted energy could be distributed more effective and more intelligent, which is almost unexplored in other WPT researches. The proposed energy distribution algorithm provides an effective charging strategy for multi-coupling WPT systems, meanwhile the capacitance buffer with the current injection topology promotes the load voltage for about 214.4% at the frequency of 22kHz by means of tune the capacitance compensation. In addition, the measured results are in good agreements with the theoretical designs and simulated results, which verify the feasibility and correctness of the proposed approach in this paper, thus effectively enhancing the performance of multi-coupling WPT systems. Besides, the detailed parameters, distribution algorithm, current injection topology, simulated results, and experimental waveforms will be presented in the full manuscript.

I. Introduction The rotor of transversally laminated synchronous reluctance motor is constructed with multi-flux barriers by stamping the laminated steel sheets and the machine is short for TLR-SynRM. It has obvious advantages of smooth rotor surface, and the lower copper loss, et al. [1]. Nevertheless, TLR-SynRM has the drawback of high torque ripple, and one of the main reasons is the non-sinusoidal distribution of the air-gap flux density caused by the spatial harmonics of stator magnetic potential and flux-barrier rotor configuration. In [2], it has been carried out the genetic algorithm (GA) optimizations to improve the angles of the flux-barrier ends to reduce the torque ripple. In this paper, it proposes the step-shaped gradient flux barriers in TLR-SynRM for torque ripple reduction .A method is presented to compute the reluctances of each layer of flux barriers through conformal mapping method. Based on this calculation, it is shown how the air-gap flux density distribution of TLR-SynRM can be analytically computed through magnetic equivalent circuit (MEC) method. Combining with the two methods, the flux-barrier parameters for torque ripple reduction can be improved and the final improved flux-barrier parameters are obtained. II. The Rotor Configuration of the Step-shaped Gradient Flux Barriers In Fig.1(a), each layer of the gradient flux barriers is divided by region Q_1,Q_2,Q_3. Where $w_{ins}(z)$ is the width of the z_{th} layer of flux barrier in region Q_3; $w_{iron}(z)$ is the width of the z_{th} layer of silicon steel sheets between the z_{th} layer of flux barrier and the$(z+1)_{th}$ layer of flux barrier, z=1,2,…,n_w-1, where x_{0z} is the z_{th} layer salient flux-barrier width; n_w is the total layers of flux barriers. This rotor configuration has two remarkable features. First, its flux barriers are step-shaped and the parameter X=[x_{01}, x_{02}, …, x_{0nw}] that makes the each layer of the gradient flux barriers change in steps has a great influence on the air-gap flux density distribution, where x_{0k} is the k_{th} layer salient flux-barrier width, k=1,2,3…,n_w. The units of the parameter X is millimeter. Second, the widths of multi-flux barriers in the middle regions are changing in a gradient fashion. III. Computed the Reluctance using Conformal Mapping The conventional method may be hardly extended to the proposed non-uniform width of the step-shaped gradient flux barriers in this paper. A method is presented to compute the reluctance through conformal mapping [3].In Fig.1(b), the k_{th} layer salient flux-barrier width x_{0k} in complex plane w is mapped into the k_{th} layer salient flux-barrier width x_k in complex plane z_1. It needs to fix Neumann and Dirichlet boundary conditions to calculate the reluctances in rectangular region Q_1, Q_2, Q_3, and the field solution inside rectangle region is given by a uniform flux density of constant magnitude B_x. IV. MEC Model The step-shaped gradient flux-barrier MEC model is established in Fig.1(c). Within each air-gap region, a MMF source F_{ij}(with i and j equal to 1,2,3 or 4) and the flux Φ_{ij} passing through an air-gap reluctance R_{gij}. The whole air-gap of TLR-SynRM is subdivided into various regions, marked as 11,12,13,14,21,31,41,22 and delimited by the end points of flux barriers. According to the last section and the formulation for the reluctance, it can be concluded that the values of R_{b11} and R_{b21} are hardly changed with x_1 and x_2 respectively, and the values of R_{b31} and R_{b41} decrease to zero along with x_3 and x_4 growing. V. The Air-Gap Flux Density Distribution and FEM Assessment Combining with the configuration characteristic of rotor, the stator inner surface is further subdivided into nine different regions, marked as S_ϕ (ϕ=1, 2…, 9), as shown the gray and white regions in Fig.1 (a). According to the last section, it can be obtained multi-group parameters X, therefore the multi-group distributions of $B_g(\theta)$ are obtained from the MEC model in Fig.1(c). It can summarize the rules as follows. First, it can be concluded that the distributions of $B_g(\theta)$ from region S_1 to region S_4 do not change with x_3 and x_4. Second, it can be concluded that the distributions of $B_g(\theta)$ from region S_5 to region S_9 are monotonically increasing along with x_3 and x_4 growing and the results are in accordance with the linear variation of the reluctances R_{b31} and R_{b41} along with x_3 and x_4 growing. In this paper, the value of the parameter X is [1.230, 1.257, 4.223, 1.493] for guaranteeing the sinusoidal distribution and continuity of $B_g(\theta)$. The air-gap flux density computed by the analytical method and FEM are shown in Fig.1 (d). A comparative observation between Fig.2 (a) and Fig.2 (b) shows that the fundamental amplitude of $B_g(\theta)$ with the step-shaped gradient flux barriers in TLR-SynRM is increased by 5.1% than the conventional rotor flux barriers in TLR-SynRM. The torque ripple is 3.76%, whereas it is decreased by 15.74% when compared with the conventional rotor flux barriers in TLR-SynRM. VI. Conclusion It can be concluded that the torque ripple of TLR-SynRM with the step-shaped gradient flux barriers can be reduced effectively and it can make the torque waveform smoother.

Abstract — The aim of this paper is to provide a detailed comparison of three stator topologies for wave-type printed circuit board (PCB) winding axial flux permanent magnet machines (AFPMSMs). This comparison is performed based on the generated back electromotive force (EMF), winding inductances, and torque production capabilities of these machines. Three topologies are investigated, overlapping radial wave, non-overlapping radial wave, and overlapping parallel wave PCB windings. 3D finite element analysis (FEA) is used for these investigations. *Introduction:* Recently the axial flux permanent magnet synchronous machines (AFPMSMs) have gained wide attention because of their planer geometries, high number of pole pairs, short end windings, and high torque density which facilitates their use in applications such as hybrid and electric vehicles, aerospace actuation, and micromachines [1-2]. The existing literatures mostly focus on the design and comparison of conventional AFMSMs. However, not many documented works are found on AFPMSMs with printed circuit board (PCB) windings. PCB winding AFPMSMs are attractive for various applications that require thinner designs. The cornerstone and main challenge in design of such machines is their PCB windings which ultimately influences the electromotive force (EMF) and electromagnetic torque of the motor. Various layouts such as spiral or rhomboidal [3-5] PCB windings are mentioned in the literature. However, these topologies suffer from having a shorter active conductor length, increased joule losses, and inefficient use of the PCB surface that is facing the magnetic field. An alternative topology can be the use of wave-type PCB windings which sufficiently use the PCB surface, while keeping the joule losses to a minimum. Thus, there is a need to have a detailed survey of wave-type PCB winding topologies for PCB AFPMSMs which would be helpful while considering innovative designs of these machines. Therefore, this paper proposes a comparative study on novel wave-type PCB winding topologies for AFPMSMs in terms of their back-EMF, inductances, and torque production capabilities. *Stator Topologies for PCB Axial-Flux PMSMs:* A double-sided 10 pole AFPMSM as shown in Fig. 1(a) is used in this study. Three two-layer three-phase PCB stator topologies are chosen for the comparison, namely: 1) overlapping radial wave winding; 2) non-overlapping radial wave winding; and 3) overlapping parallel wave winding, as shown in Fig. 1(b) to (d), respectively. In Fig. 1(b) to (d), only one side of the two-layer PCB windings are presented for better visualization; the track widths of the windings are also exaggerated for clear illustration. In all the PCB topologies, the track width is equal to 7 mil (0.178 mm) with a minimum track clearance of 6 mil (0.152 mm). Track thickness is equal to 2 oz/ft^2 (equivalent to 0.07 mm thickness). The PCBs are designed to have the maximum number of turns per phase for the given track width and clearance. Other design parameters of the machines are shown in Table I. *Evaluation of back-EMF, Electromagnetic Torque, and Inductances:* Performance characteristics of different PCB winding topologies of Fig. 1 are obtained using 3D FEA at the synchronous speed of 600rpm. The generated three-phase back-EMFs by these topologies are shown in Fig. 2(a)-(c). A comparison between the harmonic content of the generated voltages is shown in Fig. 2(d). It is observed that the non-overlapping radial wave winding generates the highest fundamental voltage harmonic; however, it contains high third harmonic content, hence the back-EMF is trapezoidal. The overlapping radial wave winding on the other hand has a lower fundamental value and third harmonic. The overlapping parallel wave PCB winding generates the lowest fundamental voltage and is the least efficient topology among the three topologies of Fig. 1. PCB AFPMSMs are air-cored motors, thus the electromagnetic torque originates only from the alignment torque which is directly proportional to the fundamental component of the back-EMF. Therefore, for a given current, among the three compared PCB winding topologies, the non-overlapping winding produces the highest electromagnetic torque. The lowest electromagnetic torque belongs to the parallel wave PCB winding which has the lowest fundamental back-EMF harmonic. The inductances for air-cored AFPMSMs are generally small, in μH since the cumulative effective airgap is high and the number of turns is limited. Among the studied PCB AFPMSMs, the non-overlapping radial wave PCB topology has the highest self-inductance and lowest mutual inductance since the adjacent windings do not overlap. The overlapping radial wave and the parallel wave windings have higher mutual inductances due to the adjacent winding tracks overlapping. However, self-inductances for these two PCB winding topologies are in the same range. *Conclusion*: A comparative study on the performance characteristics of different PCB winding topologies for PCB AFPMSMs was presented in this research. The analysis considered three PCB winding topologies and compared them in terms of their back-EMF, electromagnetic torque, and inductances. Among the three studied topologies, the non-overlapping radial wave winding has the highest fundamental back-EMF harmonic and electromagnetic torque. On the other hand, the overlapping parallel wave winding had the worst performance in terms of torque production capability. Full evaluation of the studied winding topologies will be added in the extended manuscript.

