Resent research has demonstrated the enhancement of magneto-optical effects in structured media. In particular, the attention has been paid to plasmonic crystals which are periodic structures supporting surface plasmon polaritons. It was demonstrated that the transverse Kerr effect and the Faraday effect are resonantly enhanced in magnetoplasmonic crystals, and also novel promising effects arise, namely the longitudinal intensity effect [1-3]. As a rule, these effects are of resonant nature, due to their relation to the excitation of eigenmodes, which leads to narrow spectral range of magneto-optical response. In the present work, we propose and demonstrate an approach for forming a broadband magneto-optical response using one-dimensional magnetoplasmonic quasicrystals. Plasmonic quasicrystalline structures offer advances in their optical response over their periodic counterparts, such as broadband and polarization-independent optical transmittance [4]. The considered 1D magnetoplasmonic quasicrystalline structure is formed by a metallic quasicrystal grating on top of the smooth magnetic dielectric layer on a substrate. The sequence of metal stripes and air slits of the grating can be described by symbols ‘1’ and ‘0’. Our structure is based on the 1D binary Fibonacci sequence, where ‘0’ is substituted by ‘010’. The metal grating of the experimentally studied samples is made of 80-nm-thick gold layer. The air slit width corresponding to single ‘0’ in the binary sequence is 80 nm and the metal stripes width corresponding to single ‘1’ in sequence is 600 nm. The magnetic dielectric is bismuth substituted iron-garnet of composition $Bi_{1.5}Gd_{1.5}Fe_{4.5}Al_{0.5}O_{12}$. The thickness of the magnetic film was made rather small, 80 nm, to exclude the waveguide modes excitation in the considered frequency range, so only surface plasmon polaritons (SPPs) can be excited. Spectrum of the SPPs excited by the incident light in a plasmonic grating structure is determined by the reciprocal lattice vectors which enter the phase matching condition. The numerical calculation of the Fourier transform of the quasicrystalline pattern reveals that the reciprocal lattice for the quasicrystal is discrete and it is far denser compared to the periodic-crystal’s one. In particular, it is non-equidistant. For example, the studied structure possesses reciprocal vectors equal to 15.39, 16.76 and 19.01 μm^{-1}, while the corresponding periodic structure has only reciprocal vector of 18.48 μm^{-1} in this spectral range. The excitation of the SPPs in plasmonic structures with magnetic materials is accompanied by the resonant enhancement of the Transverse magneto-optical Kerr effect (TMOKE). Experimentally measured TMOKE spectrum for the magnetoplasmonic quasicrystal is shown in Fig. 1, together with calculated SPP dispersion curves. It is far richer than the one for the corresponding periodic structure. Apart from the first pair of resonances at around λ=820 nm (for small incidence angles) that is quite similar to the resonances for the periodic structure, two other additional pairs appear at around λ=890 nm and λ=950 nm corresponding to the reciprocal vectors of 16.76 and 15.39 μm^{-1}. It demonstrates that the magneto-optical response of plasmonic quasicrystals is broadband, contrary to single narrow resonances in the case of periodic structures. It makes the proposed structures very promising for numerous nanophotonics applications including optical sensing, control of light, all-optical control of magnetization etc. Additionally, TMOKE spectroscopy is an efficient tool for investigation of the peculiarities of plasmonic quasicrystals. The multiplicity of the excited plasmonic modes attracts attention also because they possess different values of the penetration depth. Estimations show that for the plasmonic resonances shown in Fig.3a the SPP penetration depth in the magnetic dielectric varies approximately from 70 to 100 nm. This fact opens new possibilities for manipulation of the optical near field, 3D sensing, control of the inverse magneto-optical effects and optically-induced magnetization. Quasicrystalline structures provide designable reciprocal lattice, i.e. the set of reciprocal vectors and therefore, dispersion of eigenmodes, by means of adjusting geometrical parameters. In particular, plasmonic quasicrystals offer designable spectrum of magneto-optical response for light modulation, which is prosperous for parallel light information processing at several frequencies. Furthermore, the plasmonic quasicrystals are prosperous for achieving other broadband magneto-optical effects related to the excitation of eigenmodes. If the structure supports waveguide modes then there are many resonances for TE and TM modes with the resonant wavelengths close to each other. This condition is favorable for the enhancement of the Faraday effect and the longitudinal intensity effect, as the TE-TM conversion is the most effective. The work is supported by the Russian Presidential Grant MK-2047.2017.2.

Further reduction of the consumption energy for the magnetization switching of a free layer of magnetic tunnel junctions (MTJs) is required in a spin transfer torque magnetoresistive random access memory (STT-MRAM). Using ferromagnetic materials with small magnetic anisotropy for the free layer can reduce the consumption energy but it will also cause the loss of thermal stability. Our group has proposed strain-assisted magnetization reversal (SAMR) using inverse magnetostriction (IMS) MTJs to reduce magnetic anisotropy only during the switching [1]. The proposed IMS-MTJs consist of an MTJ with a magnetostrictive material for the free layer and a piezoelectric material surrounding the MTJ pillar to apply pressure to the free layer effectively. Since lowering magnetic anisotropy caused by the inverse magnetostrictive effect, which results in a reduction of the switching current, occurs only while magnetization switching, thermal stability of the free layer will be kept. Ferromagnetic materials for the free layer of IMS-MTJs are required to have both a large, negative magnetostriction constant λ and perpendicular magnetic anisotropy (PMA). $SmFe_2$ is promising as such materials since $SmFe_2$ is well-known materials with large negative magnetostriction constant [2]. In addition, $SmFe_2$ films are expected to have PMA since some amorphous rare earth transition metal (RE-TM) alloys have been reported to show PMA [3]. In this paper, we systematically investigated magnetic anisotropy and magnetostriction of sputtered $SmFe_2$ thin films, and found that amorphous $SmFe_2$ films showed PMA and large, negative λ. All the films were prepared with a facing targets sputtering system. The stack structure was quartz-substrate/W (20nm)/Sm-Fe (100nm)/W (10nm). The substrate temperature T_S during sputtering varied from RT to 400°C. The post annealing temperature T_A also varied from 300°C to 600°C. The chemical composition of deposited Sm-Fe film was determined to be 1.05:2 by inductively coupled plasma-optical emission spectrometer (ICP-OES). X-ray diffraction (XRD) analysis showed that all of the fabricated $SmFe_2$ thin films had amorphous structure. Figure 1(a) shows *M*-*H* curves for a $Sm_{1.05}Fe_2$ film formed at T_S = 200°C and post-annealed at T_A = 500°C measured by vibrating sample magnetometer (VSM) with perpendicular and in-plane magnetic fields, clearly indicating that the $Sm_{1.05}Fe_2$ film had PMA. ΔK, difference between perpendicular and in-plane magnetic anisotropy energy density, was determined to be 0.17 Merg/cc. Figure 2(b) shows ΔK of the $Sm_{1.05}Fe_2$ thin films with various T_S and T_A. PMA were observed only in the $Sm_{1.05}Fe_2$ films formed at low T_S and annealed at high T_A. One of the origin of this PMA in the amorphous $Sm_{1.05}Fe_2$ films could be anisotropic, short range order similar to other amorphous RE-TM alloys [4]. Then, IMS effect of the $Sm_{1.05}Fe_2$ thin film with T_S = 200°C and T_A = 500°C exhibiting PMA were analyzed. Pressures were applied to the sample by sandwiching it with two sample holders having the same curvature radius. In this experiment, a 0.03-mm thick quartz substrate was used to prevent it from cracking while bending. Figure 2(a) shows the demagnetization curves in the first quadrant under various applied pressures. The sample qualitatively exhibited negative λ as magnetization energy reduced (the demagnetization curve shifted in the upward direction) by compressive stress and increased by tensile stress. The change, $\Delta K_{|\sigma|}$, of the magnetization energy density of the $Sm_{1.05}Fe_2$ film by stress was quantitatively evaluated from the demagnetization curves. Figure 2(b) shows $\Delta K_{|\sigma|}$ as a function of induced stress. The slope is equivalent in -3λ and λ was determined to be -920 ppm. From these results, we concluded that the $Sm_{1.05}Fe_2$ film formed at T_S = 200°C and T_A = 500°C exhibited both PMA (ΔK = 0.17 Merg/cc) and large, negative magnetostriction ($\lambda = -920$ ppm). In conclusion, we found that $Sm_{1.05}Fe_2$ thin films formed at low T_S and annealed at high T_A showed PMA. One of the possible origins of this PMA is the anisotropic, short range order of Sm and Fe atoms. The $Sm_{1.05}Fe_2$ film with T_S = 200°C and T_A = 500°C exhibiting PMA also showed large, negative magnetostriction $\lambda = -920$ ppm. This result indicates that $Sm_{1.05}Fe_2$ thin films are promising as the free layer of IMS-MTJ for ultra-low energy STT-MRAMs.

Shape memory alloys (SMAs) are a group of metallic alloys that recover to their original form after deformation. Shape memory effect (SME) is characterized by diffusion-less transition between two phases: austenite and martensite [1]. Up to date, the Heusler alloy with chemical composition Ni-Mn-Ga (near to stoichiometry 2:1:1) is one of the prototype of SMA [2]. This alloy is known for its large recoverable deformation up to 12% strain and high-frequency response (up to 1 kHz) induced by magnetic or mechanical loadings. However, in spite of its remarkable properties, Ni_2MnGa has some drawbacks originating from the loss of Mn, relatively low Curie and martensitic transformation temperatures etc. [3]. Therefore, it is necessary to develop new alloy systems to overcome such a disadvantage. Alternatively, Ni_2FeGa alloy have been proposed as promising magnetic shape memory alloy. Taylor-Ulitovsky method for production of glass-coated microwires allows easy production of few kilometres of high quality monocrystalline wire along entire length with well oriented crystallographic axis. It is shown that such wire is characterized by temperature induced shape memory effect accompanied by ~2% reversible strain. As a result of different anisotropy of both low- and high- temperature phase, such strain is accompanied by huge variation of permeability. In the given contribution we show how magnetic parameters must be adjusted in order to achieve up to 1600% change of permeability due to the phase transition. Such variation allows us to control straining very precisely, which transforms the microwires into the SMART shape memory actuators. This work was supported by APVV-16-0079.

Voltage-controlled magnetic anisotropy (VCMA) effect is drawing attention as a promising approach for low-power spin manipulation in future spintronic devices [1,2]. Purely electronic VCMA effect originates from several mechanisms, such as the electric-field induced change in electronic occupation states [2] and induction of magnetic dipole moment [3], at the interface between ultrathin ferromagnetic metal and dielectric layers. Successful application of VCMA effect in MgO-based magnetic tunnel junctions (MTJs) [4] realized voltage-induced dynamic magnetization switching [5-7] and exhibited the feasibility of voltage-controlled spintronic devices, such as voltage-torque MRAM. For the voltage-induced dynamic magnetization switching, we need to eliminate the perpendicular magnetic anisotropy (PMA) energy to induce precessional dynamics of magnetization around an applied in-plane magnetic field. Since the higher PMA is required for smaller element to keep sufficient thermal stability, more efficient VCMA coefficient is demanded to show the scalability of voltage-torque MRAM. For example, target values are estimated to be 300 fJ/Vm for cache memory and 1000 fJ/Vm for main memory applications [8, 9], however the demonstrated VCMA effect with high speed response is limited to be about 100 fJ/Vm in practical MTJ devices [10, 11]. First principles calculations predict that utilization of large spin-orbit constant in 4*d* and 5*d* transition metals is effective to enhance the VCMA effect, for example by inserting a heavy metal monolayer at the Fe/MgO interface [12]. Stimulated by this expectation, we developed a new technique of heavy metal iridium (Ir) doping in the ultrathin Fe layer to achieve large VCMA coefficient exceeding 300 fJ/Vm [9]. Fully epitaxial MTJs consisting of Cr(30 nm)/ultrathin Fe(t_{Fe})/Ir doping layer(t_{Ir})/MgO(2.5 nm)/Fe (10 nm)/Ta/Ru were deposited on MgO(001) substrates by a combination of molecular beam epitaxy and sputtering techniques. The ultrathin Ir doping layer, ranging from $0 \leqq t_{Ir} \leqq 0.15$ nm, was inserted between the Fe and MgO layers. However, as shown in Fig. 1(a), we found that Ir atoms were dispersed uniformly into the Fe layer through the interdiffusion during the post-annealing process for the MgO layer. Figure 1(b) shows an example of polar MOKE hysteresis curves for the 1 nm-thick Fe layer with t_{Ir}=0.1 nm (red) and without doping (black). Clear transition of magnetic easy axis from the in-plane to the out-of-plane direction was induced by Ir doping. By evaluating the Fe thickness dependence of PMA, very large intrinsic interfacial PMA energy, $K_{i,0}$ of 3.7 mJ/m^2 was confirmed for the case of t_{Ir}=0.05 nm. Figure 2(a) shows bias voltage dependence of normalized TMR curves for the MTJ with t_{Fe}=0.77 and t_{Ir}=0.05 nm measured under in-plane magnetic field. Due to the orthogonal magnetization configuration for out-of-plane magnetized free layer and in-plane magnetized reference layer (top Fe) at the remanent state, saturation property in the tunneling resistance under the in-plane magnetic field application reflects the effective PMA of the free layer. Clear shifts in the saturation field were observed depending on the amplitude of the applied bias voltages. The estimated PMA change is summarized in Fig. 2(b) as a function of applied electric field. We obtained large VCMA coefficient of 320 fJ/Vm [9]. High speed response was also confirmed by voltage-induced FMR excitation. First principles calculations revealed that dispersed Ir atoms having proximity induced magnetism play a significant role to enhancing the interfacial PMA and VCMA effect. Electric-field induced modification in magnetic anisotropy energy mainly originates from the majority spin Ir-5*d* states and its amplitude can be 5-10 times larger than that of Fe atoms. Since we still have numerous choices of 4*d* and 5*d* elements, materials engineering using heavy metal doping has enourmous possibilities for further improvement in both interfacial PMA and VCMA properties. In the presentation, we'll also introduce recent effort to reduce the write error rate in voltage-induced dynamic magnetization switching [13, 14] and discuss future challenges to develop the voltage-torque MRAM. This work was supported by the ImPACT Program of the Council for Science, Technology and Innovation (Cabinet Office, Government of Japan).