DH-03. Electromagnetic Performance Analysis of a New Hybrid Excitation Synchronous Machine for Electric Vehicle Applications.

Y. Liu[1], Z. Zhang[1], C. Wang[1] and W. Geng[1]
1. Nanjing University of Aeronautics and Astronautics, Nanjing, China

I. INTRODUCTION Permanent magnet synchronous machines (PMSMs) have been attracting wide attentions and extensively applied in many fields due to their high torque density, high power density and high efficiency. However, the traditional PMSMs with constant air-gap flux hardly achieve perfect performances in an EV drive system which simultaneously requires both high output torque density and wide flux weakening range. Hybrid excitation synchronous machines (HESMs) are recently proposed as the potential candidates for EV drive systems, for the air-gap flux can be regulated by field current efficiently. The PM excitation is beneficial to improve torque density, and the field excitation brings good flux regulation capability, which is crucial for the wide flux weakening range in EV drive systems [1]. This paper studies the electromagnetic performance of a new HESM topology and the applicability of the HESM to a drive system for EV applications. A 100kW prototype HESM has been designed and developed for experimental verification. The contribution of this paper is to propose a promising solution where an HESM replaces a PMSM as a drive system in EV applications. II. OPERATION PRINCIPLE AND MACHINE SPECIFICATION Fig.1 shows the configuration of the new HESM with dual-end built-in field windings. The machine assembly axial length is not increased due to the built-in field windings. Compared to the HESM with extended magnetic bridge to embed field windings depicted in Fig. 2(a), the torque density and flux regulation capability of the new HESM are both improved with the optimized excitation structure. The operation principle of the HESMs depicted in Fig. 2(a) and (b) in a simplified form is illustrated in Fig. 3. Table I presents the design requirements of a drive motor for EV applications. Table II provides the main parameters of the designed HESM with dual-end built-in field windings. III. ELECTROMAGNETIC PERFORMANCE ANALYSIS In order to verify the applicability of the new HESM to a drive system for EV applications, the electromagnetic performance analysis mainly focuses on the torque characteristics and flux regulation capability. Fig. 4 shows the cogging torque waveforms with different field current. As shown in Fig. 5, the cogging torque magnitude increases with field current. Fig. 6 shows the torque-current characteristics with i_d=0 control strategy under different modes. As shown in Fig. 7, the rated output torque can be achieved by different combinations of armature current and field current. The output torque ripple can be optimized by the coordinated operation between field current and armature current. Fig. 8 shows the no-load flux regulation capability with field current. As shown in Fig. 9, the flux regulation capability of the new HESM can improved by the coordinated operation between field current and *d*-axis current. IV. EXPERIMENTAL VERIFICATION A 100kW prototype HESM with dual-end built-in field windings has been designed and developed for experimental verification. The prototype HESM and experimental setup are shown in Fig.10. Fig. 11 shows the back-EMF waveforms, no-load flux regulation capability and output torque capability. It can be seen that the simulated results agree well with the measured results. V. CONCLUSION In this paper, the electromagnetic performance of a new HESM with dual-end built-in field windings is investigated to verify the applicability of the HESM to a drive system for EV applications. A 100kW prototype HESM with dual-end built-in field windings has been designed and developed based on the requirements of a drive motor for EV applications, which simultaneously requires both high output torque density and wide flux weakening range.

DH-04. A New Variable Step Skew Approach for Minimizing Torque Pulsations in Permanent Magnet Synchronous Motors.

O. Ocak[1,2] and M. Aydin[2]
1. R&D, Akim Metal A.S., Kocaeli, Turkey; 2. Department of Mechatronics Engineering, Kocaeli University, Kocaeli, Turkey

I. INTRODUCTION There are several methods in order to reduce the torque pulsations for synchronous permanent magnet (PM) motors in literature [1]. These methods include design modifications both at rotor and stator sides such as using different slot/pole combinations, skewing rotor or stator, magnet grouping and adding auxiliary slots. One of the most common methods used in practice is step skew rotor. In general, adding one slot pitch step skew with several equal rotor segments increase torque quality and also decrease both cogging and ripple torque components for integer slot PM motors [2-7]. However, the skew angle and the step skew length could be optimized to get better torque quality. In this study, a new step skew technique is proposed with different segment lengths and skew angles between the segment pieces. Optimization comprising both parameters are carried out and the results compared with traditional step skew approach. 2D FEA results are obtained for conventional step skew rotor for a reference motor. Rotor optimization with varying rotor segment lengths and skew angles are attained and the optimized results are compared with the reference PM motor. II. MODELING OF PROPOSED STEP SKEW ROTOR AND ROTOR OPTIMIZATION In this study, a previously designed integer slot, 7.5kW, 4.000rpm surface mounted PM synchronous motor is used as a reference motor. 2D FEA model and mesh structure is shown in Fig 1. Both no-load and on-load FEA are performed and cogging torque, back EMF and torque output are obtained as shown in Fig 2. As observed from the analyses, the peak-to-peak cogging torque is 2.63Nm, peak back EMF voltage is 121.95V with a TDH of 8.24% and torque output is 18.75Nm with 16.2% ripple. Conventional step skew approach is applied to the reference motor. Several step skew up to 5 segments are investigated with FEA and the results are provided in Fig 3. By using 4 step skew rotor, %0.75 cogging torque, 115.85V line back EMF voltage with 0.8% THD and 3.7% torque ripple are obtained. An optimization code is developed in order to find the optimum step skew angle and the segment of the rotor segments. The flow chart is shown in Fig 4. With the developed optimization approach, the length of the rotor segments and the skew angles are varied to find the optimum torque pulsating components. 2D and 3D CAD models for standard step skew and the proposed step skew approaches are shown in Fig 5. Taking results from 2D FEA, necessary scaling and phase shifting are applied according to magnet lengths and skewing angles and results are summed to obtain the results of the proposed approaches. Rotor optimization to get minimum cogging for different segment numbers are summarized in Fig 7. As seen from the figure, optimum result for minimum cogging torque is close to the results with standard 3 step skew structure with 0.27Nm. Same analysis is repeated for torque output as seen in Fig 8 and it is found that 4 segmented rotor structure provide 17.7Nm average torque output with 1.74% torque ripple. The analyses show that manufacturing a prototype with 4 rotor segments and optimum skew angles and segment lengths provides minimum torque ripple. 3D FEA analyses are also performed for the optimized rotor. 3D FEA results and comparison with 2D FEA are also shown in Fig 9. It is seen that results are in good agreement. III. PROTOTYPE MANUFACTURING AND EXPERIMENTAL RESULTS Prototype manufacturing for the reference PM motor and the proposed PM motor are completed. Motor housing parts and sample laminations are illustrated in Fig 10. Experimental results and comparison between the test data and FEA simulations will be provided in the paper. IV. CONCLUSION In this study, a new step skew approach for surface PM motors is proposed for the first time in literature. The proposed step skew approach relies on varying both the length of the step skew and the angle between the rotor segments. It is shown that it is possible to optimize both parameters and obtain less torque pulsations as opposed to the conventional step skew. Prototypes are built for both the reference and the proposed motors. Detailed test results and the comparison with FEA will be provided in the final version of the paper.

DH-05. Suppression of Even-Order Harmonics and Torque Ripple in Outer Rotor Consequent-Pole PM Machine with Multilayer Windings.

F. Li[1] and H. Zhang[1]
1. Institute of automation, Nanjing University of Aeronautics and Astronautics, Nan Jing, China

I. Introduction Due to the excellent performance of permanent magnet (PM) machine with high power density, small volume and high efficiency, they are widely used in the aerospace field, high performance servo field, distributed power generation and flywheel energy storage [1-2]. But the use of rare earth materials especially the high energy product PM, such as NdFeB, is expensive. To reduce the cost, the research on the less-PM machines has drawn much attention over the last few years. The consequent pole rotor was proposed for low speed direct drive [3-5], where its electromagnetic performance was analyzed. However, for some specific slot and pole combinations of CP PM machines, the even harmonics exist in the phase back-EMFs can't be counteract and this will increase the torque ripple. In order to suppress its even harmonics, the multilayer windings are employed. The purpose of this paper is to suppress even-order harmonics in Back-EMFs and torque ripple in out rotor CP PM machine by multilayer winding and the principle is verified by FEA and experiment results. Compared with the traditional 27-slot/30-pole 2 layer PMSM, the average torque of 27-slot/30-pole 4 layer PMSM with CP rotor can maintain 98.47% by saving 28.2% amount of PM. Furthermore, the efficiency of the 27-slot/30-pole 4 layer CP SPM machines is almost the same as the traditional 27-slot/30-pole 2 layer SPM machine when operate at rated speed. However, the torque ripple of the 2 layer CP SPM machines is highest of the analyzed machines. The prototype of traditional 27-slot/30-pole with 2 layer winding and CP rotor with 4 layer winding are fabricated to verify the FEA results. II. MACHINE TOPOLOGIES, FEA RESULT AND EXPERIMENTAL VALIDATION The traditional 27-slot/30-pole 2 layer PMSMs with traditional and CP rotor and 27-slot/30-pole 4 layer PMSMs with CP rotor are employed to analyze the electromagnetic characteristics of the machines. Figs. 1 (a), (b), (c) shows the rotor, the stator together with the winding connections employed for the three machines respectively. The star of slot of the unit machine for the 27-slot/30-pole 4 layer SPM machine is given in Fig. 1 (d). The Back-EMFs phasors A+, A- and A++, A-- belongs to phase-A defined as the first and second set winding of the machine, respectively. Figs. 2 (a), (b) show the Back-EMFs waveform and harmonics contents of 27-slot/30-pole CP SPM machine, it can be seen the resultant Back-EMF of the first and second set windings suppressed the even harmonics contents effectively in the 27-slot/30-pole CP SPM machine with 4 layer winding. The electromagnetic torque varies with rotor position for the three machines are given in Fig. 2 (c). As can be seen average torque of the 27-slot/30-pole 4 layer CP SPM machine can maintain 98.47% by saving 28.2% amount of PM compared with the traditional SPM machine, while the torque ripple is 5% lower than the 27-slot/30-pole 2 layer CP SPM machine and 0.98% higher than the 27-slot/30-pole 2 layer SPM machine. The prototype of 27-slot/30-pole 2 layer SPM machine is shown in Fig. 2 (d). The prototype of 27-slot/30-pole 4 layer SPM machine with CP rotor is in manufacture and will be shown together with the experimental results in the full paper.

DH-06. A Unified Design Approach of a Direct Drive External-Rotor Switched Reluctance Motor (Ex-R SRM) and its Implementation for a Low-Speed Domestic Appliance with R-dump Converter.

R. Azhagar[1] and A. Kavitha[1]
1. Electrical and Electronics Engineering, College of Engineering, Anna University, Chennai, India

ABSTRACT This paper demonstrates a unified design approach of an 8/6 External-Rotor Switched Reluctance Motor developed for a 150 RPM domestic application as direct drive. Here, the initial sizing of dimensions is determined by the analytical design calculation. The feasibility of the analytical design has been verified through Finite Element Analysis (FEA) under static and dynamic conditions. Further, a detailed fractional factorial design study has been conducted using Design of Experiments (DOE) to identify the critical design parameters which are sensitive to peak and average torque. This data from DOE is analysed through regression technique and fit a transfer function. This transfer function is helpful in finding the optimum design without spending much time in finite element analysis. Finally, the design is further optimized for conduction angles with R-dump converter to reduce the torque ripple. As a consequence, an optimum on/off angle has arrived which gives high average torque compared to the initial design. A prototype has been developed for the domestic appliance and tested with the actual load. INTRODUCTION The external rotor configuration of the motor provides many advantages over internal rotor such as it provides higher air gap radius, higher torque to ampere ratio hence increased efficiency. Additionally, it is well suited for high torque density applications and allows direct integration with the load like a fan, in wheel direct drives, hybrid electric vehicles, and wind turbines. In these applications, the mechanical construction is not a difficult one [1]. So, here, the application requires high torque at low speed where this motor can be directly coupled to the load. Also, the external motor with 6/8 pole switched reluctance motor has been developed and tested for a fan application at a minimum speed of 200 RPM [2]. In this digest, a unified design approach of an 8/6 Ex-R Switched Reluctance Motor and its implementation to use it as a direct drive for a low speed of 150 RPM in a domestic appliance has been proposed in detail. DESIRED DOMESTIC APPLIANCE REQUIREMENTS AND CONSTRAINTS To design an Ex-R SRM, the specification of the motor has to be defined first from application requirements. The domestic application considered for the study is a wet grinder. The grinders have a drum with stones which is driven by the conventional induction motor. The belt or gear mechanism is used for speed reduction [4]. Basically, wet grinder uses stone for grinding and the drive runs at low speed. The low-speed grinding is advantageous over high-speed grinding appliances (mixers or blenders) since it does not generate much heat which is very important for better food quality [5]. The motor design has to meet both electrical requirements and mechanical constraints of the application. Since the motor is going to be used as direct drive it should fit within the periphery of drum[5]. The drum diameter is 250 mm. Also, the height of the motor should be as low as possible to have a better mechanical stability. So, its axial length is restricted to 40 mm. The proposed direct drive Ex-R SRM based wet grinder is shown Figure 9. The rated torque required for the application is 12 Nm at the low speed of 150 RPM with the peak torque of 14 Nm. The peak current of the motor should not exceed 10 A. UNIFIED DESIGN APPROACH INITIAL DESIGN OF Ex-R SRM The initial dimensions of the 4-phase, 8/6 Ex-R SRM is calculated from the analytical design equation modified from Inner rotor configuration[6]. VERIFICATION WITH FINITE ELEMENT ANALYSIS (FEA) The SR motor model shown in Fig.1 with initial and final design dimensions are modeled and analyzed using a 2-Dimensional (2D) FEA under static and transient conditions. The static torque, inductance profile and flux linkages for various currents with respect to rotor position are predicted through static simulation by exciting the phase coil with the current value of up to 10 Amps. In order to study the effect of on/off conduction angles on torque ripple are simulated during transient conditions by energizing semiconductor switches in R- dump converter circuit model at speed of 150 RPM. SENSITIVITY ANALYSIS USING DESIGN OF EXPERIMENTS (DOE) It has been identified from the initial study that there are 6 parameters which directly affect both peak and average torque of motor output. A.Fractional factorial design As the FE analysis is a time-consuming one, in order to save the simulation time, the full factorial has been converted into fractional factorial with 32 runs and the average and torque results are tabulated. B.ANOVA Analysis The simulation results of fractional factorial are further analyzed using ANOVA method and main and interaction effects are predicted. The main effects plot (Fig.4) show that the 3 factors which significantly affect the torque such as Outer diameter, stack length and no of turns. From the regression fit, optimum dimensions are finalised based on the high average and peak torque. EXPERIMENTAL VERIFICATION Finally, a prototype of the domestic appliance has been developed and tested with the actual load conditions. CONCLUSION In this digest, an 8/6 External-Rotor Switched Reluctance Motor for a low-speed has been designed and developed. This motor used as direct in the actual domestic application and tested with the actual load.

DH-07. Characteristic Analysis of Turn-to-turn Short Circuit Current Mitigation Method for Concentrated Winding Permanent Magnet Machines.

Y. Jiang[1], Z. Zhang[1], W. Jiang[1], J. Huang[1] and Y. Xu[1]
1. Nanjing University of Aeronuatics and Asrtonautics, Nanjing, China

I. INTRODUCTION Fractional slot concentrated winding (FSCW) permanent magnet synchronous machines (PMSMs) with high power density, fault tolerance and wide constant-power speed range are gaining increasing attention in the aircraft starter generator (SG) system. However, the short circuit (SC) fault, especially the turn-to-turn SC fault, is the obstruct crux in aviation applications. The high reluctance permanent magnet machine (HRPMM) can inherently limit the SC current with high self-inductance and low mutual inductance. Combining with the current injection mitigation method, it can limit turn-to-turn SC current to a permissible level [1] [2]. But higher reluctance always leads to lower power density. So far there has been no numerous criteria on trading off between the two characteristics. In this paper, analytical model based on flux distribution [3] is established to estimate the SC current. The requirement for HRPMMs to survive the turn-to-turn SC fault is deducted. The derived expression is aimed to provide guidelines for designing HRPMMs. The theoretical analysis is verified by finite element analysis (FEA) and experiments on a 24-slot, 16-pole PMSM. The paper provides guidelines for designing high-performance HRPMM for aviation power system. II. ANALYSIS OF THE SC CURRENT FOR PMSMS For PMSMs with series windings, it is assumed that the full-stage turn-to-turn SC fault occurs in winding a_1, as shown in Fig.1-2. The SC current I_s is shown in equation (1), where E_2 is back electromotive force (BEMF), I_a, I_b and I_c are phase currents, M_{hs} is mutual inductance between the healthy and faulty turns, L_s is faulty turns self-inductance, r_s is faulty turns resistor, M_{sb} and M_{sc} are mutual inductances between B, C phases and the faulty turns. The magnitude of no load SC current is shown as equation (2). For FSCW-PMSMs, the phase mutual inductance can be ignored. The typical current mitigation method is injecting flux-weakening current (i_d) to reduce flux linkage of the faulty turns, as shown in in equation (3). Analytical model is established according to the flux distribution as shown in Fig.3. Equation (4) is used to compute L_s and M_{hs}. Where, x is the ratio of healthy turns and faulty turns number in one slot. γ is coupling factor of different windings in a phase, as illustrated in Fig.3 and equation (5). The factor represents the influence of stator and rotor core reluctance on the inductance. L_{sm} and L_{sl} are winding self-inductance and leakage inductance, as derived by equation (6). Where L_m and L_l are phase self-inductance and leakage inductance, n is number of the windings in a phase. By replacing (4) into (3), the SC current can be expressed as equation (7). An ideal post-fault condition for the HRPMM is that the SC current and i_d share the same magnitude I_1. Under this condition, the no-load SC current can be expressed as equation (8). In the SG system with high speed, the resistance of armature winding can be neglected. Furthermore, the winding leakage inductance is far more less than self-inductance, leading to equation (9). To ensure long-term operation after the SC fault, I_1 should be no more than the rated current. Since the single-turn SC fault is the most critical condition, it can be inferred that HRPMM should satisfy equation (10) to guarantee survival of turn-to-turn SC fault. For PMSMs with parallel winding connection in Fig.4, the SC fault lowers the impedance in the faulty winding, affecting the current distribution. Thus, the designing equation is shown as equation (11). III. FINITE ELEMENT ANALYSIS AND EXPERIMENT VERIFICATION FEA and experiments are carried out on a 24-slot, 16-pole series-connected FSCW-PMSM as shown in Fig.5 and Tab.I. For the coils' safety, two-turn SC fault is conducted under no-load condition at 600rpm. The control structure is shown in Fig.6. Once the fault is detected, i_d would be injected to reduce the BEMF in the shorted turns, thus diminishing the SC current. The PMSM prototype and experiment platform are shown in Fig.7. Two turns of the same slot are brought out and shortened externally to emulate turn-to-turn SC current. The contact resistor is 29mΩ. Varied i_d is injected to observe the respond of SC current. Equation (3) is used to calculate the SC current. Figure 8 and 9 illustrate the analytical, simulation and experiment results. The results are in accordance with each other. When i_d varies from 0A to -150A, the SC current can be reduced from 130.5A to 83.1A. The FEA results and the experiment results are slightly higher than the analytical results because of the neglected core saturation in analytical model. The experiment results are slightly lower than the FEA results because the heat produced during the rotation magnifies the resistance of the copper conductors, reducing the SC current. From the results, it can also be seen that I_1 is about 80A. The value agrees with the equation (12). The FEA and experiment results verify the conclusion in part II. IV. CONCLUSION In this paper, analytical models of the SC current of the FSCW-PMSMs with series and parallel winding connections are established. Analytical expression is derived for designing HRPMM which could ensure long-term operation under turn-to-turn SC fault. FEA and experiments on a 24-slot, 16-pole PMSM are conducted to verify the deduction. The paper provides guidelines to trade off between the high power density and high reliability when designing HRPMM for the safety critical application. It widens the application foreground of PMSM for the aviation power system.

DH-08. Design and Performance Assessments of a Surface-mounted Permanent-magnet Vernier Motor for Exoskeleton System Application.