Flexible electronic devices are emerging in many areas, providing novel features and creating new applications [1]. Due to their ubiquitous utilization, flexible magnetic sensors [2] play a critical part in this development. In particular, magnetic tunnel junctions (MTJs) are of great interest, because of advantages like low power consumption or high sensitivity. We report the development of flexible MTJs on a silicon substrate fabricated by a low-cost batch process [3]. Thereby, conventionally fabricated MTJ devices are transformed into flexible ones by thinning down the silicon wafer from 500 μm to 5 μm. This process leads to thin, bendable silicon devices, while maintaining their original performance. The fabrication process steps are shown in figure 1a to e. The MTJs were fabricated by standard multilayer magnetic stack deposition with an MgO tunnel barrier of 1.6 nm thickness. After backside etching of the wafer the thickness of the substrate was reduced to 5 mm as shown in the inset of figure 1f. The resulting flexible MTJ films are extremely bendable with a diameter down to 500 mm (figure 1f). The magnetic properties and magneto-transport properties of the flexible MTJs were the same as those of the rigid ones. The TMR ratio was tested under different bending conditions (figure 2a) and no degradation was found as shown in figure 2b. The reliability of the flexible MTJs was evaluated by exposing them to periodic strain cycles. To this end, an MTJ sample was mounted to an elastomeric support, which was repetitively stressed moving it from a flat state to a tensile state and visa-versa. Figure 2c shows that even after 1000 cycles, the TMR ratio showed no relevant differences (figure 2c). The presented method enables fabricating silicon devices without comprising any of their performance characteristics like cost/yield advantage or integration density. Entire devices can be fabricated prior to thinning, benefiting from standard batch processes without introducing any constraint in design, thermal budgets or fabrication methods. Therefore, these flexible silicon-based MTJs are a crucial contribution on the way to integrated state-of-the-art flexible magnetoelectronics. The maturity of silicon fabrication techniques makes the flexible MTJ sensors on silicon semiconductor substrates the natural choice for very large integration of high-performance electronic applications on flexible substrates.

EC-03. Tunneling anisotropic magnetoresistance driven by magnetic phase transition.

X. Chen[1], C. Song[1], J. Feng[2], X. Zhong[1] and F. Pan[1]
1. Tsinghua University, Beijing, China; 2. Institute of Physics, Chinese Academy of Sciences, Beijing, China

The independent control of two magnetic electrodes and spin-coherent transport in magnetic tunneling junctions (MTJs) are strictly required for tunneling magnetoresistance (TMR), while MTJs with only one ferromagnetic electrode exhibit tunneling anisotropic magnetoresistance (TAMR) [1] dependent on the anisotropic density of states and no room temperature performance so far. Apparently, during the ferromagnetic switching for the tunneling effect, only the magnetization direction is changed, where no modulation of intrinsic magnetism is involved, irrespective of one or two magnetic electrodes. Now the interest is whether there exists an elegant approach via the manipulation of the intrinsic magnetic ground state to manipulate the spin transport, which would provide an alternative opportunity to obtain tunneling magnetoresistance and make the tunneling behavior more designable. CsCl-ordered FeRh (a'-FeRh) films, show a first order phase transition from antiferromagnetic (AFM) to ferromagnetic (FM) order, which can be driven by temperature or magnetic field above room temperature [2]. Such an AFM–FM transition means a strong variation of magnetic ground state accompanied by a large DOS variation at the Fermi level. Thus, it would be fundamentally transformative if the magnetic phase transition of a'-FeRh was used to drive the tunneling effect. Basically, the AFM–FM transition itself is associated with an obvious change of resistance, but the current-in-plane geometry is not capable for implementing high density storage, thus demanding the experimental exploitation of MTJs structure with current-perpendicular-to-plane geometry as the basis of memories with a cross bar structure. Furthermore, considering the low lattice misfit between MgO and a'-FeRh, a MgO (001) substrate is commonly chosen for the deposition of epitaxial a'-FeRh, while epitaxial growth of MgO tunneling barrier is highly expected on the top of a'-FeRh bottom electrode, which would be beneficial for achieving sizeable tunneling effect. We demonstrate an a'-FeRh magnetic phase transition TAMR (PT-TAMR) with the ratio up to 20% at room temperature in MTJs with only one a'-FeRh magnetic electrode, and the polarity and magnitude of PT-TAMR are profoundly dependent on the design of the a'-FeRh/MgO interface [3].

One of the central challenges in realizing magnetoelectric (ME) devices lies in finding a deterministic way to modulate magnetism in integrated circuits with a circuit-operation voltage [1-4]. Ionic liquid (IL) gating on magnetic thin films with abundant electronic, chemical and magnetic interactions at the interface has become an emerging technology for controlling magnetism in a fast, compact and energy-efficient way. [5-7] Compared with conventional strain effect dominated piezo/ferroelectric layer multiferroics, IL gating method has advantages like small gating voltage (V_g<5 V), easy-to-integration and compatibility with varied substrates such as Si, flexible substrates etc. In additional, unlike the oxide structures require a high temperature to overcome the oxidation energy barrier, the IL gating control process can be operated at room temperature, suitable for applications in room temperature environment. Here, we will summarize our recent progresses of IL gating control of magnetism in varied magnetic heterostructures, including: 1) IL gating of ultrathin Co magnetic film as the first demonstration of quantitatively determination of spatial magnetic anisotropy;[8] 2) IL gating of perpendicular magnetic anisotropy structure (Co/Pt) with record high >1500 Oe ferromagnetic resonance field shift as well as a reversible in-plane and out-of-plane anisotropy switching; 3) IL gating of spinel ferrite (Fe O) with 600 Oe FMR field switching with great reversibility and voltage controlled phase transition; 4) IL gating of spin-orbital coupling that leads to ~1400 Oe FMR field tunability with the greatest ME coupling figure of merit in ferrites: ΔH /ΔH ~30; As thus, the IL gating process, proven to be a truly powerful and compatible gating method, enables giant ME tunability in different heterostructures and provides a tremendous potential in next generation of voltage-tunable spintronics/electronics.

EC-05. Tailoring magnetic properties of giant magnetoresistance spin-valves by inserting ultrathin noble metals between pinned and pinning layers.

S. Kim[1], J. Choi[2] and S. Lim[1]
1. Materials Science and Engineering, Korea University, Seoul, The Republic of Korea; 2. Center for Spintronics Research, Korea Institute of Science and Technology, Seoul, The Republic of Korea

In this study, the interlayer exchange coupling field (H_{int}) in giant magnetoresistance spin valves (GMR SVs) is manipulated by inserting an ultrathin noble metal spacer between pinned and pinning layers. Among many noble metals, Cu and Pt are used as a single or dual spacer layer, with the spacer thickness varied from 1 to 8 Å in steps of 1 Å. Figures 1 and 2 show in-plane MR-H curves measured along the easy and hard directions, respectively (MR and H are the magnetoresistance and applied magnetic field, respectively). It is seen from the results that there is a large change in H_{int}, the maximum GMR ratio, and the low field sensitivity depending on the type and thickness of the spacer layer. For example, an H_{int} value of 5.3 Oe observed in the sample without the spacer is dramatically reduced to 0.25 Oe after inserting a Pt/Cu dual spacer. This reduction mainly results from the increase in the switching field from anti-parallel to parallel state. It is noted that the switching field from parallel to anti-parallel state remains nearly unchanged. The increase in the maximum GMR ratio is approximately 10%, probably owing to the specular scattering at the interfaces between noble metal and its adjacent layers [1]. The low field sensitivity, an important parameter in magnetic sensor applications, is dominantly affected by H_{int}; for example, a decrease in H_{int} from 5.3 to 0.5 Oe with the insertion of the Cu/Pt dual spacer results in a significant improvement of the sensitivity from 6.01 to 12.01 mV/ mA×Oe. In summary, with the insertion of a spacer between the pinned and pinning layers, it is possible to control the H_{int} value and hence the performance of GMR sensors such as biosensors and oscillation detectors for microelectromechanical systems (MEMS) [2]. 2. Center for Spintronics Research Network, Tohoku University, Sendai, Japan

Current-perpendicular-to-plane (CPP) giant magnetoresistance (GMR) junctions are of interest for potential application to magnetic sensor elements. Half-metallic Heusler alloys are a promising class of materials for realizing a large MR ratio and an areal resistance change (ΔRA) for CPP-junctions. Interfacial properties are crucial for the value of MR ratio because the interfacial spin-scattering plays an important role for CPP-GMR as well as the bulk contribution according to a theoretical model [1]. To modify the interface contribution to CPP-GMR, ultrathin inserts have been studied for the Heusler layer/spacer interfaces to tailor the interfaces. According to previous papers [2, 3], either ultrathin non-magnetic inserts or ferromagnetic inserts drastically changed an MR ratio. Previously we reported the development of CPP-GMR junctions with an $L1_2$-type Ag_3Mg ordered alloy spacer and half-metallic $Co_2Fe_{0.4}Mn_{0.6}Si$ (CFMS) electrodes, which exhibited an enhanced MR ratio and ΔRA of 63% and 25 mΩ μm^2 at room temperature [4]. To realize a higher output for the CPP-GMR, the interface tailoring effect between $L1_2$-Ag_3Mg and CFMS has been investigated in this study. Layered film samples were deposited onto MgO (100) single crystalline substrates by using an ultra-high vacuum magnetron sputtering system (base pressure < 1 × 10^{-7} Pa). The materials for the insert were Mg or Fe with the thickness, $t_{\mathrm{Mg\ or\ Fe}}$, in the range of 0 to 0.60 nm in 0.15 nm increments. The stacking structure of the samples was MgO substrate | Cr (20) | Ag (40) | CFMS (20) | Mg or Fe ($t_{\mathrm{Mg\ or\ Fe}}$) | Ag_3Mg (5) | Mg or Fe ($t_{\mathrm{Mg\ or\ Fe}}$) | CFMS (7) | Ag (2) | Au (5), unit in nanometer. The deposition temperature was room temperature for all layers, and *in situ* post annealing was carried out at 650°C and 550°C after the depositions of Cr layer and CFMS layer, respectively. The crystal structure of surface of the upper CFMS layer was characterized by reflection high energy electron diffraction (RHEED). CPP-GMR effects were measured by a four-probe method at room temperature. For the insert thickness dependence of CPP-GMR, the bias current density, J, was set so small that the applied bias voltage was about 1 mV for the parallel magnetization configuration. The J dependence of the output voltage, ΔV for the CPP-GMR junction was also investigated. Figure 1 shows RHEED images of the upper CFMS surface for the layered film with t_{Mg} = 0.60 nm. Streak patterns are clearly observed for both azimuths of CFMS[100] (Fig. 1(a)) and CFMS[110] (Fig. 1(b)). In addition, superlattice streaks of the $L2_1$ phase are also observed for CFMS[110] azimuth, which are pointed by white markers. All other RHEED images with different inserts showed similar features. These results suggest that the epitaxial growth and the $L2_1$ phase of CFMS layer are maintained for all the samples using Mg or Fe inserts with thicknesses up to 0.60 nm. Figure 2 shows the insert thickness dependence of MR ratio and ΔV. ΔV is defined as $\Delta V = (R_{\mathrm{AP}} - R_{\mathrm{P}}) \times |I_{\mathrm{bias}}|$, where R_{AP}, R_{P}, and I_{bias} are the junction resistance at antiparallel configuration, that at parallel configuration, and applied bias current, respectively. For both insert materials, the MR ratio decreases with the thickness of the insert. On the other hand, ΔV is nearly independent of t_{Mg} and t_{Fe} up to the thicknesses of 0.60 nm and 0.45 nm, respectively. The critical current density, J_c, for the spin-transfer-torque (STT) effect was also evaluated by the shape of MR curves. With increasing the insert thickness, J_c increased slightly. These results imply that the fluctuation of magnetization suppressed because of the suppressed STT effect at a high bias J, which resulted in relatively large ΔV. The suppression of STT can contribute for reducing the noise in sensor devices, which is an attractive feature of the junctions with inserts. In summary, the interface tailoring effects for CPP-GMR junctions were investigated using Mg or Fe inserts. Although the MR ratio at low bias J decreased with the thickness of inserts, ΔV was nearly independent of the inserts' thickness. The relatively large ΔV was possibly caused by the suppressed STT effect for the junctions with the inserts, which is favorable from a view point of reducing STT-noise. EC-07. Perpendicular Anistropy in $Co_2FeAl_{0.5}Si_{0.5}$ for CPP-GMR devices.