C. Liu[1], K. Yang[1], Z. Cai[1], P. Shih[1] and C. Hwang[2]
1. Department of Electrical Engineering, National Sun Yat-Sen University, Kaohsuing, Taiwan; 2. Department of Electrical Engineering, Feng Chia University, Taichung, Taiwan

Introduction: By appropriately adjusting the induced back electromagnetic forces on the stator windings, similar to those of a magnetic-geared motor, extra torque components can be generated from a surface-mounted permanent-magnet Vernier motor (VM) [1]. Since the joint parts of an exoskeleton system are generally equipped with appropriate motor-gear sets to provide the desired driven torques, the costs of these incorporated mechanical components can greatly be reduced with smaller gears ratios. With its relatively larger torque output, as long as the output speeds of the motor-gear set can still meet operational specifications, the VM will thus offer a competitive alternative for such applications. Following the same physical and operational constraints, an optimized VM (Opt. VM) capable of generating twice the torque output of an existing commercial VM (Ref. VM) that is commonly adopted on the exoskeleton system will thus be expected. By setting adequate design objectives and adopting the Taguchi's methodology, from the results calculated by thorough finite element analyses (FEA), the designed Opt. VM will be constructed and the related experimental measurements will be supplied to validate the design adequacies. The Scheme: Based on the related design concepts as discussed in [2], with proper selections of the VM parameters for optimizations, the air-gap flux density distributions of the Opt. VM and the Ref. VM are shown in Fig. 1(a). These two VMs, all have 18 stator slots and 12 rotor pole pairs, as illustrated in Fig. 1(b), and the larger flux densities of the Opt. VM compared with those of the Ref. VM at the designed harmonic orders are evident. To provide better comparisons for application assessments, the detailed performance indices of these two VMs are described by a radar chart as shown in Fig. 1(c). Clearly, at the same material costs and external physical volumes, the Opt. VM can exhibit its superiorities than those of the Ref. VM within the specified operational ranges of the exoskeleton system. The Results: The constructed laboratory Opt. VM is shown in Fig. 2(a), and the comparison results about the torque-speed characteristics among the Ref. VM and the Opt. VM are illustrated in Fig. 2(b). It is obvious that the output torques can almost be doubled from the designed Opt. VM at the lower speed range, with the sacrifices of about 1/2 of the rated and maximum speed levels than those of the Ref. VM. However, from the standard operational specifications, an exoskeleton system must be capable of rotating $\pi/2$ mechanically in 2.5 s to comply the desired stand-up operation, which indicates the standard operational speed is 6.0 rpm. This confirms that by equipping the Opt. VM with a 50:1 gears set, which is only halved the ratio of the one equipped by the Ref. VM will be sufficient enough for the objective exoskeleton system application.

PL-01. Spintronics Nanodevices.

H. Ohno[1,2]
1. Laboratory for Nanoelectronics and Spintronics, Research Institute of Electrical Communication, Tohoku University, Sendai, Japan; 2. Center for Spintronics Integrated Systems, Tohoku University, Sendai, Japan

Development of spintronics nonvolatile nanodevices and their integration with CMOS circuits are critical to realize standby power free, low-power consumption, yet high performance integrated circuits for Internet-of-Things (IoT), high performance computing and artificial intelligence. Endurance and low supply-voltage operation make these spintronics device capable of being used in the place of current volatile working memories such as DRAM and SRAM [1] and beyond. Magnetic tunnel junction (MTJ), a two-terminal nonvolatile spintronic device that can scale down to 20 nm with the perpendicular-easy-axis CoFeB-MgO system [2, 3], is the device most widely employed for such a purpose. I will review the development of MTJs, and discuss about its ultimate scalability beyond 10 nm by showing MTJs with current induced switching and high thermal stability in the range of 4-8 nm [4]. I will then describe the work on three-terminal devices that separate the write current path from the read current path. Here I focus on devices that utilize spin-orbit torque arising from structures involving heavy metals as well as from antiferromagnets [5-9]; the latter is shown to operate as analog memory suitable for neuromorphic applications [10]. Work supported in part by the ImPACT Program of CSTI, the R & D for Next-Generation Information Technology of MEXT, Grant-in-Aid for Specially Promoted Research (17H06093) and the FIRST Program.

EA-01. Heavy rare earth free, free rare earth and rare earth free magnets - vision and reality.

O. Gutfleisch[1] and K. Skokov[1]
1. Material Science, TU Darmstadt, Darmstadt, Germany

It is commonly understood that among the intermetallic phases used for permanent magnets, practically none can fully realize its potential based on the intrinsic magnetic properties. We discuss different reasons leading to this limitation, known as the Brown paradox, and discuss some possible ways of overcoming it. We look into Dy- and Tb-less grain boundary diffused magnets and the scope for the complete elimination of the heavy rare earth elements. Then we compare the intrinsic magnetic properties of (Nd1-xCex-)2(Fe1-yCoy)14B single crystals with the extrinsic characteristics of sintered and hot compacted magnets, so-called rare earth balance magnets, made from the very same alloys. Finally, assessing RE-free materials, our results obtained on Mn- and Co-based RE-free single crystals are compared with the hard magnetic properties of Mn-based permanent magnets.

EA-02. $Fe_{16}N_2$: from a 40-year mystery of magnetic materials to one of promises for rare-earth-free magnets.

J. Wang[1,2], Y. Jiang[1], M.A. Mehedi[2], J. Liu[1], Y. Wu[3] and B. Ma[1]
1. Electrical and Computer Engineering, University of Minnesota, Minneapolis, MN, United States; 2. Chemical Engineering and Materials Science, University of Minnesota, Minneapolis, MN, United States; 3. Niron Magnetics, Minneapolis, MN, United States

ABSTRACT $Fe_{16}N_2$ is one of the most promising rare-earth-free magnet candidates with high magnetic energy product. Iron nitride magnet is of great interest as a magnetic material for applications at relatively low temperature (<150 ^oC) ranging from magnets in hard disk drives for data storage and in all kinds of electrical motors, wind turbines, and other power generation machines. A perspective review on our research work on bulk $Fe_{16}N_2$ compound permanent magnet in past years is presented on the aspects of material processing and magnetic characterizations. Specifically, we will introduce and discuss our effort to prepare bulk $Fe_{16}N_2$ compound permanent magnet by using three different approaches, including an ion implantation method, a ball milling method and a strained-wire method. A feasibility of free-standing iron nitride foils with magnetic energy product up to 20 MGOe was successfully demonstrated based on an ion implantation method. Based on our theoretical and experimental progress, we believe that $Fe_{16}N_2$ compound permanent magnet is currently in an accelerating step to be an alternative magnet candidate. TECHNICAL RESULTS AND DISCUSSION During past decades, several permanent magnet materials were discovered, especially those based on rare-earth intermetallic compounds [1,2,3]. The key figure of merit of permanent magnets is the energy product $(BH)_{max}$. Figure 1 lists the development in the maximum magnetic energy product $(BH)_{max}$ at room temperature of market-available hard magnetic materials so far [4] and our predicted value for iron nitride magnet. It is interesting to note that this value, starting from 1MGOe for steels discovered during the early part of last century, increasing to 3MGOe for ferrites, and finally that peaks at 56MGOe for neodymium-iron-boron magnets during the past twenty years. However, new magnets with more abundant and less economically-limited and environmentally-restricted elements is highly demanded to supplement rare earth magnets [3]. At the same time, the saturation magnetization of rare earth magnets may not be high enough to satisfy the requirements for the applications of electric machines. One of basic function of permanent magnets used in electric vehicles and wind turbines is to provide magnetic flux. This function requires a higher saturation magnetization as well as an appropriate coercivity to against self-demagnetization. The most ideal permanent magnet should have the following features: (1) be composed by abundant and environment friendly elements; (2) large saturation magnetization; (3) large energy product; (4) reasonable high coercivity; $(BH)_{max}$ has doubled every 12 years during the 20th century mainly with the progress due to improvements in coercivity [4]. Next generation permanent magnet would be expected with a higher remanent magnetization while with a reasonable coercivity. $Fe_{16}N_2$ has been viewed as a controversial material or mystery before 2000. We have started to work on this material since 2003. Besides reporting a systematic experimental study on $Fe_{16}N_2$ thin films and confirmed its giant saturation magnetization and large anisotropy constant [5], we proposed a "cluster + atom" model based on the first-principles calculation to explain the giant saturation magnetization of $Fe_{16}N_2$ [6]. This model is supported by the discovery of partially localized 3d electrons in $Fe_{16}N_2$ [5]. After those validations, $Fe_{16}N_2$, with a magnetic flux density as high as 2.9T and an anisotropy constant up to 1.0-1.8 MJ/m^3 [7] has been expected to be one of possible rare-earth-free magnet candidates. Moreover, $Fe_{16}N_2$ has combined features of low cost with most redundant elements on earth, environment-friendly and theoretically two times higher energy product than the current market available rare earth magnets, as shown in Fig. 1. In this paper, we introduce three approaches, including an ion implantation approach, a strained-wire method and a ball milling method, which we developed in past six years, for the synthesis of bulk $Fe_{16}N_2$ magnets. By using a nitrogen ion implantation approach [8], we successfully synthesized free-standing $Fe_{16}N_2$ foils with a coercivity of up to 1910 Oe and a magnetic energy product of up to 20 MGOe at room temperature. An integrated synthesis technique was developed, including a direct foil-substrate bonding step, an ion implantation step and a two-step post-annealing process. With the tunable capability of the ion implantation fluence and energy, a microstructure with grain size 25-30 nm is constructed on the FeN foil sample with the implantation fluence of 5×10^{17} /cm^2. To the best of our knowledge, this could be the first experimental evidence of the existence of a giant saturation magnetization, an obviously large coercivity with a magnetic energy product of up to 20 MGOe in a bulk-type FeN magnet sample. Ball milling is one of the other approaches to prepare the $Fe_{16}N_2$ powder [9]. Shock compaction using a gas gun was used to compact the powder into a dense disk shape. We experimentally demonstrated that the volume ratio of the $Fe_{16}N_2$ phase is 70% and that it is stable under shock compaction, without obvious phase decomposition. This approach presents the possibility of mass producing bulk permanent magnets using $Fe_{16}N_2$ with enhanced magnetic properties. Furthermore, we proposed and demonstrated a novel synthesis method for bulk anisotropic $Fe_{16}N_2$ magnet, named as the "strained wire method" [10]. Based on this method, an anisotropic bulk iron nitride magnet with 9 MGOe was achieved for the first time.

EA-03. Rare earth permanent magnets with ultimate hard magnetic properties.

K. Hono[1,2]
1. Elements Strategy Initiative Center for Magnetic Materials, National Institute for Materials Science (NIMS), Tsukuba, Japan; 2. Research Center for Magnetic and Spintronic Materials, National Institute for Materials Science (NIMS), Tsukuba, Japan

There has been much research interest during the past decade to attain high coercivity in Nd-Fe-B magnets without using heavy rare earth (HRE) elements. Now that the supply of rare earth elements has been stabilized, the renewed goal is how to achieve the highest permanent magnetic properties with a balanced use of rare earth elements. In this talk, we will present an overview on our recent progresses on the development of high-coercivity Dy-free Nd-Fe-B magnets that were carried out at NIMS in collaboration with many industrial partners. Thereafter, we will discuss how to achieve ultimate permanent magnet properties by adding trace amounts of HRE to the Nd-Fe-B system. To obtain better understandings of the microstructure-coercivity relationships, we have investigated the microstructures of experimental magnets with wide ranges of coercivities that varied depending on chemical compositions, processing routes and post-manufacturing heat treatments. The microstructure and magnetic domain observations have been carried out using aberration-corrected STEM, atom probe tomography (APT), magneto-optical Kerr microscopy and finite element micromagnetic simulations. We found that the intergranular phase parallel to the c-planes are mostly crystalline with a higher Nd concentration in contrast to the phase lying parallel to the c-axis that contains higher Fe content with an amorphous structure in both sintered and hot-deformed magnets. Micromagnetic simulations suggest that the reduction of magnetization in the latter phase is critical for enhancing the coercivity. Based on these new experimental findings together with our detailed characterization results of the intergranular phases in Nd-Fe-B magnets, we propose a method to increase the coercivity of Nd-Fe-B magnets while maintaining high remanence. Lastly, we will discuss the possibility of industrially viable high-performance magnets other than the Nd-Fe-B system. This talk includes results obtained in collaboration with industrial collaborators including TOYOTA, Toyota Central Research Lab. Intermetallics, YSM and Daido Steel conducted under JST's Collaborative Research Based on Industrial Demand projects.

10:30

EA-04. Recent developments in melt-spun Nd-Fe-B bonded magnets for automotive applications.

Z. Chen[1], W. Zhao[1], N.K. Sheth[1], A. Meerani[1] and J. Herchenroeder[1]
1. Magnequench Technology Center, Neo Performance Materials (S) Pte Ltd, Singapore, Singapore

In recent years, there has been a significant increasing use of Nd-Fe-B permanent magnetic powders and its bonded magnets in the mobility/automotive applications. High performance bonded magnets helps in achieving smaller, lighter and more efficient motors leading to green and efficient vehicles. This also brings new challenges for bonded Nd-Fe-B magnets with requirement of higher mechanical strength, better thermal stability and improved corrosion resistance due to harsh working environment. In this talk, we will review Magnequench's comprehensive efforts with case studies to promote spreading applications of bonded Nd-Fe-B magnets into the automotive industry. These include the development of higher-performance melt-spun Nd-Fe-B powders with more uniform microstructure, development of novel compounds for making bonded Nd-Fe-B magnets with higher mechanical strength, better aging and improved corrosion resistance, and novel design of magnet and magnetizing fixture leading to the optimal use of the magnet.

11:00

EA-05. Effects of Cerium on Magnetic Properties of Sintered R-Fe-B Permanent Magnets.

X. Rao[1], E. Niu[1], F. Du[1] and B. Hu[1]
1. Zhong Ke San Huan Research, Beijing, China

As an element in Lanthanide, Cerium has the highest reserve in global rare earth resources (up to 40 ~ 50 % of total RE). To make the best use of Ce will improve the balance of rare-earth applications. Originating from the mixed valence characteristics of Ce ions in rare-earth transition compounds, its physical and chemical properties usually deviate from the trend of whole RE family. Ce exists in $Ce_2Fe_{14}B$ almost as Ce^{4+} ion. The lack of 4f electron leads Ce^{4+} to make no contribution to magnetism, especially the magneto-crystalline anisotropy. Small ion radius shrinks the Fe-Fe distances and consequently decreases the exchange interaction of Fe sub-lattice, which makes $Ce_2Fe_{14}B$ have lower Curie temperature T_C than other $R_2Fe_{14}B$ compounds. The T_C of $Ce_2Fe_{14}B$ is 422 K which is 164 K less than $Nd_2Fe_{14}B$. J_s is 1.17 T, 0.43 T less than $Nd_2Fe_{14}B$. The anisotropic field μ_0H_a is 3.6T, only 47% of $Nd_2Fe_{14}B$. In addition to decreasing the intrinsic magnetic properties in $Ce_2Fe_{14}B$, Ce also makes heavy damage on the coercivity of sintered Ce-Fe-B magnet. Because the conventional powder metallurgic procedure is in favor of forming $CeFe_2$ Laves phase instead of Ce-rich phase that magnetically decouple $Ce_2Fe_{14}B$ grains. Even so, $Ce_2Fe_{14}B$ still has comparable J_s to that of $SmCo_5$ and reasonable μ_0H_a for permanent magnet development. To add La, the RE element with the largest ion radius, is possible to improve the intrinsic magnetic properties of $(La_xCe_{1-x})_2Fe_{14}B$ [1]. The lattice parameters increase linearly with Ce content x which gives a = 0.8763 + 0.0033x (nm) and c = 1.2135 + 0.0114x (nm). As a result, T_C do increase linearly with T_C = 427.4 + 59.0x (K). Unfortunately the J_s at the temperature of 5K do not indicate the same increase with lattice expansion and keeps approximately a constant of 1.51 T. The practical way of preparing Ce-contained permanent magnet is to let Ce replace Nd to its upper limit. Rapidly quenching routine is straight forward to get rid of the necessity of Ce-rich phase. As shown in Fig.1 [2], even though all the permanent magnetic parameters drop linearly with Ce content x, isotropic $[(Nd_{0.75}Pr_{0.25})_{1-x}Ce_x]_{11.65}Fe_{82.75}B_{5.6}$ powder can still realize reasonable H_{cJ} and $(BH)_{max}$ for certain applications. For example, B_r = 8.54 kG, H_{cJ} = 9.4 kOe and $(BH)_{max}$ = 14.8 MGOe when Ce replaces Nd-Pr by 20 at% (x=0.2). At x=0.5, H_{cJ} keeps about 6.8 kOe with $(BH)_{max}$ of 11.6 MGOe. And the B_r is 7.82 kG. T_C at this composition is reasonably high as 509 K. In preparation of sintered magnets containing Ce, dual-alloy or dual main-phase techniques are usually applied. With Ce-rich/Nd-lean alloy and Nd-rich/Ce-lean alloy as starting materials, sintered (Ce,Nd)-Fe-B magnet is commercialized with high ratio of performance to cost. The key point is to let plenty of Nd-rich phase magnetically decouple $(Ce,Nd)_2Fe_{14}B$ grains. As shown in Table 1 [3], by mixing strip casted Nd-Fe-B and (Ce-Nd)-Fe-B alloy powder with different ratio, the sintered magnet with 45wt% Ce and 55wt% Nd in total rare earth composition gives B_r = 12.4 kG, H_{cJ} = 6.2 kOe and $(BH)_{max}$ = 33.4 MGOe. At Ce of 20wt%, the correspondent parameters are 13.7 kG, 12.0 kOe and 45.0 MGOe, which is good enough to many applications. The melting points of R-rich phase decrease with Ce composition. This implies that sintering temperature for high Ce-containing magnet can be lower than low Ce-containing magnet. Another example is to directly use misch-metal (MM) as raw material [4]. The typical composition of MM is La 27.06 wt%, Ce 51.46 wt%, Pr 5.22 wt%, and Nd 16.16 wt%. When MM to total RE ratio is 21.5%, B_r = 12.09 kG, H_{cJ} = 10.70 kOe and $(BH)_{max}$ = 34.04 MGOe. For magnet only with MM, H_{cJ} is as low as 0.46 kOe. $(BH)_{max}$ is just 2.40 MGOe. Microstructure observation shows that RFe_2 grains, in which Ce is the main component of R, distribute in triangle junction area formed by neighbor $R_2Fe_{14}B$grains. The lack of inter-granular R-rich phase is responsible for low H_{cJ} in sintered MM-Fe-B magnet.

EA-06. The advances of high-performance permanent magnets by microstructure designing.

W. Cui[1]
1. Northeastern University, Shenyang, China

Since discovered in 1983, Nd-Fe-B magnets have been developed for more than 35 years and its applications have been widened greatly1. The theoretical μ0Ha was predicted to be 7.5 T and (BH)max to be 512 kJ/m3. However, the coercivity of commercialized Nd-Fe-B permanent magnets was still be of ~1.5T, which inhibits its wide applications in hybrid/electric motors and wind powder generators. A general approach is to add heavy rare-earth (HRE) Tb or Dy to enhanced the μ0Ha and subsequent coercivity. Due to scarcity of HRE, many efforts were paid to reduce the addition or get rid of HRE. In a modeled Ta(50 nm)/Nd15Fe75B10(100 nm)/Ta(10nm) single-layer (SL) thin film system, Nd(20nm), Nd70Cu30(20 nm), Nd80Ag20(20nm) layers were diffusion-processed (DPed) into Nd-Fe-B layer. The ambient coercivity is greatly increased from 1.4 T in SL film to ~ 3 T after diffusion process with good squareness(as seen in Fig.1a). The microstructure observation shows the columnar shapes with c-axis perpendicular to substrates. The in-plane view TEM shows that the grains sizes in diffusion-processed films are more refined compared with that of SL film(as seen in Fig.1b-e). And Nd-rich grain boundaries (GBs) are observed, which is the microstructural reason for increased coercivity2. By using diffusion process, the coercivities of Ce-contained Nd-Fe-B magnets was also investigated. Many efforts had been paid to explore hard/soft-magnetic nanocomposite with high-performance. However, the experimental results are far behind such a theoretical prediction. The major challenge is to modify the interface between hard/soft-magnetic phase. Between Nd-Fe-B and F2Co soft-magnetic phase, a Ta(1nm) spacer layer was deposited. And a supereme (BH) max of 486 kJ/m3 and the coercivity of 1.38 T have been obtained as seen in Fig.2a.3 From cross-sectional TEM image, Nd2Fe14B grain was covered by a thin Nd-rich layer. Both Nd2Fe14B grain and soft-magnetic Fe phase were observed without contacting with each other(as seen from Fig.2b-d). Due to the existence of spacer layer, the interfacial coupling cannot be explained by the conventional exchange coupling mechanism. By tuning the thickness of spacer layer, the coercivity, demagnetization process and recoil curves had been analyzed. It was found that the exchange coupling was dominated when Ta spacer layer was less than 2 nm while dipolar coupling became dominated when Ta layer was thicker than 2 nm. Further semi-quantitative dependence between coupling energy and thickness of Ta spacer layer was established4. The dipolar coupling is related with the configuration of magnetic moments. By using quasi-epitaxial growing Sm(Co,Cu)5 films onto Cr-buffered MgO[110] substrate and Ru-buffered Al2O3[001] substrates, the easy axis of Sm(Co,Cu)5 phase can be tuned along either in-plane direction or out-of-plane direction, which provides the opportunity to study the coupling geometry effects on the magnetic properties of Sm(Co,Cu)5/Fe2Co bilayer films. Further TEM observations showed the high-density stacking faults caused by slipping within c-plane of Sm(Co,Cu)5 phase. The crystallographic relationshipe between SmCo3, Sm2Co7 and SmCo5 was caused by periodic slipping within c-plane.5

EB-01. Polymer-based magnetoelectric materials: from fundamentals to applications.