W.J. Frost[1], M. Samiepour[1] and *A. Hirohata*[1]

Heusler alloys have signicant potential for application in giant magnetoresistance (GMR) and tunelling magnetoressitance (TMR) devices [1]. However for the next generation of devices with a current-perpendicular-to-plane (CPP) geometry it would be required that the Heusler alloys were grown with perpendicular anisotropy. For perpendicular anisotropy to be achieved it is required that a significant anisotropy be generated to meet the condition such that $K > 2\pi M_S^2$. This then requires films with a high degree of crystallisation. In general the crystallisation of Heusler alloy films requires annealing at relatively high temperatures T>300°C. In this work we describe the fabrication of Heusler alloys based on $Co_2FeAl_{0.5}Si_{0.5}$ on substrates heated to modest temperatures which nonetheless result in films exhibiting significant perpendicular anisotropy and coercivities of over 1 kOe. Previous work has shown that perpendicular anisotropy can be induced in Heusler alloys using a vanadium or tungsten seed layer deposited at 400°C [2]. The coercivity of the films is highly dependent on layer thickness and as such spin valve structures are easily constructed. In this work modest substrate temperatures T_S < 75°C have been used prior to deposition. Samples with the structure Si/W(10nm)/$Co_2FeAl_{0.5}Si_{0.5}$(12.5nm)/W(1.2nm)/$Co_2FeAl_{0.5}Si_{0.5}$(2.5nm)/Ru(3nm) were used as a basic spin valve structure. As shown in fig. 1 even the modest values of TS > 45°C lead to a partially crystallised tungsten seed layer, with a weakly crystallised $Co_2FeAl_{0.5}Si_{0.5}$ layer. Nonetheless these samples had a significant coercivity out-of-plane of up to 500 Oe. The crystallisation was enhanced by T_S being increased to 60°C. With increasing crystallisation the tungsten reflection also relaxes towards the bulk position. The increasing crystallisation is matched by a large increase in the coercivity out-of-plane up to 1 kOe. This is caused by the increase in the grain size of the films from 3.5nm to 8 nm. The nature of the magnetic reversal also changes. At low values of T_S the switching is characteristic of a film with strong intergranular coupling, with a sharp reversal at a nucleation field H_n. The presence of the intergranular exchange field is confirmed by DCD and time-dependence measurements, which gave an effective activation volume V_{eff} = 30nm. The value of the H_n increases with the crystallinity of the film. However so too does the rotation in the film, reaching almost $0.5M_S$ before H_n is reached. This is partly due to the increasing grain size. However, this is also due to an increase in the perpendicular anisotropy in the films overcoming the intergranular coupling. However, no layer thickness dependent coercivity was observed, with only one nucleation in the hysteresis loop. In order to improve the spin valve properties of the film a silver barrier layer was used instead with a thicker top $Co_2FeAl_{0.5}Si_{0.5}$ layer to improve the signal. An optimised 3nm layer of silver was found for production of CPP-GMR devices giving a device structure of Si/W(10nm)/$Co_2FeAl_{0.5}Si_{0.5}$(12.5nm)/Ag(3nm)/$Co_2FeAl_{0.5}Si_{0.5}$(5nm)/Ru(3nm) deposited at 70°C. Figure 2 shows an example of a CPP-GMR measurement of a pillar with dimensions (150 x 100) nm. The observed ΔRA is very small at around 0.03% but a sharp and distinct switch was observed. The GMR ratio will be improved by further optimising layer thickness and deposition temperatures. In this work we have shown that perpendicular anisotropy can be induced in $Co_2FeAl_{0.5}Si_{0.5}$ with modest substrate temperatures. Furthermorewe have shown that the anisotropy is strongly dependent upon the crystallisation of a tungsten seed layer and the grain size. Finally, these Heusler alloys layers can be incorporated into CPP-GMR devices operated out of plane, with a small but distinct GMR. The authors would like to acknowledge Kevin O'Grady, University of York for fruitful discussion and Seagate Technology, Derry for their support.

EC-08. Mn-composition dependence of strength of bi-quadratic interlayer exchange coupling in Co_2MnSi-based pseudo spin-valves.

M. Inoue[1], D. Mouri[1], K. Inubushi[2], K. Nakada[2], M. Yamamoto[1] and T. Uemura[1]
1. Division of Electronics for Informatics, Hokkaido University, Sapporo, Japan; 2. Technical Center, TDK Corporation, Ichikawa, Japan

Co-based Heusler alloy thin films are promising ferromagnetic electrode materials for spintronic devices, including magnetic tunnel junctions (MTJs) [1-4] and current-perpendicular-to-plane (CPP) giant magnetoresistance (GMR) devices [5-11], and for spin injection into semiconductors [12,13]. We have shown that harmful defects in Heusler alloy thin films of Co_2MnSi (CMS), $Co_2(Mn,Fe)Si$ (CMFS), and Co_2MnGe (CMG) can be suppressed by appropriately controlling the film composition; *i.e.*, Co_{Mn} antisites detrimental to half-metallicity can be suppressed and half-metallicity was enhanced by preparing CMS and CMFS thin films with a Mn-rich composition [1-5]. In light of these findings, we have demonstrated giant tunneling magnetoresistance ratios of 1995% at 4.2 K and 354% at 290 K for CMS/MgO MTJs [3] and up to 2610% at 4.2 K and 429% at 290 K for CMFS/MgO MTJs [4]. Moreover, we have observed an increase in the magnetoresistance (MR) ratio with increasing Mn composition in CMS-based CPP spin valves, and demonstrated that Mn-rich CMS is highly effective in GMR devices, as it is in MTJs [5]. However, the MR ratio decreased as the temperature decreased in a certain low temperature region [5]. A similar decrease in the MR ratio at low temperatures was previously reported for other CPP-GMR devices based on CMS, CMG, and CMFS [6-9], and its origin is still an open question. Goripati *et al*. reported that the decrease in the MR ratio at low temperatures was alleviated by spin transfer torque (STT) switching, and suggested that the origin of the reduction of MR ratio is the presence of a bi-quadratic interlayer exchange coupling (90° coupling) between the upper and lower ferromagnetic layers [6]. Thus, it is important to investigate the strength of the 90° coupling systematically to fully utilize the half-metallicity of Mn-rich CMS in GMR devices. The purpose of this study was to clarify how the strength of the 90° coupling changes with the Mn composition, α, in $Co_2Mn_\alpha Si$ electrodes. To do this, we fabricated CPP pseudo spin valves (PSVs) having CMS electrodes with various Mn compositions, α, and an Ag spacer, and investigated the influence of α on the MR characteristics and STT properties. The fabricated CPP-PSV layer structure was as follows: (from the substrate side) MgO buffer (10 nm)/CoFe (10)/Ag (100)/CoFe (10)/CMS lower electrode (10)/Ag spacer (5)/CMS upper electrode (3)/Ru cap (5) with various Mn compositions, α, in $Co_2Mn_\alpha Si_{0.82}$ electrodes ranging from $\alpha = 0.62$ to 1.40, grown on MgO(001) substrates. The preparation procedure of the CMS electrodes with various values of α was the same as the one for the CMS/MgO MTJs [1-4] and the CMS-based CPP spin valves [5]. Just after deposition of the upper electrode, the layer structure was *in-situ* annealed at 550°C. We fabricated CPP-PSVs with the junction sizes ranging from 26 × 50 nm to 320 × 525 nm by electron beam lithography and Ar ion milling. The MR curve and STT curve were measured using a dc four-probe method by sweeping the magnetic field (H) and bias current, respectively. Both measurements were done at room temperature. Figure 1(a) and 1(b) compares the MR curve and STT curve for CPP-PSVs with Mn compositions of (a) $\alpha = 0.62$ and (b) $\alpha = 1.40$. Clear MR characteristics with a hysteretic nature were obtained for both devices. Since the anti-parallel (AP) state appears around $H = 0$ without bistability, an anti-ferromagnetic coupling intrinsically existed. There were also clear changes in resistance due to switching of the magnetization configuration between the parallel (P) and AP states driven by the STT. The resistance in the AP state obtained by STT ($R_{AP}^{(STT)}$) was larger than that for the AP state obtained by the magnetic field sweep ($R_{AP}^{(Mag)}$) in all devices. This indicates that the AP state was not perfectly formed by sweeping the magnetic field due to the presence of the 90° coupling and that the STT brought the magnetization configuration more closely to the perfect AP state. Figure 2 shows the ratio of $R_{AP}^{(STT)}$ and $R_{AP}^{(Mag)}$ as a function of the Mn composition, α. The ratio increases as the Mn composition increases, indicating that the strength of the 90° coupling increases with increasing Mn composition. In summary, we investigated the influence of the Mn composition on the strength of the 90° coupling in CMS-based CPP-SVs through evaluating the MR characteristics and STT properties, and found that the strength of the 90° coupling increases with increasing Mn composition. This indicates that the Mn involved in the CMS/Ag/CMS trilayer structure plays a critical role in regard to the presence of the 90° coupling. These findings help to clarify the origin of the interlayer exchange coupling. This work was partly supported by the Japan Society for the Promotion of Science (KAKENHI: Grant Number, 17H03225).

EC-09. Control ferromagnets all electrically at room temperature without external magnetic field.

K. Wang[1]
1. Institute of Semiconductors, Chinese Academy of Sciences, Beijing, China

Electrically control the spin state in solids is the core of spintronics. We investigated the spin Hall effect control the magnetization switching in heavy metal/ferromagnet/heavy metal multilayers and also piezo voltages control the magnetization switching of heusler ally Co2FeAl. By design the device structrue, we demonstrate a strong damping-like torque from the spin Hall effect and unmeasurable field-like torque from Rashba effect. The spin-orbit effective fields due to the spin Hall effect were investigated quantitatively and were found to be consistent with the switching effective fields after accounting for the switching current reduction due to thermal fluctuations from the current pulse[1]. The spin-orbit torque switching controllablly in above structures have to have the assistant of the external magnetic field. Without breaking the symmetry of the structure of the thin film, we realize the deterministic magnetization switching in a hybrid ferromagnetic/ferroelectric structure with Pt/Co/Ni/Co/Pt layers on PMN-PT substrate. The effective magnetic field can be reversed by changing the direction of the applied electric field on the PMN-PT substrate, which fully replaces the controllability function of the external magnetic field[2]. We also investigated the planar Hall effect devices based on the tunability of the planar Hall resistance in ferromagnetic Co_2FeAl devices solely by piezo voltages, which can largely reduce the energy consumption. The room temperature magnetic NOT and NOR gates have been demonstrated based on the Co_2FeAl planar Hall effect devices without external magnetic field[3].