P. Martins[1] and S. Lanceros-Mendez[2,3]
1. Physics, University of Minho, Braga, Portugal; 2. BCMaterials, Leioa, Spain; 3. Ikerbasque, Basque Foundation for Science, Bilbao, Spain

Developing new smart materials and exploring their applicability has been in focus in the field of materials, sensors, actuators and biomedical applications. Smart and functional polymers are taking advantage on the understanding and control of their physico-chemical properties leading to a suitable tailoring of processability, shape control and performance[1,2]. In particular, magnetic devices have become an essential measuring/actuation tool in a range of application areas including biomedicine, multimedia, automobile and military, just to mention some of them, being the magnetoelectric (ME) effect increasingly considered as an attractive alternative for magnetic field sensing/actuation, able to sense/induce static and dynamic magnetic fields[3]. In contrast with ceramic-based ME composites, polymer-based ME composites can be easily fabricated by conventional low temperature processing into a variety of forms, such as thin sheets or molded shapes and can exhibit improved mechanical properties, meeting the latest magnetic sensing market demands[4,5]. This work reports on the development of novel composites based on the understanding of the magnetoelectric coupling as well as on the development of magnetic sensors, magnetic actuators, energy harvesters and biomedical applications, not only understanding and optimizing their magnetoelectric coupling, but also demonstrating their practical characteristics as technological devices. Thus, sensors are developed based on PVDF/Metglas and PVDF-TrFE/$CoFe_2O_4$(CFO) composites (Figure 1a,b) and the ME coefficient (Figure 1c,d), full scale input (FS), hysteresis, sensitivity, linearity and resolution of the materials will be demonstrated and discussed. Further, the main characteristics and potential applicability of polymer composites based on isotropic and anisotropic magnetostrictive magnetic nanoparticles within a piezoelectric polymer will be introduced. This work provides an overview of the frontline research of this fascinating research field and will present the open questions and open needs to reach full applicability of the novel materials[6]. Acknowledgements The authors thank the FCT- Fundação para a Ciência e Tecnologia- for financial support in the framework of the Strategic Funding UID/FIS/04650/2013 and under project PTDC/EEI-SII/5582/2014. P.M also support from FCT (SFRH/BPD/96227/20130 grants). MREs (Magneto-Rheological Elastomers) are composite materials based on magnetic particles dispersion within a non-magnetic and elastic soft matrix. Combination of these two properties leads to classifying these materials as smart materials using the conversion between the magnetic energy and elastic energy; one property is tunable through the second one. Such MREs were studied for the magnetically tuned stiffness, better known as ΔG effect corresponding to an increase of the elastic modulus G_0 of the composite as a magnetic field is acting on the particles [1]. Here, we study this material for generating electricity [2]. For this purpose, a magnetic circuit with an excitation coil and a search coil are used. A DC flux is generated by the excitation coil (a permanent magnet can also be used). Along with the magnetic circuit, a MRE which can be sheared is placed. The search coil will detect a varying magnetic flux Φ due to the effect of the MRE under shear. Experimental evidences and models can be found in the papers [2-3]. In this study, we used COMSOL® to simulate the pure shear effect on the magnetic properties of a magnetic particle and a representative composite at different magnetic field. At the particle level, assuming that the particle is a homogeneous sphere (with the demagnetizing factor N=1/3 and magnetic saturation $\mu_0 M_{p\_sat}$=2.14 T) placed in a non-magnetic medium where a magnetic field H_a exists, the particle magnetization M_p at low field is $M_p = 3H_a$. In the case of anisotropic MRE, where the composite was cured under an applied magnetic induction field, the particles form chain-like structures. The field H_a is the superposition of two contributions: the external field H_0 (along z-axis) and the field due to other particles in the chain H_p, so that $H_a = H_0 + H_p$. In this case, the field generated by other particles depends on the inter-particles distance as seen in Fig1. As the particles are getting farther, the field chain H_p is getting weaker. In a pure shear of the chain, the field H_p will change in direction and strength and consequently the particle induction magnetic state will also change as seen in Fig.2. For a representative composite cell with a filling factor of 30%, the saturation is 510000 A/m. At low shear ($dy/2a$=0.1) the particles are magnetically saturated by a magnetic induction field around B_0=0.5 T whereas at relatively high shear ($dy/2a$=1.3) the particles are magnetically saturated around B_0=0.8 T which is the usual saturating field of an isolated (non-interacting) ferromagnetic sphere. As the composite is sheared, the average volume of the representative composite cell induction is decreased to the non-interacting position. Moreover, as the inter-particles distance dz is reduced, the change ΔB is larger. This is this change of induction ΔB which can be converted into electricity.

EB-03. Dynamic Characterization of a Magnetostrictive-based Sensor for Fast Force Profile Detection.

V. Apicella[1], C.S. Clemente[1], D. Davino[1], D. Leone[1] and C. Visone[1]
1. Department of Engineering, University of Sannio, Benevento, Italy

Force detection in mechanical systems is a task of great interest in several technological applications and hence the development of new force sensors able to operate without undergoing measurement alterations due to electromagnetic disturbances, focused the attention of both industry and research in last years. Attention is so focused on new materials able to exploit the simplest transduction principle, in order to guarantee the easiest sensor design and, at the same time, show good durability properties that allows the sensor to be employed in the widest application range. These features make *Galfenol,* an *Fe-Ga* alloy, a suitable candidate for the development of force sensors. In [1], a new methodology based on the anisotropy energy measurement has been exploited with the aim of estimate the stress state of a Galfenol sample if subjected to external compressive forces. Since the procedure makes use of the well-known *quasi-static* magnetic characteristic of the magnetostrictive material, it has proved to be effective only if slow varying force profiles are applied to the sensing device. Actually, there are lots of applications which require the detection of forces with high rate of variation. In limit cases, the detection of impulse-like forces, i.e. crashes, would also be required. A remarkable example is represented by automotive applications, such as crash sensors for air-bag actuation systems, [2]. It is clear that, when fast force profiles are of concern, the procedure described in [1] is not appropriate, since it neglects any dynamic effect that can appear into the material for fast input variations, [3], as, for example, magnetic diffusion phenomena, [4, 5]. In this work, a dynamic characterization of a Galfenol cylindrical sample of *30 mm* length and *5 mm* diameter is carried out, with the aim of develop a magnetostrictive force sensor able to detect and measure fast inputs, up to the crash limit. As often proposed in literature, for example in [6], the idea is to use a *Hammerstein-like* system which assumes the splitting of the nonlinear static characteristic and hence to identify the dynamic contribution to the whole magneto-mechanical sample response. The starting point is represented by the *quasi-static* Galfenol characteristic, shown in Figure 1. In particular the figure shows the *Flux Density, B,* with respect to the external applied compressive stress, σ. Different curves are represented for different values of the magnetic bias field. These curves could be used to measure a slow varying force profile, by a proper modeling of the rate-independent memory effect. Conversely, if fast input forces are applied to the specimen, the dynamic behavior can be taken into account and modeled through the exploitation of the *Hammerstein system* sketched in Figure 2. The first block refers to the above described *quasi-static* characteristic of the material. At this stage the hysteresis is neglected and, as a consequence, Π[σ] is a non-linear function without memory. The second block describes a *linear dynamic* system and *G(s)* is its transfer function in the *Laplace* domain. The first block, Π[σ], could be identified by a suitable quasi-static measurements set, while the linear dynamic subsystem *G(s)* is identified by standard methods, from experimental data collected in dynamic conditions. This preliminarily requires the compensation of the nonlinear static part of the system accomplished through the construction of the inverse (or compensator) of Π[σ] operator. It is also important noting that, as described in [7], a special attention must be paid to the bias value which modifies the working point on the static characteristic which could affect the entire identification procedure. Finally, once the whole response of the specimen has been completely described, arbitrary force profiles can be applied to the sample in order to validate the proposed model.

EB-04. Effect of substrate temperature driven magnetic anisotropies on the magnetostrictive behaviour of Tb-Fe-Co thin films.

U. K[1,2], A. Talapatra[3], *A. Chelvane*[1], J. Mohanty[3] and J. V[2]
1. Defence Metallurgical Research Laboratory, Hyderabad, India;
2. Physics, National Institute of Technology Warangal, Warangal, India;
3. Physics, Indian Institute of Technology Hyderabad, Kandi, Sangareddy, India

Rare earth transition metal based alloy thin films exhibit giant magnetostriction owing to the large magnetic anisotropy arising from the rare earth sub-lattice. Elaborate studies carried out on these films have shown that Tb-Fe-Co based thin films are promising candidates for magnetostrictive applications as their magnetic anisotropy and thermal stabilities are large [1,2]. Tb-Fe-Co magnetic phase diagram shows that films with compositions $Tb_{10}(Fe,Co)_{90}$ and $Tb_{50}(Fe,Co)_{50}$ exhibit strong in-plane (IP) magnetic anisotropy which is an important mandate for realizing high magnetostriction [3,4]. Recent studies carried out on $Tb_{10}(Fe,Co)_{90}$ films have shown that presence of competing IP and out-of-plane (OOP) magnetic anisotropies has been found to be detrimental for magnetostriction [4]. Hence, there is an interest to explore the magnetic properties of $Tb_{50}(Fe,Co)_{50}$ films. It has also reported recently, that a considerable improvement in the magnetostriction has been obtained for thin films processed with in-situ substrate heating during thin film deposition [5]. In this context, a study has been planned to investigate the magnetic and magnetostrictive behaviour of $Tb_{50}(Fe,Co)_{50}$ films grown with different substrate temperatures. $Tb_{50}(Fe,Co)_{50}$ films were grown on Si <100> substrates by dc magnetron sputtering employing an alloy target. Prior to deposition a base vacuum of 1 x 10^{-8} torr has been achieved in the sputtering chamber. During deposition films were grown with different substrate temperatures (T_s) *viz*., 30, 300, 400, 450, 500 and 550^o C. Deposition parameters such as sputtering power (50 W) and gas pressure (5 m.torr) were kept constant for all the depositions. Structural and microstructural investigations were carried out using X-ray diffraction (XRD) and scanning electron microscopy (SEM) respectively. Simultaneous atomic and magnetic force microscopy (AFM/MFM) studies were carried out for the as-deposited and films processed with various T_s to observe the topography and magnetic domains. IP and OOP magnetization curves were traced upto maximum magnetic field of 15 kOe. IP magnetostriction measurements were measured using a homemade optical setup. The thickness of the as-deposited and films processed with different substrate temperatures are found to be ~150 nm. Structural studies showed that the as-deposited Tb-Fe-Co film is amorphous in nature. Upon increase in T_s, formation of $Tb_2(Fe,Co)_{17}$ phase could be noticed. Surface roughness estimated from AFM studies indicated an increase in the surface roughness with increase in T_s. SEM studies exhibited a globular kind of surface morphology whose sizes increased with increase in T_s owing to the growth of Fe-Co grains. Magnetization studies showed an IP magnetic anisotropy for the as-deposited film with low coercivity. With increase in T_s, a spin reorientation transition (SRT) from IP to OOP direction (SRT1) could be noticed (Fig. 1). Accordingly, the OOP coercivity was found to increase with increase in T_s. With subsequent increase in T_s (> 450^o C) the film undergoes one more SRT from OOP to IP direction (SRT2) (Fig. 2). The possible reason for SRT1 could be attributed to the magnetoelastic anisotropy arising due to the interfacial stresses developed in the film owing to the difference in the thermal expansion co-efficient between the film and interface [6]. The large formation of randomly distributed $Tb_2(Fe,Co)_{17}$ phase induces SRT2 at higher T_s. MFM image of as-deposited film indicate weak domain contrast with no identifiable domain pattern. However, with increase in T_s the OOP magnetic contrast is found to be enhanced (Fig. 1). The magnetic phase difference (MPD) which is a figure of merit to quantify the strength of OOP magnetic components show a considerable increase with increase in T_s upto 400^o C (Fig. 2). With subsequent increase in T_s the MPD decreases. Finally, the film grown at 550^o C shows a weak domain contrast devoid of any domain pattern. The microscopy results further confirms the SRT transitions observed from magnetization studies. Magnetostriction estimated from tip deflection measurement has been found to decrease marginally with increase in T_s upto 300^o C. Films deposited with higher substrate temperatures such as 400 and 450^o C show small change in magnetostriction owing to strong OOP magnetic anisotropy [4]. With subsequent increase in T_s, the magnetostriction was found to increase considerably. The possible reason for the increase in magnetostriction at higher substrate temperatures (> 450^o C) can be attributed to the formation of crystalline $Tb_2(Fe,Co)_{17}$ with enhanced grain sizes and relaxation of residual stresses. Based on the structural, microstructural (surface and magnetic), magnetization and magnetostriction studies a strong correlation between magnetic anisotropy and magnetostriction has been established.

Magnetic shape memory materials display multifunctional properties (e.g. magnetomechanical, magnetocaloric, magnetoreisistive) arising from the presence of a martensitic transformation and magnetic states [1]. Low-dimensional materials, mainly thin films, have recently attracted much interest for their possible integration in micro/nanosystems for the realization of new-concept devices (e.g. microactuators, energy harvesters, solid-state microrefrigerators) [2]. Microstructure engineering is crucial for the optimization of their functional behaviour, where twin variant configuration plays a major role. The intimate link between magnetic and structural degrees of freedom and the hierarchical twin-within-twin martensitic structure makes epitaxial films and nanostructures a unique platform for the precise control of the structural and magnetic configuration from the atomic to the macroscale We have shown that in epitaxial thin films the magnetic and structural properties can be optimized at the different length-scales by an appropriate choice of substrates/underlayers, thickness and growth parameters [3, 4]. In addition, we have found that lateral confinement in patterned thin films in able to strongly influence the twin variants configuration [5]. In the present paper we will mainly focus on the relation between the film microstructure and magnetization processes by performing micromagnetic simuations. Ni–Mn–Ga thin films of thickness ranging from 75 to 200 nm were epitaxially grown in the temperature range T=200-400 °C by rf sputtering on a 50 nm on MgO (001) and Cr/MgO(100) changing sputtering rate and applied stress at the substrate during growth. Thermal treatments in the same T range were done after growth also in presence of applied stress along selected substrate crystallographic directions. The films were deposited from a target of composition $Ni_{49.3}Mn_{27.8}Ga_{22.9}$ (at%) and show a monoclinic martensitic structure at RT. Their characterization was carried out by different techniques, thus realizing a multi-scale structural and magnetic study. The sample microstructure was studied by means of Scanning Electron Microscopy in conventional and backscattered mode. The microstructure at the nano and atomic scale was investigated by Scanning Transmission Electron Microscopy (STEM), high resolution TEM imaging and Electron Diffraction. X-ray diffraction was collected using a diffractometer equipped with a solid-state Si(Li) Peltier detector and an environmental chamber. Atomic Force and Magnetic Force Microscopy were performed to correlate the magnetization patterns and the magnetic domain structure to the microstructural pattern. A thorough magnetic study was performed in the temperature range 4-300 K by means of Alternated Gradient Force, SQUID and Vectorial Vibrating Sample magnetometry. By applying T and stress to the substrate during and after growth, a variety of martensitic patterns (i.e. orientation and spatial organization of the martensitic twin variants) can been obtained for epitaxial thin films of different thickness, giving rise to peculiar magnetization processes. Metamagnetic processes characterized by magnetization jumps of variable intensity along different crystallographic directions have been found and correlated with the orientation and spatial organization of the martensitic twin variants. The micromagnetic simulations demonstrate that magnetization jumps, typically attributed to the magnetically induced reorientation of twin variants, similarly to what occurs in bulk materials, can have a purely magnetic origin and can take place in the first quadrant of the (M,H) diagram, with variable intensity (Figure 1). The results of the simulations have been compared with a detailed experimental investigation realized by magnetometry and vectorial magnetometry: we have measured magnetization curves along different directions of the substrate crystal, simultaneously recording parallel and transverse components of magnetization

EB-06. Magnetostrictive Behaviors of fcc-Co Single-Crystal Films under Rotating Magnetic Fields.

T. Kawai[1], K. Serizawa[1], M. Ohtake[2] and M. Futamoto[1]
1. Chuo Univ., Tokyo, Japan; 2. Kogakuin University, Tokyo, Japan

Introduction Meta-stable fcc-Co structure has been stabilized in thin films prepared by molecular beam epitaxy or by sputter deposition[1] and much interest is paid for their magnetic properties in comparison to those of stable hcp-Co structure. The magnetic anisotropy of fcc-Co film has been already reported[2]. However, there is no systematic study on magnetostriction. In this study, fcc-Co single crystal films with three major planes of (100), (110), and (111) were prepared and the magnetostrictive behaviors were investigated under rotating magnetic fields up to 1.2 kOe. The experimental results were analyzed by using a coherent rotation model of magnetization under applied magnetic fields. Experimental procedures Co films with 500 nm thickness were deposited on MgO(001) and MgO(110) single-crystal substrates with under layers of Pd and Cu and on Al_2O_3(0001) single-crystal substrate directly using an UHV RF magnetron sputtering system at a substrate temperature of 300 °C for MgO and 150 °C for Al_2O_3 substrates[3]. The film structure was analyzed by RHEED and XRD. The film structures were confirmed to be fcc(001), fcc(110), and fcc(111) single-crystal respectively. Magnetostriction was measured by using a cantilever method under rotating magnetic fields up to 1.2 kOe. Magnetostriction observation directions were along [100] and [110] for (001) and (110) films and along [112] for (111) film. Assuming a coherent rotation of magnetization, the magnetostrictive behaviors were analyzed. Results and discussion Figure 1 shows the magnetostrictive behaviors measured for fcc-Co films with different orientations measured under a magnetic field at 1 kOe. For the (001) film, the output waveform is triangle along [100], which is the hard magnetization axis, and bathtub-like along [110], which is the easy magnetization axis. The experimental results reflect four-fold in-plane anisotropy. On the other hand, the output waveforms for the (110) film are different from those of (001) film, even though the observation directions are similar. The output waveform is sinusoidal for the (111) film. The experimental results were analyzed by using a coherent rotation model of magnetization. The behaviors for (001) film show good agreement with the calculated results assuming a four-fold in-plane magnetocrystalline nisotropy, whose easy magnetization axis is along <110> and hard axis along <100>. Under the condition, the magnetization tends to keep the direction along the easy magnetization direction under rotating magnetic filed. The results for (110) film along <100> is similar to the calculation showed in the Fig. 1 (d) assuming the uni-axial anisotropy, where the easy axis is along <100>. In the (110) plane, the anisotropy due to hetero-epitaxial growth is considered to be dominant. For the (111) film, the magnetic property is almost isotropic because K_1 can be neglected in the plane. Therefore, the magnetization rotates simultaneously with applied rotating magnetic fields and the output looks like sinusoidal as expected. The magnetostriction constants, λ_{100} and λ_{111}, are respectively estimated to be 90×10^{-6} and -40×10^{-6}. The large positive value of l_{100} is consistent with those of fcc Co-Ni alloys[4] and also consistent with that of the first-principle calculation[5].

EB-07. Microstructure and elastocaloric effect in as-undercooled $Pd_{59.3}In_{23.2}Fe_{17.5}$ magnetic shape memory alloys.