Department of Mechanical and Aerospace Engineering, University of California, Los Angeles, CA, United States

Spin-orbit torque (SOT) represents an energy efficient method to control magnetization in magnetic memory devices. However, deterministically switching perpendicular memory bits requires the application of an additional effective bias field for breaking lateral symmetry. Here we present a new perpendicular switching method of using voltage induced strain coupled with SOT. The strain-induced magnetoelastic anisotropy breaks the lateral symmetry which provides deterministic control of perpendicular magnetization. A finite element model and a macrospin model are used to numerically simulate the strain-mediated SOT switching mechanism. Experimental tests are being conducted to validate the models predictions. Fig. 1a shows the magnetoelastic/heavy metal/piezoelectric heterostructure simulated in the finite element model. The magnetic element is a CoFeB disk with a 50 nm diameter and a 1.5 nm thickness. Underneath the CoFeB disk, there is a thin (< 10 nm) heavy metal (e.g., Ta) strip with the SOT current applied 45° from the *y* axis. At t = 0, a ±0.5 V voltage is applied to the two top electrodes while a current density of 5×10^7 A/cm^2 is applied to the heavy metal strip. Both voltage/current inputs are removed at t = 2 ns. The simulation results shown in Fig. 1b clearly demonstrates that the switching direction ('up' or 'down') is dictated by the voltage polarity (positive or negative) applied to the piezoelectric layer. Removing the voltage/current any time after 0.2ns produces successful perpendicular switching corresponding to 5 GHz write frequency. Fig. 2 shows the results from parametric studies using the macrospin model to investigate the impact of strain amplitude, current density, and relative orientation of strain/current. Fig. 2a illustrates the principal strain directions and defines the relative orientation angle θ. For simplicity, producing a biaxial strain defined by. Fig. 2b illustrates the four different types of magnetic state that are possible. The first parametric study consists of 2,601 cases that varies the magnitude of the biaxial strain and the current density with fixed SOT orientation as θ = 45°. Fig. 2c shows the switching phase diagram with the four separate regions corresponding to the four magnetic states shown in Fig. 3b. The successful switching cases (region I) are further examined in Fig. 3d. The m_z amplitude at t = 2 ns is illustrated in color for each case. Switching initiates when the biaxial strain is as low as. As the strain increases, the threshold current (i.e., the minimum current that enables switching) decreases. In other words, a tradeoff exists between the threshold strain and threshold current. Fig. 2e shows the switching phase diagram for the second parametric study, which consists of an additional 2,061 cases with fixed biaxial strain while varying θ and current density. Only three types of magnetic states (type I, II, and III) are discovered, i.e. the magnetic oscillation (type IV) is absent due to the relatively small strains investigated. Fig. 2f further examines all the successful switching cases (region I). The results show that switching is absent when the current is parallel (θ = 0°) or perpendicular (θ = 90°) to the magnetoelastic field (i.e., *y* axis). This feature can be explained using symmetry analysis (not shown here). It is also interesting to note that the dashed cut-lines in Figs. 3d and 3f have similar profiles because they both represent switching behaviors as a function of current density for a fixed current direction θ = 45° and a fixed biaxial strain. In conclusion, the simulation results from the finite element model and the macrospin model show that the strain-induced magnetoelastic anisotropy can break lateral symmetry and produce field free deterministic perpendicular switching in SOT devices. The switching is field-free, fast, and deterministic. Using the uniaxial anisotropy to break the in-plane symmetry opens a new genre of field-free deterministic perpendicular switching in SOT devices and paves the way for next-generation non-volatile memory.

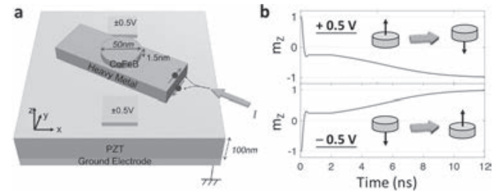

Fig. 1. Finite element simulation: model setup and results. (a) Schematic illustration of the simulated structure and the direction of applied current. (b) Finite element model results of strain-mediated SOT switching for different voltage polarities (positive or negative). The voltage/current application and removal are identified as the blue and red portions of the response, respectively. For +0.5V applied voltage, the final magnetic state is down. For –0.5V applied voltage, the final state is up.

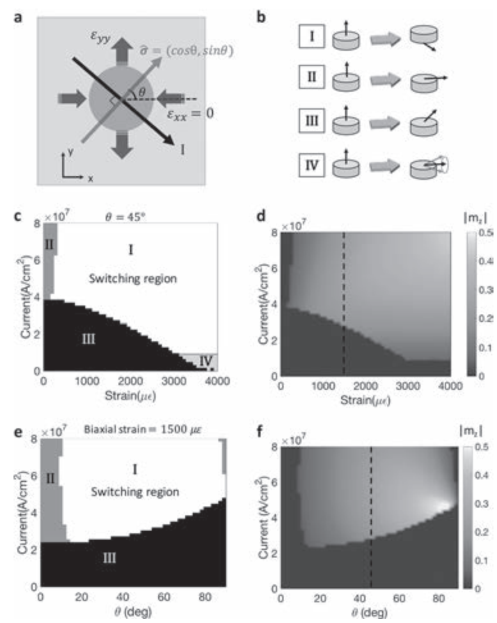

Fig. 2. Switching phase diagrams drawn from the parametric studies using macrospin model. (a) Definition of θ and in-plane principal strain directions. (b) Illustrations for different switching behaviors at t = 2 ns found in the simulations, which correspond to region I, II, III, and IV, respectively in following figures. (c) Switching phase diagram for fixed θ = 45° with varying biaxial strain and current density. (d) Amplitude of m_z after switching for cases in the region I in b. (e) Switching phase diagram for fixed biaxial strain with varying θ and current densities. (f) Amplitude of m_z after switching for cases in the region I in e.

ED-02. Switching of exchange-coupled perpendicular magnetized layers driven by spin orbital torque with low power consumption.

S. Wang[1] and J. Luo[1]
1. Institute of Microelectronics, UCAS, Beijing, China

Extensive experiments have been devoted to study the deterministic switching of perpendicularly magnetized layers in heavy metal/ferromagnet devices driven by spin orbital torque by the spin Hall effect [1-4]. A perpendicular magnetized layer has been proved to be successfully and deterministically switched under certain circumstances experimentally and theoretically [5-8]. To obtain high perpendicular anisotropy, the thickness of the film needs to be sufficiently small (<1nm). To resist the thermal fluctuations during operation, we proposed a multilayer structure including exchange-coupled perpendicularly magnetized layers to switch at relatively low currents and maintain thermal stability, inspired by the ECC media in HDD systems [9]. Without loss of generality, we simply used an in-plane field along the charge current direction (y) to describe the effective field to break the symmetry of rotation in response to the spin orbital torque in our simulation. Fig.1(a) illustrates our design: the bottom magnetic layer is softer ($K_1<K_2$) and is relatively vulnerable to the reversal torque. We used typical magnetic parameters for each layer: the saturation magnetization M_{s1}=1200 emu/cm^3 and M_{s2}=800emu/cm^3, and the effective anisotropy constants K_1=0.5×10^6 erg/cm^3 and K_2=2×10^6 erg/cm^3. We assume only the bottom magnetic layer is subject to the spin orbital torque as the torque originates from spin orbit interaction. Without any applied currents the multilayer relaxes to its equilibrium state and the average magnetization is slightly tilted towards y axis (about 12°). In the switching process, the softer magnetic layer tends to reverse first and the harder layer follows driven by the exchange interaction. The critical spin current density is 5MA/cm^2. Our new structure provides a way to design and optimize the spintronic device.

ED-03. Spin orbit torque via interfacial oxidation in magnetic heterostructures.

X. Qiu[1] and H. Yang[2]
1. Department of Physics Science and Engineering, Tongji University, Shanghai, China; 2. Department of Electrical and Computer Engineering, National University of Singapore, Singapore

Realizing energy efficient SOT devices essentially relies on the magnitude of SOT. On the other hand, constructing multifunctional spin logic and memory devices requires an enhanced control of SOT. Here, we report on the manipulation of the sign and magnitude of SOT via interfacial oxidation in Pt/CoFeB/MgO heterostructures. As the oxygen level in the CoFeB layer goes above a threshold level, SOT suddenly reverses its direction while its magnitude remains roughly invariant. As the Pt is strong against oxidation which is further confirmed by the X-ray photoelectron spectroscopy (XPS) measurements, the sign reversal of SOT via oxygen manipulation cannot be explained by the spin Hall theory and instead it suggests the important role of interface Rashba effect in SOT generation in HM/FM heterostructures. [1] To examine the proportion of SHE and Rashba effect contributions, the samples with varied Pt thickness (t_{Pt}) are studied. The variation of t_{Pt} enables the tuning of the proportion between SHE and Rashba effect based SOTs. H_{SHE} = 155.1 Oe and H_{Rashba} = -143.8 Oe are obtained from the analysis, showing SOT originated from SHE and Rashba effects are of comparable magnitude but opposite in sign in the magnetic heterostructures with oxygen incorporation.[2]

ED-04. Spin Hall magnetoresistance in Co / transparent-conductive-oxide bilayers.

S. Isogami[2] and M. Hayashi[1,2]
1. The University of Tokyo, Tokyo, Japan; 2. Research Center for Magnetic and Spintronic Materials, National Institute for Materials Science (NIMS), Tsukuba, Japan

Introduction : Spin Hall magnetoresistance (SMR) in metallic bilayers [1-5] and heterostructures consisting of ferromagnetic insulator (FI) / heavy metal (HM) [6-8] are widely studied, moreover, the experimental results can be explained by theoretical models that invoke spin accumulation at the FI / HM interfaces [9-11]. To extend the previous pioneering works to the case of heterostructures with the other spin Hall materials and to survey their potentials, we newly focus on the In_2O_3 based transparent-conductive-oxide such as In-W-O (IWO) in this study. It was reported that thin film transistors (TFTs) were achieved when the IWO was used as an active channel semiconductor in the TFTs [12-14]. The transport and output properties of the IWO-TFTs demonstrate both the high stability and high field-effect, therefore, the IWO is considered beneficial to future application products in addition to the conventional TFT with e.g. amorphous In-Ga-Zn-O (IGZO) [15,16]. On the other hand, it is still unknown that the doped W atoms with strong spin-orbit interaction would induce spin Hall effect in IWO films. The present study is intended to confirm the spin Hall effect in the IWO by measuring the SMR for Co / IWO heterostructures. Experimental procedure : The heterostructures, capping layer / Co (3 nm) / IWO (t_{IWO} = 4, 6, 8, 10 nm) / thermally oxidized Si substrate, were fabricated using a magnetron sputtering machine at room temperature. To prevent crystal growth and reduce surface roughness of the IWO, oxygen additive sputtering with 0.5 % O_2 and Ar mixture gas was performed in the IWO film deposition. A metal mask was used to produce Hall bar samples with dimensions of L = 1.2 mm and W = 0.8 mm. The longitudinal resistance (R_{xx}) was measured with DC bias current of 5 μA using PPMS at room temperature while scanning magnetic field (H) from - 6 T to 6 T. The SMR ratio was defined as the R_{xx} change at H = 4 T, namely, [R_{xx} (H_y = 4 T) - R_{xx} (H_z = 4 T)] / R_{xx} (H_z = 4 T). The sheet electric conductance was defined as the product of conductivity and film thickness. Results and discussion : Figure 1 shows the typical SMR curves in which the H were applied in H_x, H_y and H_z directions. For the SMR curve with H_z (shown by open circles), convex downward behavior was observed up to $|H_z|$ = 2 T, which corresponds to the magnetic saturation of the 3-nm-thick Co film in H_z direction, then monotonic decrease was observed. Unlike the case with H_z, the dip patterns were observed at H_x and H_y = 0 T (shown by solid triangles and circles). Therefore, it was found that the 3-nm-thick Co film involved in-plane magnetization. The different R_{xx} at H_y and H_z = 4 T could be attributed to the spin accumulation at the interface that strongly depends on the adjacent Co magnetization. Resultant SMR ratio was estimated to be - 0.12 %. Figure 2(a) and 2(b) show the t_{IWO} dependences of the SMR ratio and the sheet electric conductance, respectively. As for Fig. 2(b), the sheet electirc conductance exhibited slight variation with t_{IWO}, around 0.003 Ω^{-1}. The solid line shows calculation results assuming the parallel circuit of the Co and IWO layers, which agreed well with the data points using ρ_{IWO} = 11800 μΩcm and ρ_{Co} = 90 μΩcm. Note that the value of 10-nm-thick IWO film obtained in another experiment was adopted to the ρ_{IWO}. While further investigation might be necessary, the fitting parameter of ρ_{Co} on the IWO layer was increased compared with that of bulk Co. Fig. 2(b) revealed significantly weak t_{IWO} dependence, which can be attributed to that ρ_{IWO} was over 100 times higher compared with ρ_{Co}. As for Fig. 2(a), calculation was conducted based on the extended SMR model that can account for the spin absorption in metallic interfaces [4], because electric conduction is expected in both the Co and IWO layers. The results revealed that the spin diffusion length of IWO (λ_{IWO}) = 1.5 nm and minimum limit of spin Hall angle (θ_{SH}) = 0.57, which led us to conclude that the presence of spin Hall effect in the Co / IWO heterostructure was confirmed. To clarify such the spin Hall mechanisms involved, further discussion on the microstructure at the interface as well as transport properties of IWO will be presented at the conference.

We report the direct observation of uniform in-plane spin accumulation at room temperature by magneto optical Kerr effect, at the interface formed between nonmagnetic metal (Cu, Ag) and oxide (Bi_2O_3). Recent reports show spin to charge conversion at these interfaces suggesting the presence of Rashba like spin orbit coupling (SOC). The formation of spin accumulation is the result of current induced spin polarization at our interfaces (direct Rashba–Edelstein effect), without external magnetic field or proximity to ferromagnetic materials. We observe opposite orientation of spin accumulation at Cu/Bi_2O_3 and Ag/Bi_2O_3 interfaces reflecting their opposite sign of Rashba SOC (Rashba parameter). Moreover, estimation of spin accumulation from values of Rashba parameters obtained by independent spin pumping measurements, agrees well with the difference in amplitude of our normalized Kerr signals for Cu/Bi_2O_3 and Ag/Bi_2O_3 interfaces. Uniform in-plane spin accumulation due to Rashba-Edelstein effect can be applied for spin filter devices and efficient driving force for magnetization switching.

A diversified demand stemming primarily from consumer products and Internet of Things (IoT) devices has led to a spurt in the growth of the memory industry in the past decade. This has also led to a faster adoption of Non-Volatile Memory (NVM) technologies such as Magnetic Random Access Memories (MRAM). MRAMs are high-speed, low-power and non-volatile spintronic memories. It uses the Tunneling Magneto-Resistance (TMR) mechanism for the read out of the memory bit and can use either the Spin-Transfer Torque (STT) or the Spin-Orbit Torque (SOT) mechanism for the write operation. In SOT-MRAM, the write current is injected in the plane of the magnetic bit, decoupling the read and write paths. This leads to a lower current flowing through the oxide tunnel barrier, slowing the oxide aging and enhancing the overall endurance of the bit. Furthermore, this also enables the use of a tunnel barrier with a higher Resistance Area (RA) product, leading to a lower read disturb and hence increased reliability. SOT-MRAMs typically use a tri-layer structure with inversion asymmetry. A current injected in to the heavy metal (HM) layer with high Spin Orbit Coupling (SOC) gives rise to various torques, namely the Field-Like (FL) torque and the Damping-Like (DL) torque. These torques act on the magnetization of the adjacent Ferro-Magnetic (FM) layer in order to switch it during the write operation [1-2]. They originate from two distinct mechanisms – the Spin Hall Effect (SHE), which is a bulk effect and the Inverse Spin Galvanic Effect (ISGE), which is an interfacial effect. The efficiency of these torques determine the write energy. It also determines the size of the switching transistor and correspondingly the overall memory density. Hence it is vital to determine the contributions of these two effects. One of the ways of ascertaining this is by oxidizing the HM layer to determine the bulk and interfacial contributions. The presence of interfacial oxygen at a cobalt-metal oxide interface can lead to an increased asymmetric band splitting of the Co 3*d* bands [3]. This can induce a Perpendicular Magnetic Anisotropy (PMA), and has been widely studied in the development of perpendicular Magnetic Tunnel Junctions (pMTJ) [3-4]. However, the role of oxygen on SOTs is only starting to be explored experimentally [5-7]. Here we present the enhancement of DL torques by oxygen implantation of the FM/HM interface in a Ta/Cu/Co/Pt hetero-structure. Figure 1 shows the DL field corresponding to the top platinum thickness. As the platinum thickness is reduced, a higher concentration of oxygen atoms reach the Co/Pt interface. Up to a certain reduction in Pt thickness, we see no significant variation of the DL torques. However when the amount of oxygen present at the interface crosses a certain threshold, we see a sharp increase in the DL torques. This signifies a dominant interfacial effect in our samples. Further, in the sample with a thinner Cu layer, we notice this increase to be even higher as less current is shunted through the Cu layer. Such an enhancement of torques could lead to a lower write current, and thereby higher energy efficiency and bit density of SOT-MRAMs. This increase in DL torques has also been observed to correspond to an increase in PMA, which determines the thermal stability of pMTJs. Hence, the oxidation of the FM/HM interface appears as a valuable tool in the development of SOT-MRAMs for longer retention times and a net reduction in write energy.

The requirement of low power consumption, high speed, high endurance for emerging next generation universal memory, a three terminal (separate read/write terminals) spin-orbit-torque (SOT) based non-volatile memory (SOT-MRAM) devices have been gaining much interests than two-terminal spin-transfer-torque MRAM (STT-MRAM) due to its improved magnetization switching, exploiting the spin Hall effect (SHE) mechanism [1-6]. The free layer of SOT-MRAM devices, consists of heavy metal (HM)/ferromagnet metal (FM) bilayer structure, essentially rely on two factors, first the magnitude of SOT from HM which is proportional to spin Hall angle (SHA), and the second is the effective damping constant (α_{eff}) of FM in FM/HM bilayer structure. Since the switching current in SOT-MRAM using in-plane magnetization of magnetic tunnel junction (i-MTJ) is inversely proportional to HM's SHA and directly proportional to FM's α_{eff}, we need to search for HM materials with high SHA and at the same time with low α_{eff} of FM for HM/FM bilayer structure combination. Previously, we have shown the excellent magnetization switching behavior of SOT-MRAM using $Ta_{50}B_{50}$ (HM), and evaluated its SHA by spin Hall magnetoresistance (SMR) measurement [7]. However, analysis of SHA based on SMR assume a simple drift-diffusion model and as for estimation of the effective damping constant, SMR cannot be applied. In this study, the spin-transfer ferromagnetic resonance (ST-FMR) method was used to evaluate both SHA of $Ta_{50}B_{50}$ (HM) and α_{eff} of $Co_{40}Fe_{40}B_{20}$ (FM) for $Ta_{50}B_{50}$ (*t* nm)/$Co_{40}Fe_{40}B_{20}$ (4 nm) bilayer structure. The ST-FMR mixed-signal can be fitted by the combination of symmetrical and asymmetrical components by $V_{Total} = V_{Sym} + V_{Asym}$, where V_{Total} is total mixed signal, V_{Sym} is total symmetrical signal due to spin current, and V_{Asym} is total asymmetrical component due to charge current. The ST-FMR signal, its fitting and extracted each individual components are shown in Fig. 1 (a). The SHA evaluation is not straightforward, since other parameters/mechanisms, which are taking place simultaneously, have to be taken into account. At ferromagnetic resonance two phenomenons are taking place concurrently, the SHE from HM to FM and spin pumping (SP) from FM to HM. The SP induced spin current is converted back to charge current in HM through the inverse spin Hall effect (ISHE) which is reflected in symmetrical ST-FMR voltage signal and can be represented by $V_{Sym} = V_{ST\text{-}FMR} + V_{ISHE}$. In order to remove the SP influence or considering contribution only from SHE i.e. $V_{ST\text{-}FMR}$, the ratio of $V_{ST\text{-}FMR}$ to V_{Sym} defined by η, is crucial and can be expressed as $\eta = V_{ST\text{-}FMR}/ V_{Sym} = V_{ST\text{-}FMR}/ (V_{ST\text{-}FMR} + V_{ISHE})$. This ratio η is very important, since both SHE and ISHE have the same angle dependence (due to similar mechanism), it is very difficult to isolate them, as suggested by other groups too [8, 9]. In addition, the influence of transparency *T* at $Ta_{50}B_{50}/Co_{40}Fe_{40}B_{20}$ interface has to be taken into account for reliable SHA estimation [9, 10]. The transparency, which controls the spin trasnmittance at interface, is related to spin mixing conductance at the HM/FM interface. The spin mixing conductance was calculated from the enhancement of damping constant ($\Delta\alpha$) of FM due to spin pumping from its intrinsic value (α_0). The real value of SHA can be calculated by incorporating interface transparency *T* and isolating the ISHE (V_{ISHE}) contribution from V_{Sym}, that is η. These contributions are incorporated by mathematically multiplying *T* and η to conventional SHA $\Theta_{SH(r)} = \eta T\, \Theta_{SH(m)}$, where $\Theta_{SH(r)}$ is the real value of SHA while $\Theta_{SH(m)}$ is the observed value of SHA estimated by typical approach. In the observed SHA value, neither SHE contributions were separated nor was interface transparency considered, which leads to the overestimation of SHA. The values η, *T* and ηT are shown as a function of $Ta_{50}B_{50}$ layer thickness in Fig. 1 (b). As it is clear that the ratio η decreases systematically with $Ta_{50}B_{50}$ layer thickness, however the interface transparency *T* increases steeply and then saturates at around 2.5 nm. Their product ηT shows initial enhancement and after peak, a systematic decrease is observed. It is obvious that at lower $Ta_{50}B_{50}$ thickness, interface transparency controls whereas at higher thickness the $V_{ST\text{-}FMR}$ contribution dominates. In the Fig. 1 (c), each individual symmetrical components are shown, which is required for reliable SHA estimation. The dependency of $\Theta_{SH(r)}$ on $Ta_{50}B_{50}$ layer thickness is illustrated in Fig. 1(d). By considering only SHE contribution and interface transparency we are able to evaluate the real value of SHA. This SHA value is nearly consistent with the derived SHA from separately fabricated SMR devices [7]. In conclusion, we have successfully estimated the SHA (-0.18) of $Ta_{50}B_{50}$ by isolating SHE contribution from total ST-FMR signal combined with transparency at $Co_{40}Fe_{40}B_{20}/Ta_{50}B_{50}$ interface. Additionally, we were able to achieve desired low damping constant (α_{eff}) ≈ 0.008 for $Co_{40}Fe_{40}B_{20}/Ta_{50}B_{50}$ bilayer which is also crucial factor for realizing low switching current for future SOT-MRAM applications. This work was partly supported by the ImPACT Program of the Council of Science, Technology and Innovation (Cabinet Office, Government of Japan).

With a fast writing speed and less disturbance for the insulating barrier, the spin-orbit torque (SOT) switching is regarded as a promising writing method for next-generation magnetic random-access memory (MRAM). All of magnetization switching by SOT is performed for ferromagnetic (FM) layers with uniaxial anisotropy, that is, the switching occurs between two degenerate energy states. Therefore, the thermal stability to have good data retention while scaling down has been a critical challenge. Here, we demonstrate that the perpendicular magnetization of a ferromagnetic (FM) Co layer with a perpendicular exchange bias (EB) can be switched by the spin-orbit torque when passing current pulses through the underlayer Pt layer. Not only the Co magnetization is switched, but the direction of the EB, established between Co and antiferromagnetic (AFM) IrMn, is simultaneously switched. Due to the existence of the EB, the FM possesses a uni-directional anisotropy and FM magnetization is in its universal minima state. The current-pulse-induced magnetization switching by SOT, accompanying the change of EB direction, can significantly relieve the concern of thermal stability because there is only one stable state at zero field with unidirectional anisotropy so the thermal stability is greatly enhanced. Furthermore, the spin-orbit torque mechanism provides an innovative method to control the exchange bias by electrical means, which enables us to realize the new switching mechanism of highly stable perpendicular memory cells. We prepare the sample by dc sputtering. The perpendicular EB exists in the as-deposited Ta (2.5)/Pt (2)/Co (1.2)/IrMn (8)/Pt (4)/Ta (2.5) stacks (in nm). The magnetic properties are verified by the vibrating sample magnetometer (VSM). Then, the specimens are patterned from the as-deposited films into 5μm×10μm single wire with current pulses running along the x-axis as shown in Figure 1(a). We applied the current pulses with the duration of 10 μs through the single wire in the presence of an in-plane magnetic field (Hx=300 Oe) and measured the SOT switching by the focused polar magneto-optical Kerr effect (FMOKE). As shown in Figure 1(b), when the current density surpasses the threshold Jc, the magnetization exhibits a sharp transition due to the spin-orbit torque. To further examine the magnetic property after the SOT switching, as shown in Figure 1(c)(d), we measured the out-of-plane hysteresis loop (no current flowing now) and found the direction of EB changed along with the FM magnetization switching. That is, in the Pt/Co/IrMn tri-layer structure, the SOT not only flips the magnetization but also changes the EB accordingly. It is rather remarkable that, with the insertion of the IrMn layer, the SOT switching between states with unidirectional anisotropy is achieved. We then further explore to verified (1) the dominate spin current source is from the bottom Pt layer and (2) Joule heating effect cannot explain the change of the direction of exchange bias alone. For the first one, we fabricate the devices with different IrMn thickness. From the SOT switching polarity (Figure 2(a)), the dominant spin current source is from bottom Pt for IrMn≥2nm. As for the second one, we first measure the blocking temperature (T_B) for the device. The T_B is about 150°C. The device temperature at critical switching current density is estimated to be about 90°C from the temperature-dependent resistance (Figure 2(b)), which is much lower than the blocking temperature. Thus, the thermal fluctuations associated with Joule heating is not sufficient to explain the observed EB shifts induced by current pulses. We believe the SOT may also disturb the interfacial spins between FM and AFM, leading to the change of EB direction by current pulses. In conclusion, we demonstrated that SOT can not only switch FM magnetization but also change the EB direction simultaneously. This finding provides an innovative method to redefine EB via electrical means and enhances the thermal stability tremendously. With further investigation and optimization along this direction, the current-pulse-induced EB shall have significant impacts on the SOT-MRAM and other spintronics devices.