Q. Shen[1] and J. Liu[1]
1. Key laboratory of Magnetic Materials and Devices, Ningbo Institute of Material Technology and Engineering, Ningbo, China

Based on the reversible martensitic transformation (MT) induced by uniaxial stress accompanying a large latent heat release/absorption, the research on elastocaloric effect (eCE) refrigeration has been rapidly developed due to the relatively simple design of cooling systems. Shape memory alloys (SMAs) undergoing a diffusionless MT exhibit large eCE owing to a stress driven MT from cubic austenite to a lower symmetric martensitic phase [1]. The outstanding superelastic behavior, good ductility and metamagnetic transformation suggest Pd-In-Fe magnetic SMAs as a great candidate of eCE. From the previous report [2], the MT temperatures of Pd-In-Fe alloys are sensitive to the Pd content. In addition, the annealing at high temperature of 1473 K for 24 h is required to obtain a homogeneous microstructure. The high undercooling solidification treatment has been proposed to refine grains and increase the MT temperatures, as well as to directly obtain the chemically homogenized samples [3]. In this study, we have prepared $Pd_{59.3}In_{23.2}Fe_{17.5}$ alloys by undercooling process upon a degree of 170 K below the liquid temperature. Microstructure was observed by Scanning Electron Microscopy (SEM) and transmission electron microscopy (TEM) and eCE was investigated by universal testing machine with a K-type thermocouple. Fig. 1 shows the SEM backscattered image and TEM microstructure of as-cast and as-undercooled $Pd_{59.3}In_{23.2}Fe_{17.5}$ alloys, respectively. For the as-cast sample, typical dendritic morphology is observed (a), whereas homogeneous austenitic phase at room temperature is obtained by annealing at 1473 K, indicating it transforms below room temperature (~ 250 K). In contrast, a 2*M* martensitic structure with typical microtwins at room temperature can be seen in (b) for the as-undercooled sample. The appearance of martensitic phase in the as-undercooled sample is ascribed to the large recalescence inducing residual internal stress. Fig. 2 shows adiabatic temperature change (ΔT) as a function of temperature of the as-undercooled sample when loading the stress of 154 MPa in the temperature range of 312 - 361 K. As the loading stress is up to 500 MPa, there is no MT recorded for the as-cast sample with dendritic structure, and thus the ΔT is negligible. The value of ΔT is 2.1 K at 312 K as the sample still contains a part of martensitic phase. With increasing temperature, the ΔT starts to increase up to 2.8 K until 326 K due to the larger fraction of austenite phase. Then ΔT decreases with further increasing the initial temperature as the critical stress to induce MT becomes higher and correspondingly the transformation fraction is smaller. The temperature window is as wide as 50 K. Our results indicate that the highly undercooled $Pd_{59.3}In_{23.2}Fe_{17.5}$ alloy is promising to be a new magnetic SMA with large eCE and easy to be prepared.

1. Introduction Magneto-optical (MO) effects enable non-reciprocal optical components like optical circulators and isolators as well as a magneto-optical spatial light modulator with switching speeds superior to a digital micromirror and a liquid crystal device. To develop a magneto-optical device with high performance, it is desirable to use materials with large rotation angles and small extinction coefficients. In other approaches introduction of nanostructures, magnetophotonic crystals [1] and localized surface plasmon resonance (LSPR) [2] has been shown to provide enhancement of the Faraday effect for distinct wavelengths. This work shows how rectangular arrays of gold (Au) particles embedded into thin films of bismuth-substituted yttrium iron garnet (Bi:YIG) offer different phenomena in comparison with the square arrays previously studied [3] [4] [5]. This enhancement of Faraday rotation was first observed in samples fabricated and characterized experimentally [6]. 2. Simulation approach Our finite-difference time-domain (FDTD) simulations focus on a periodic array of spherical Au particles embedded into a film of Bi:YIG on a fused quartz substrate, as shown in figure 1. The structure uses a rectangular unit cell with a width of 200 nm and a depth of 200 to 300 nm. A diameter of 120 nm was chosen for the Au particles. The dimensions are chosen this way to observe the enhancement of the Faraday effect, as similar to previous experimental samples [6]. The magnetic field is oriented perpendicular to the surface. Large rotation of several tens of degrees of linearly polarized light incident at an angle of 45° between the x and Y axes of the unit cell is mainly caused by the structure effect of the rectangular array of Au particles. To determine the Faraday rotation (FR), it is necessary to remove this structure effect from the results through simulations for both positive and negative magnetic fields, which is the same procedure as the conventional measurement method of Faraday rotation angle. 3. Results and Discussion From components of the electrical field of the transmitted light, it was observed that this large rotation can be attributed to different transmission minima for the x- and y- polarized components of the field. Figure 2 shows FR and transmission of a 200 by 250 nm array after removal of the effects mentioned above. While enhanced FRs were observed for distinct structure geometries for incident polarizations of 0° and 90°, transmissivity minima coincident with the Faraday rotation maxima were caused by the excitation of surface plasmon resonance for the polarized incident light waves in x- and y-directions. However, for diagonally polarized incident light at 45°, the FR maximum does not coincide with any minima, which is not observed in the square arranged particles. At 45° the peak in FR occurs at the wavelength where the structure-induced polarization rotation becomes zero. FDTD simulations with varied Bi:YIG layer thickness and particle spacing in y-direction were performed in search of the optimum geometry. Taking into account the transmission as well through computing a figure of merit as the product of the absolute value of the FR and the square root of the transmission is a well-established method to gauge the utility of magneto-optical materials and devices. There appears to be a specific Bi:YIG layer thickness for each y-direction array spacing where significant Faraday rotation enhancement happens, which can be attributed to coupling of the plasmon and waveguide modes of the structure. The wavelength where this maximum enhancement occurs was found to increase linearly with the y-direction particle spacing when the Bi:YIG layer thickness is chosen optimally. A Bi:YIG layer thickness of 160 nm and a particle spacing of 260 nm in y-direction appeared to provide the highest figure of merit, and thus seem favorable for experiments. 4. Conclusion The extraordinary enhancement of the Faraday effect in thin garnet films through rectangular Au particle arrays, as previously observed experimentally, has been thoroughly examined and visualized by simulation. The non-square geometry can help overcoming the spectral coincidence of high magneto-optical response and low transmissivity, known as a major problem in the efforts to achieve high-performance, thin MO devices through utilization of LSPR. Experimental analysis based the ideal geometric parameters determined by simulation is ongoing in order to corroborate the simulation results as well as prior experiments. Generation and manipulation of spin (angular momentum) is an important step in developing spintronics devices. One priority is to combine and convert spin information in current electronic technologies, such as charge current, voltage or light. Especially, optical generation of spin current or spin-polarized charge current has attracted attention for contemporary spintronics, aiming at efficient energy conversion with spin information. Splitting the electron band by spin-orbit interactions allows creation of photocurrent by injection of circularly polarized light. Signature of the photocurrent appears under illumination of circularly polarized light and reverses its direction when the polarization is changed to opposite direction due to the Circular Photogalvanic effect (CPGE) [1]. This effect has been already studied in many materials such as topological insulator, Rashba bulk and semi-conductor quantum wells. Our work focuses on the optical characterization of the interface between Copper(Cu) and Bismuth Oxide(Bi_2O_3). Interestingly, recent works done with electrical spin pumping experiment [2] and characterization using MOKE system [3] showed that Cu/Bi_2O_3 interface present Rashba-like spin orbit interaction. Here, we demonstrate a new functionality of a spinphotovoltaic converter at room temperature at an all-nonmagnetic interface, in visible range energies occurring at Cu/Bi_2O_3 interface. The oblique incidence dependence at two distinct laser energies, reflects independent signatures for spin-photovoltage excited above and below the optical transition of Bi_2O_3. This interface is formed between a 30 nm thick Cu layer and 20 nm thick Bi_2O_3, these thicknesses are selected to avoid interaction with the Si/SiO_2 substrate and the excitation light. The texture of the Cu layer at the interface reflects preferential (111) orientation while our Bi_2O_3 layer is amorphous in alpha-phase which is the most stable phase at room temperature with an expected energy band gap E_g=2.85 eV. Our light excitation are continuous wave lasers at energies of 1.15eV, 1.96 eV, and 3.05 eV. The photon polarisation is controlled by a linear polariser and a quarter wave plate mounted on a rotator. As the workfunction of Cu (4.45 eV) is lower than the workfunction of Bi_2O_3 (4.92 eV), it forms a Ohmic junction. In figure 1, we show a typical result of our helicity dependent photovoltaic measurement, obtained with an excitation laser energy of 1.96eV. Changing contributions of polarized light due to the rotation of the quarter wave plate leads to periodic modulation in photovoltage with a periodicity of 90 deg. Photovoltage peaks have different amplitudes, showing periodically two different values. This asymmetry comes from the circularly polarised light modulation. From this asymmetry, at a laser energy of 3.05eV at 1mW, we estimated the spin current by taking the voltage due to circular polarisation from fitting and obtained $J_s = 1.3*10^7$ A/m^2 which is comparable with spin current generated by spin pumping experiments [2] but significatively better than previous report on Pt/GaAs [4]. An other interesting result is showed Figure 2 and represents the dependence of the circularly polarised voltage V_C on the angle of incidence, for a laser energy of 1.96eV and power of 50uW. In contrast to previous experiment, the energy of the laser does not excite the direct optical transition of Bi_2O_3. The photovoltage excited by 1.96eV laser can be attributed to metal induced gap states at our Cu/Bi_2O_3 interface. At metal/semiconductor interface, the electron wavefunction of the metallic side penetrates into the forbidden gap creating the so-called metal induced gap states (MIGS) and presence of MIGS states have been observed in metallic interfaces with both semiconductor and insulator [5]. Regarding these results, we discuss the conversion process. Photovoltaic conversion efficiency is mainly determined by two factors, efficiency in optical absorption and efficiency in carrier disassociation (electron-hole). At the Cu/Bi_2O_3 interface, the lack of inversion symmetry induces spin orbit interaction of Rashba type. Recent reports [6-7] showed reduced carrier recombination due to the appearance of Rashba spin orbit coupling, enhancing the carrier disassociation in perovskites. Our study reflects the relevance of selecting appropriate engineering of heterojunctions. In conclusion, we showed the photovoltaic conversion with helicity dependence at Cu/Bi_2O_3 interface at visible energies where solar spectrum peaks. Due to the increase number of interfaces with spatial broken symmetry, we expect that the present work motivates further studies, advancing conversion efficiencies and further understanding.