Spin orbit torque (SOT) has attracted much attention and interest as it provides a new way to manipulate the magnetization of ferromagnetic metal (FM) in heavy metal (HM)/FM heterostructures by electrical current instead of external magnetic field.[1-2] Various approach for getting lower switching current density and higher switching efficiency have been reported in recent years, such as improving chemical ordering, oxygen incorporation, controlling composition of FM alloys. These published works mostly focused on enhancing spin current originated from either the SHE or the interfacial Rashba effect, and we will focus on how to enhance the spin current absorption in the FM layer. In recent years, Ru has attracted great attention due to its significant role in enhancing giant magnetoresistance and substantial reduction of critical current for magnetization switching in a vertical spin valve.[3] In this work, we attempt to modulate the switching current density and SOT efficiency in the Pt/Co/Pt films via a Ru insertion. Figure 1(a) and (b) show the spin current originate from the charge current in the Pt/Co/Pt and Pt/Co/Ru/Pt multilayers, respectively. After inserting a Ru layer, the majority spins of the polarized spin current flowing to the Co layer in the top Pt layer will be reflected at the Ru/Pt interface,[3] whereas the minority spins are easily absorbed in the Ru. In this case, the spin accumulation at the top and bottom interface of the Co layer have uniform spin polarization, which can theoretically enhance the overall torques exerting on the magnetization of the Co layer. Figure 1(c) and (d) show the magnetic field H dependence of the out-of-plane magnetization M and the anomalous hall resistance R_H at room temperature for the two multilayers, respectively. The reduced saturation magnetization of the multilayer with a Ru layer insertion can also contribute to the reduction of the critical current, which are shown in the Figure 2(a) and (b). The non-adiabatic harmonic Hall voltage measurements with external sweeping magnetic field along the longitudinal and transversal of the hall-bar were carried out at room temperature to quantitatively determine the strength of the spin orbit effective field. The results of the first and second harmonic voltage with the out-of-plane magnetization component $M_Z>0$ and $M_Z<0$ are shown in the Figure 2(c) and (d) respectively. According to the harmonic voltage measurement, we have calculated the damping-like torque H_D to be 41.66 Oe per 10^7 A/cm^2 and 49.04 Oe per 10^7 A/cm^2 in the Pt/Co/Pt and Pt/Co/Ru/Pt multilayers, respectively. The field-like torque H_F in the Pt/Co/Pt and Pt/Co/Ru/Pt multilayers is 8.91 Oe per 10^7 A/cm^2 and 30.49 Oe per 10^7 A/cm^2, respectively. The more evident change happened in the H_F, which is larger in Pt/Co/Ru/Pt multilayers than that in the Pt/Co/Pt multilayers. The result has proved our supposition that the Ru insertion can enhance the SOT.

Spin-orbit torque (SOT) is induced by an in-plane current flowing in heterostructures with broken inversion symmetry, e.g., a tri-layer system consisting of heavy metal/ ferromagnetic metal/ oxide. Because the SOT can bring about magnetization reversal in ferromagnetic layers [1-3] without applying much stress to the barrier layer in magnetic tunnel junctions (MTJs), it has attracted great attention as a new ingredient for the writing scheme of nonvolatile spintronics memory or logic. SOT is generated by a spin accumulation due to the spin Hall effect and/or the Rashba-Edelstein effect, and is known to have two components with different symmetries, i.e., Slonczewski-like (SL) and field-like (FL) torques. The strength of SOT is characterized by dimension-less spin-torque efficiencies ξ_{SL}, ξ_{FL} that represent conversion ratio from the charge current to SL and FL components of SOT, respectively. We here note that ξ_{SL} corresponds to the spin Hall angle in case that the SOT originates from the spin Hall effect. Large ξ_{SL} is desirable for low-power switching. FL torque was also revealed to effectively reduce the switching current [4], but could cause switch-back events according to recent studies [5]. β-W is one of the promising candidates for the heavy metal material owing to its large ξ_{SL} = -0.2 ~ -0.5 [6-8]. Since an increase in ξ_{SL} with W resistivity ρ_W in the range of 100-300 μΩcm has been reported in previous works [7,8], larger ξ_{SL} is expected be obtained in W with higher ρ_W. On the other hand, FL torque of the systems with W has not been well investigated yet. Here we study both components of the SOT in CoFeB/MgO stacks on high-resistivity (470 μΩcm) W underlayers with various thicknesses t_W. We find a very high ξ_{SL} exceeding 1, relatively small ξ_{FL}, and different t_W dependence of ξ_{SL} and ξ_{FL}. The stacks of W(t_W)/ CoFeB(1.8)/ MgO/ Ta(1) are prepared on thermally oxidized Si substrates by dc/rf magnetron sputtering, where the numbers in parentheses are nominal thickness in nanometer. The films are processed into Hall bar devices with a channel of 10×50 μm^2. The Effective fields of SL and FL components of SOTs, H_{SL} and H_{FL}, are determined by an extended harmonic Hall resistance measurement, which is capable of excluding artifacts originating from the anomalous Nernst and spin Seebeck effects [9]. Figure 1 shows the sheet conductance versus t_W for W(t_W)/ Ru(1) blanket films. The linear relation indicates that ρ_W is almost constant in the studied range (t_W = 2–10 nm) and the slope gives ρ_W = 470±28 μΩcm. This is the highest value of W resistivity reported so far. A similar measurement is conducted for CoFeB layer and the resistivity of CoFeB is obtained to be 142±4 μΩcm. We then perform the harmonic measurement using Hall devices to evaluate SOT. 10-Hz AC current is applied to the Hall bar and harmonic Hall voltages are measured by lock-in amplifier while rotating an external magnetic field H_{ext} in the film plane. Figures 2(a) and (b), respectively, show a typical first (R_ω) and second ($R_{2\omega}$) harmonic Hall resistances as a function of the azimuthal angle ϕ of the field. Note that R_ω reflects the planar Hall resistance and $R_{2\omega}$ reflects the current-induced effective fields. H_{SL} and H_{FL}, respectively, are obtained by fitting H_{ext} dependence of cosϕ and 2cos³ϕ - cosϕ contributions in $R_{2\omega}$-ϕ curves [9, 10]. $\mu_0 H_{SL,\,FL}$ as a function of J_W are summarized in Figure 2(c) and (d) (μ_0: permeability of vacuum), where J_W is the current density flowing in W layer determined from the resistivity and thickness of W and CoFeB layers. We obtain ξ_{SL} = -1.03±0.05, ξ_{FL} = -0.12±0.01 for t_W = 6 nm by using an expression $\xi_{SL(FL)} = (2eH_{SL(FL)}M_St)/(h\_barJ_W)$, where e is electron charge, M_St is magnetic moment per unit area, and h_bar is the Dirac constant. The obtained ξ_{SL} is much higher than any previous reports on tri-layer systems except for those with topological insulators. We also confirm ξ_{SL} = -0.15 when we use a device with low resistivity W (ρ_W = 150 μΩcm), in agreement with previous works [6,8]. ξ_{FL} is one order of magnitude smaller than ξ_{SL}. The relatively low ξ_{FL} is also consistent with an implication in our previous work [8] and is contrasting to the perpendicular magnetized systems with Ta [4] and Pt [11] underlayers. In addition, we also investigate t_W dependence of ξ_{SL} and ξ_{FL}, which show contrasting trend. The former is well described by a drift-diffusion model [2], suggesting its origin in the spin Hall effect, whereas the latter does not show clear dependence on t_W, suggesting its origin in interfacial effects. In summary, we evaluate SOTs in high-resistivity-W/CoFeB/MgO heterostructures by the extended harmonic Hall techniques and the structure exhibits a large ξ_{SL} of -1.03±0.05 and relatively small ξ_{FL} = -0.12±0.01. Our results suggest that the heterostructures using high-resistivity-W as a heavy metal layer can offer a low power switching and have a potential for MTJ devices. This work was partly supported by ImPACT Program of CSTI, JST-OPERA, and GP-Spin of Tohoku Univ.

The conversion of charge current into pure spin current based on the spin Hall effect provides a new way of spin injection and manipulation in novel spintronic architectures. The seeking for materials with large spin Hall angle (SHA) values is important for both scientific interest and device applications. Compared to a rather small value in GaAs when it was first observed a decade ago, much larger SHAs have been observed in heavy metals such as Pt, Ta and W [1,2]. Ta and W have the benefits such as the economic advantage as well as the largest SHA reported to date. However, the Joule heating due to the rather high resistivity of both β-W and β-Ta becomes of a great concern for the applications, combined with the excessive challenges in achieving a stable β form of W and Ta. Pt possesses low resistivity and high stability, but the high cost and the rather small spin diffusion length hinders its further development in this field. With a similar structure to Pt, but a much larger spin diffusion length [3], Pd has anomalously small SHA values reported, and has little been explored. Understanding the underlying mechanism plays an important role in the enhancement of SHA in different materials. It could be of intrinsic origin connected with the band structure or device geometry, or extrinsic origin due to impurities [4,5]. As a common element and doping source in a spintronic device/structure, the role of boron in the enhancement of spin Hall effect is largely unexplored, when discussed into the mechanisms involved. Here we report a giant enhancement of SHA in palladium through boron engineering. We measure a large SHA of 0.16 in palladium, with perpendicular magnetic anisotropy in the Pd/CoFeB-based structure compared to the Pd/CoFe-based structure (SHA=0.02). Combined with theoretical calculations, it is found that both intrinsic and extrinsic spin Hall effects have been significantly enhanced through the introduction of boron. The incorporation of boron in the thin films results in significant microscopic and electronic changes in the Pd host metal. Our result provides a further understanding of the spin Hall effect in metals, leading to a new exploration of material engineering for large SHA sources. Together with high conductivity and long spin diffusion length, this work makes Pd a promising candidate for spintronic devices with magnetization switching by current pulse injection. The film stacks Pd(5 nm)/$Co_{40}Fe_{40}B_{20}$(1 nm)/MgO(2 nm)/Ta(5 nm) and Pd(5 nm)/$Co_{50}Fe_{50}$(1 nm)/MgO(2 nm)/Ta(5 nm) are sputtered on thermally oxidized Si substrates. The stacks are patterned into Hall bar devices using photolithography (Fig. 1a and 1b). Fig. 1c and 1d shows the longitudinal and transverse effective field as a function of the injected current density for the CoFeB-based sample, with the magnitude of the former about three times larger than that of the latter, indicating a strong Slonczewski-like torque. Based on the data, the SHA determined is 0.16. It is the largest SHA reported so far for Pd based PMA structures. Fig. 1f shows the magnetization switching loop measured by the magneto-optical Kerr effect (MOKE) from a 5 μm×20 μm device. To explore the possible origins, we carry out synchrotron X-ray photoelectron spectroscopy (XPS) study of the samples for depth profiling. Fig. 2 shows that the introduction of B results in a highly pure metallic Pd state, as well as a high concentration of metallic contents of Co and Fe in the Pd layer for the CoFeB based sample, which is strikingly different to that observed in the CoFe based sample. The consumption of oxygen by B, leads to the highly metallic Pd state as well as reduced Co/Fe oxidation in Pd. We perform *ab initio* calculations of spin Hall conductivity (SHC) of B-, Fe- and Co-doped palladium as well as pure palladium metal based on the density functional theory. The calculated SHCs for pure Pd, B_1Pd_{31}, Fe_1Pd_{31} and Co_1Pd_{31} are 2852, 1818, 3114 and 3758 (h/2e)(S/cm), respectively. Interestingly, doping Pd with ~3% B reduces the SHC by ~36%. In contrast, doping Pd with ~3% Co (Fe) increases the SHC by ~32% (~9%). Pure palladium metal has a large SHC which is further enhanced by substitutional Fe- and Co-doping. The experimental results comply well with the theoretical modelling.

EE-01. Steady state solution of periodically excited nonlinear eddy current problems.

O. Biro[1] and G. Koczka[2]
1. TU Graz, Graz, Austria; 2. Siemens AG Österreich – Transformers Weiz, Weiz, Austria

Abstract In many cases the steady state periodic solution of eddy current problems with periodic excitation is needed only. If the problem is linear, it is straightforward to obtain this solution either in the frequency domain applying harmonic balance techniques or in the time domain using discrete Fourier transforms. For nonlinear problems, this cannot be done, since the harmonics are all coupled. Using a fixed-point method to solve the nonlinear equations, however, enables using harmonic balance or discrete Fourier transforms within each nonlinear iteration. The method is described in the presentation and examples of its application are given. Introduction The most straightforward method of solving nonlinear electromagnetic field problems in the time domain by the method of finite elements (FEM) is using time-stepping techniques. This requires the solution of a large nonlinear equation system at each time step and is, therefore, very time consuming, especially if a three-dimensional problem is being treated. If the excitations are non-periodic or if, in case of periodic excitations, the transient solution is required, one cannot avoid time-stepping. In many cases however, the excitations of the problem are periodic, and it is only the steady-state periodic solution which is needed. Then, it is wasteful to step through several periods to achieve this by the "brute force" method [1] of time stepping. A successful method to avoid stepping through several periods in such a case is the time-periodic finite element method introduced in [2]. To accelerate the originally slow convergence of the method a singular-decomposition technique has been introduced in [3] and it has even been parallelized in [4]. A time domain technique using the fixed-point method to decouple the time steps has been introduced in [5] and applied to two-dimensional eddy current problems described by a single component vector potential. The optimal choice of the fixed point permeability for such problems has been presented in [6] both in the time domain and using harmonic balance principles. The method has been applied to three-dimensional problems in terms of a magnetic vector potential and an electric scalar potential (A,V-A formulation) in [7] and, employing a current vector potential and a magnetic scalar potential (T,Φ-Φ formulation), in [8] and [9]. In contrast to the time-periodic finite element method, the periodicity condition is directly present in the formulation instead of being satisfied iteratively. The aim of this work is to present a review of the fixed-point based method and to show its application to industrial problems. A detailed version has been published in [10]. Summary of the method The problem is formulated in terms of vector and scalar potentials approximated by edge and node based finite element basis functions. The application of Galerkin techniques leads to a large, nonlinear system of ordinary differential equations in the time domain. The excitations are assumed to be time-periodic and the steady state periodic solution is of interest only. This is represented either in the frequency domain as a finite Fourier series or in the time domain as a set of discrete time values within one period for each finite element degree of freedom. The former approach is the (continuous) harmonic balance method and, in the latter one, discrete Fourier transformation will be shown to lead to a discrete harmonic balance method. Due to the nonlinearity, all harmonics, both continuous and discrete, are coupled to each other, so the size of the equation system is the number of harmonics times the number of degrees of freedom. In the time domain approach, the number of discrete harmonics is equal to the number of the time values within one period. The harmonics would be decoupled if the problem were linear, therefore, a special nonlinear iteration technique, the fixed-point method is used to linearise the equations by selecting a time-independent permeability distribution, the so called fixed-point permeability in each nonlinear iteration step. This leads to uncoupled harmonics within these steps resulting in two advantages. One is that each harmonic is obtained by solving a system of algebraic equations with only as many unknowns as there are finite element degrees of freedom. A second benefit is that these systems are independent of each other and can be solved in parallel. The appropriate selection of the fixed point permeability accelerates the convergence of the nonlinear iteration. The applications presented concern the simulation of the steady state of large power transformers with time-harmonic excitations. In addition to taking account of the nonsinusoidal time variation of the electromagnetic field due to saturation, direct current bias in the magnetizing currents can also be allowed for.

EE-02. Advanced soft- and hard-magnetic material models for the numerical simulation of electrical machines.

K. Hameyer[1], S. Steentjes[1], N. Leuning[1], G. Bravendiek[1] and S. Elfgen[1]
1. IEM, RWTH Aachen University, Aachen, Germany

The development of energy-efficient electrical machines requires an accurate knowledge of the soft- and hard-magnetic material behavior already in the design stage. Accurate numerical models are required which offer the ability of better understanding and modelling in an appropriate accuracy. With such model properties on the one hand accurate simulations can be performed and on the other hand the best possible material choice for a particular application, i.e. for an electrical machine, can be done. The soft-magnetic material constitutes the magnetic core of an electrical machine and its properties. On that account, the accurate prediction of iron losses of soft-magnetic materials for various frequencies and magnetic flux densities, i.e., arbitrary magnetic field waveforms, is eminent for the design of electrical machines [1]. For this purpose different phenomenological iron-loss models were proposed, which describe the loss-generating effects, i.e., hysteresis, non-local eddy currents and anomalous eddy currents. Most of these suffer from poor accuracy for not considering the effect of high frequencies and high material utilization as well as the material degradation due to the magneto-elastic coupling [2,3,5]. This paper presents a comparison of common iron-loss models. The IEM-formula used, resolves the limitation by introducing a high-order term of the magnetic flux density and considers the alteration of material-dependent loss-parameters due to the magneto-elastic coupling [3]. The knowledge of the magnetic property deterioration due to induced residual stress occurring during the manufacturing or operation of the electrical machine is indispensable for the contemporary design. It has been widely ascertained that processing of electrical steel laminations significantly alters the magnetic properties of the electrical steel [2-6]. Cutting induces plastic deformation and residual stress in the laminations. Due to their strong sensitivity to mechanical stress, the magnetic properties are locally degraded near the cut edge. The extent of the degradation depends substantially on the process characteristics, i.e., the cutting procedure and cutting parameters in combination with material properties, such as mechanical strength and grain size [4-6]. In [7] a continuous material model for an efficient numerical model of the local magnetization was introduced. By replacing numerically expensive sliced models, the continuous model (CM) is independent of the discretization and converges in the case of coarse meshes to the sliced model [7]. Measured single-sheet specimens are used to identify the different model parameters. In Fig. 1 results on hysteresis loss distribution are presented. The vital advantage of the proposed CM is that properties depend only on the distance to the cut edge. For improved estimation of penetration depth and mechanical stress distribution, novel experimental procedures are utilized [8] and mechanical simulations are evaluated [6] to further advance the cut-edge model. Permanent magnets are central to the electromagnetic energy conversion process in permanent-magnet synchronous and flux-switching machines. In order to design the magnetic circuit and a magnetizing circuit for post-assembly magnetization as well as to analyze the resistance to being demagnetized during the simulation of electrical machines, it is indispensable to describe the magnetization behavior of the permanent magnets accurately. However, due to the complex interplay of the non-linear and hysteretic magnetization behavior and the magnetic anisotropy, it is a complex problem. Commonly, simplified models are used, which are based on empirical and phenomenological approaches. These describe the major loop of the permanent magnets only. However, the magnetization state of the permanent magnet depends on the magnetic and thermic history, i.e., it is indispensable to account for minor loops or incompletely magnetized permanent magnets. In this paper, a pragmatic methodology to replicate the hysteresis of permanent magnets is presented, which uses first-order return curves and the magnetization behavior starting from the virgin state for model-parameter identification [10]. Efficient parametric models with low additional computational effort are perfectly suited for the finite-element analysis. Starting from these advanced models of soft- and hard-magnetic materials, a methodology for selecting the optimal steel grade during the design-stage of electrical machines in due consideration of the application-specific requirements on torque-speed operating points, i.e., all have to meet the requirements of the same driving cycle, is presented [1]. This allows one to study the effect of different electrical steel grades on the operational characteristics along the torque-speed map [11]. In order to determine the efficiency of each combination of machine topology and lamination type, the iron-loss model with material degradation is used in combination with a machine simulation scheme of the entire operating range of the machine. In the light of this, this paper will give an overview on the current modeling approaches applied at the Institute of Electrical Machines (IEM) for soft- and hard-magnetic materials in the simulation of rotating electrical machines.

EE-03. Modern Finite-Element Discretization Techniques for Electromagnetic Field Simulation.

H. De Gersem[1] and S. Schöps[1]
1. Technische Universitaet Darmstadt, Darmstadt, Germany

Today, Finite-element (FE) analysis is one of the main workhouses in design procedures for electrical devices. 2D cartesian, 2D axisymmetric and 3D FE simulation have become standard and are embedded in almost all professional design packages. The performance of FE analysis needs to keep pace with the increasing complexity of contemporary devices and with new designer needs such as e.g. parameter studies, uncertainty quantification and optimization. Only part of the envisioned performance increase is to be expected from hardware improvement. The remainder part is guaranteed from recent advances in field modeling and field discretization methods. This paper gives an overview about recent developments in the domain of electromagnetic field simulation. Contemporary designs consist of multiple components which interact as a system. Often, simulations of the different components are not sufficient for a complete characterization of the device. Moreover, failing to model the interactions may lead to a suboptimal or even wrong design. In a cascadic approach, the component field models are reduced to surrogate models (e.g. a circuit model) and put together in a later design phase. In a co-simulation approach, the components are simulated, each with their own appropriate simulation platform, and data are exchanged at synchronization points and time instants. A proper co-simulation needs waveform relaxation, which in turn needs to be checked for convergence [1]. In a few cases, a full strong coupling is indispensable. Co-simulation approaches allow to select different spatial discretization techniques for different parts of the overall model, e.g. a field solver for the electric machine and a circuit solver for the power converter. The necessary field-circuit coupling is carried out along so-called winding functions [2]. Also for complicated winding types (e.g. foil windings), appropriate coupling or homogenization techniques exist [3,4,5]. Many contemporary problems suffer from multiple spatial scales, e.g. when large devices suffer from eddy-current effects with small skin depths or when the macroscopic material behavior can only be predicted from microscale models. Then multiscale models [6,7] or homogenization techniques [8] are applied. The case where one part of the model needs a fine spatial resolution, whereas in other parts a coarse resolution will do, fits in this class of problems as well. The paper shows impressive results for dealing with small-scale eddy-current effects in magnetic brakes [9], machine windings [10] and ferromagnetic lamination stacks [11], and for dealing with highly accurate field solutions in the aperture of a Stern-Gerlach magnet [12,13,14]. Many designs feature geometric symmetries. These are typically exploited in FE analysis by choosing for a 2D cartesian or 2D axisymmetric solver, thereby saving more than one order in magnitude for the computation time. A more exotic symmetry is radial symmetry as occurring in e.g. axial-flux machines [15] and induction-heating devices [16]. More frequently, however, one encounters designs where only parts feature a certain symmetry or where the symmetry is disturbed by a few items or by asymmetric excitations or boundary conditions. For e.g. a pallet heating device [17], an inductive sensor for artificial lenses [18] and a high-accurate current sensor [19], the paper will show how dedicated FE discretization methods enable 3D FE simulation outperforming standard 3D FE analysis tools by orders of magnitude.

EE-04. Advanced constitutive laws for computational magnetics: The case of magneto-mechanical behaviour.

L. Daniel[1]
1. GeePs-CentraleSupelec, Gif sur Yvette, France

Abstract – Ferromagnetic materials in electromagnetic devices are subjected to multiaxial stress states. Stress significantly affects the material behaviour, and appropriate modelling tools are required to describe this coupling effect. Multiscale approaches for magneto-elastic behaviour can provide a useful description of the complex interaction between magneto-mechanical loading and material response. However, these models are not easily implementable into numerical simulations. This paper gives a brief overview of different strategies to extract information from multiscale approaches so as to use them in standard numerical tools for the design of electromagnetic devices.

It is known for long that mechanical stress state significantly influences the magnetic and magneto-mechanical behaviour of ferromagnetic materials [1]. The different stages required in the manufacturing of electrical machines and electromagnetic devices, as well as the operational conditions, generate a variety of mechanical stress states in the ferromagnetic materials used in their fabrication. These mechanical loadings usually have a detrimental effect on the material behaviour and hence on the device performance [2-4]. It is then highly desirable that the designer of electromagnetic devices can have access to constitutive equations representative for the magneto-mechanical behaviour of ferromagnetic materials. The stress being described by a second order tensor (six independent components), and the magnetic field by a vector (three independent components), it is easy to understand that the possible combinations for the magneto-mechanical loading are huge. Many experimental and numerical studies are restricted to 1D configurations considering uniaxial stress (usually tensile) applied in the direction parallel to the magnetic field. Although these studies are very useful to explore the mechanisms of magneto-mechanical coupling, they obviously need to be generalised in order to cover the practical configurations encountered in most real devices. The problem seems too complex to be described by macroscopic phenomenological approaches, as often used in the modelling of – uncoupled – magnetic behaviour. A variety of approaches have been developed to describe and understand magneto-mechanical coupling effects, based on different levels of approximations. Among them, multiscale approaches (MSA [5-11]) appear particularly promising to capture the complexity of magneto-elastic behaviour. These approaches are based on an energetic description of the magneto-elastic equilibrium at the magnetic domain scale combined to a statistic description of the average magnetic domain distribution. A main strength of MSA is that they can naturally deal with heterogeneous and anisotropic materials. They also naturally introduce the multiaxiality of magneto-mechanical loadings (3D stress state and any relative orientation between stress and magnetic field). Some of the MSA can also consider hysteresis effects. However MSA remain usually too complex to be easily implemented into numerical analysis tools for the design of electromagnetic systems. Hence modelling strategies are required to take benefit from the output of MSA while keeping the numerical burden acceptable. A first idea is to use MSA as a "numerical testing machine" and consider it as a tool to identify the material parameters of macroscopic models. Indeed, macroscopic constitutive models, notably those based on thermodynamic approaches [12-15], are capable of tackling the multiaxility of magneto-mechanical effects. However they are more reliable if the modelling parameters are obtained from more complex configurations than simple uniaxial magneto-elastic tests. An option is to develop multiaxial experimental setups [16-19], but the use of MSA is an alternative path. The modelling parameters of MSA can usually be identified on simple experimental tests due to their univocal physical meaning. MSA can then be used to perform ''numerical tests" in any loading condition suitable for the identification of macroscopic model parameters. Another strategy is to derive simplified models from full MSA, usually neglecting the effects of material heterogeneity [20-22]. The multiaxial feature of MSA is preserved, and the constitutive equations can incorporate anisotropy [22,23] or hysteresis effects [21,24]. Such approaches have been shown to be efficient to describe the behaviour of simple test structures [25], transformers [22,26] or electrical machines under magneto-mechanical loading [23,24]. The simplest – but also less accurate - strategy is probably to use the concept of equivalent stress [27,28] or equivalent strain [29]. An equivalent stress is a uniaxial stress that – applied in the direction parallel to the magnetic field – would have the same effect as the real multiaxial stress existing in the structure. Heterogeneity and initial anisotropy effects are neglected, but it is a simplified way to take into account the multiaxiality of stress in electromagnetic structures without developing fully multiaxial magneto-mechanical numerical tools. This approach has been applied successfully to evaluate the potentiality of smart materials to perform flux weakening in electrical machines [30] or to analyse the effect of stress on the losses in electrical machines [31].

EE-05. High Resolution Modeling of Magnetic Field Exposure Scenarios in the Vicinity of Inductive Wireless Power Transfer Systems.

M. Clemens[1], M. Zang[1], M. Alsayegh[2] and B. Schmuelling[2]
1. Chair of Electromagnetic Theory, University of Wuppertal, Wuppertal, Germany; 2. E-Mobility Research Group, University of Wuppertal, Wuppertal, Germany

The increasing development and commercialization of electric and hybrid electric vehicles includes the challenge of enabling an efficient and comfortable charging process of a car‘s battery. A promising solution for this purpose is provided by the use of inductive power transfer (IPT) technologies for a contactless charging with an electric power in the order of several kW [1]. A current driven charging coil (primary coil) is positioned on the floor below the car and coupled via an airgap with a secondary coil attached to the bottom of the car. IPT systems generate magneto-quasistatic fields with frequencies from 80 up to 140 kHz. A person positioned inside or near the car, however, will also be exposed to these magnetic fields. Exposure related changes of the electric field strength inside the human body can lead to stimulations of nerve and muscle tissues. Therefore, limits for the volume-averaged body-internal electric strength are proposed by the International Commission on Non-Ionizing Radiation Protection (ICNIRP) [2]. Investigations of the human exposure to magneto-quasistatic fields require the use of high-resolution numerical simulation techniques such as the Finite-Difference Time Domain (FDTD) method. Complex geometries of conductive and/or permeable sheets contained in the IPT system and the car body as well as anatomical body phantoms have to be considered in exposure simulations. Also, potential misalignments between the IPT system’s coils might have an influence on the exposure and need to be taken into account. A high-resolution discretization of such scenarios within commercially available eddy current solvers is often unfeasible as it requires the solution of very high-dimensional and extremely ill-conditioned algebraic systems of equations. As an alternative, three two-step methods have been introduced in [3] and [4] making use of domain decomposition approaches enabling a division of the exposure scenario into two domains: the source area including the influence of shielding geometries and the area occupied by the exposed body. These three two-step methods – the Coupled Scaled-Frequency (SF-)FDTD method, the Co-Simulation SF-FDTD method and the Co-Simulation Scalar-Potential Finite Difference (SPFD) method – are used here for a high-resolution modeling of magneto-quasistatic exposure scenarios including realistic models of various IPT systems, the car and the human body. With the application of the two-step methods a reduction of the memory demands and the simulation time is achieved in comparison to a monolithic application of the SF-FDTD method and the simulations can be performed on a standard computer workstation. Figure 1 a) shows an exposure scenario where a human body model (body phantom Duke [5]) is positioned beside a car model with an IPT system positioned below the car. For an improvement of the coupling between the IPT‘s coils, optimization analyses are conducted using an FEM-based magneto-quasistatic field solver included in the software ANSYS Maxwell 3D [6]. Here, different geometry designs are compared to each other regarding an optimization of the coupling coefficient and a reduction of the magnetic leakage fields, coincidentally. The optimized model geometries of different IPT systems are used in exposure analyses carried out with the abovementioned two-step methods. In a first step, the magnetic source field simulation is performed with the software CST Microwave Studio (MWS) [7]. The simulation model includes the IPT system and the car body sheets, but not the human body model, since its interaction with the magnetic source field is negligible. Source field simulations are also carried out considering lateral misalignment of the IPT system’s coils and different values for the thickness of the car body sheets for an analysis of a consequential variation of the leakage fields – and thus the exposure of the human body. Figure 1 b) shows the magnetic flux density in a cross section of the car and in the center of the IPT system with the designated position of the human body model indicated. In a second step, the exposure of the human body is calculated, i.e., the exposure-related distribution of the body-internal electric field strengths, using the previously calculated source fields. Within the two-step SF-FDTD methods this second step is also carried out using CST MWS or, alternatively, using the software Sim4Life [8], whereas within the Co-Simulation SPFD method a discrete Poisson equation is solved using a preconditioned conjugate gradient solver. A high flexibility is achieved by the use of the Co-Simulation SPFD method (as well as with the Co-Sim SF-FDTD method), since the magnetic source field simulation can be computed using any magnetic field simulation tool. Figure 1 c) shows the electric field strength in the median plane of the human body voxel model. The maximum voxel-averaged electric field strength is evaluated for each scenario to analyze the influence of each configuration (different IPT systems, coil misalignments and car body sheet thicknesses) on the exposure and for an exposure assessment according to the ICNIRP guidelines.

EE-06. Design and Optimisation of Magnetic Devices.

D. Lowther[1]
1. Elec and Comp Eng, McGill University, Montreal, QC, Canada

Magnetic devices are found in applications ranging from power generation and electric vehicles to domestic equipment and industrial processes. The design of these devices has become more complex as the requirements become more demanding [1]. Frequently, a designer is expected to generate more output from a smaller frame size, lower the production cost and increase the overall efficiency as well as producing more versatile devices driven by power electronic systems capable of generating variable frequency and voltage excitations. The problem is beyond the conventional multi-physics analysis and is truly multi-domain where the physics of the device and its coupling with the drive system have to be considered together, [2]. Finding a design which can meet the specifications is an optimisation process and, in most situations it is now a multi-objective, multi-domain problem. In addition, manufacturing processes can introduce tolerances on many of the parameters which can have a significant effect on the device performance [3]. Thus, the design finally chosen should be robust, i.e. insensitive to small parameter changes, [4]. Computer simulation of magnetic devices can now provide the designer with advanced multi-physics representations, [5], which can model the magnetic, mechanical, thermal and acoustic performance and can couple to the power electronics drive. However, such systems, particularly in three-dimensions and driven with pulse-width modulation excitations, involve significant amounts of computational effort and solutions can take of the order of hours. Recent advances in multi-objective optimization using stochastic algorithms, [6], when combined with the concept of robustness [7], [8] have provided a possible solution to the design problem. However, such systems often need thousands of solutions during the search process and this is currently infeasible using full multi-domain simulations. In the early stages of the design process, it is unnecessary to consider the full virtual simulation since the shape of the design space is controlled by a few critical factors such as the dimensions of the magnetic flux paths, the excitation windings, etc. In many devices, the influence of these parameters can be studied through two-dimensional field simulations which can generate performance characteristics including the local losses needed for efficiency. While much faster than three-dimensional systems, such analyses can still be too slow for the initial stages of an optimization process. To avoid this computational bottleneck, optimizers can estimate the effect of parameter variations through the use of a surrogate model – typically a response surface. This can be generated iteratively through approaches such as Kriging [9], [10] or prior to the optimization process through the use of a high performance computer system. In the latter approach, the data generated can be used to predict the information needed by the optimizer, [11]. Once a likely solution to the design problem is found, the system can automatically move towards a full, multi-domain simulation of the prototype solution. The presentation will consider the current state of reduced order and surrogate modeling, including robustness issues, for the optimization of magnetic devices.

EF-01. Micromagnetics of FePt-$L1_0$ Media with Thermally Insulating Magnetic Grain Boundaries.

J. Zhu[1] and Y. Qin[1]
1. Data Storage Systems Center, Carnegie Mellon University, Pittsburgh, PA, United States

In heat assisted magnetic recording (HAMR), grain-to-grain Curie temperature variation presents a practical limit to grain size reduction hence, the scaling of recording area density capability (ADC), for the advancement of granular FePt-$L1_0$ media[1][2]. At small grain sizes, a reduction of grain size yields an increase of surface-to-volume ratio, thereby, a reduction of Curie temperature [3]. The resulting grain size dependence of Curie temperature gives rise to the cause of the Curie temperature variation due to unavoidable grain size distributions with today's film fabrication technique. Aiming at this grand challenge, a recent experimental study has shown a potentially practical solution by successfully fabricating granular FePt-$L1_0$ media with thermally insulating magnetic grain boundaries [4]. In this paper, we present a systematic modeling study on the micromagnetic recording characteristics of such media. In the study, both the FePt-$L1_0$ grain core and a thin layer of ferromagnetic grain boundaries are meshed and modeled using dynamic Landau-Lifshitz-Bloch (LLB) equations. The room temperature anisotropy field of the FePt core is assumed to be H_k=80 kOe and zero magnetocrystalline anisotropy is assumed for the soft magnetic grain boundary material. Gaussian geometric thermal profile is assumed along with realistic media motion are used to simulate practical recording process. Figure 1(a) shows the M_s(T) curves for both the FePt grain core and the insulating magnetic grain boundary material assumed. Note that the assumed magnetic grain boundary has a Curie temperature significantly higher than that of the FePt core. For all the results presented in this digest, the diameter of the FePt core is assumed to be 6nm with 1nm thick magnetic grain boundary. The modeling simulation shows that the ferromagnetic grain boundary provide significant assist in the magnetization process of the FePt grain core during recording. With the grain boundary coupled to the FePt core, the magnetization process of the core becomes significantly more deterministic. Figure 1(b) shows the switching probability of the FePt grain core as a function of recording field amplitude with the medium moving at a speed of 15 m/s and a spatial thermal gradient of 8 K/nm. The case "Not Coupled" indicating no exchange coupling between the grain boundary and the FePt core is plotted for comparison. With the magnetic grain boundary exchange coupled to the core, full saturation recording can be reached at lower field values in comparison with the case of non-magnetic grain boundaries. The effect is even more enhanced for smaller size of FePt grain cores, which will be presented in the full paper. Please note the "Not Coupled" case is essentially the same as the case with non-magnetic grain boundaries. Figures 2(a) and 2(b) show the writing of a transition when the head field direction is reversed (black dashed lines). The case with the exchange-coupled grain boundary and FePt core shows more rapid and better defined magnetization switching with the magnetizations of the core and grain boundary switching together. Whereas for the case that the core and grain boundary are not coupled, the switching of the FePt core is much more gradual with noticeably fluctuations. Also note that the grain boundary actually magnetizes a little faster than the FePt core does. In summary, the magnetic grain boundary exchange coupled to the FePt core provides significant assistance to the magnetization process of the FePt core during recording, both in heat assisted magnetization process and in transition magnetization process with field reversal. Therefore, it is important for the Curie temperature of the grain boundary material to be higher than that of the FePt core for the obvious reasons. The level of grain boundary magnetization at the recording temperature is important and the higher the magnetization level, the more enhanced assisting effect will be during recording. It is also important to note that the exchange coupling between the grain boundaries of adjacent grains needs to be minimized in practice. The experimental study has shown that this objective could be achieved in practice [4]. In conclusion, granular FePt media with a thin layer of soft magnetic grain boundaries that are exchange coupled to the FePt cores not only can suppress or eliminate grain-to-grain Curie temperature variation, but also can assist the magnetization process, especially for small size grains, during recording in HAMR. The more deterministic magnetization processes helps to suppress thermal-induced transition jitter during recording process, consequently enhancing the scalability of both the linear recording density capability and the overall ADC.

EF-02. Sources and Impact of Media Thermal Fluctuations in Heat Assisted Magnetic Recording.

P. Jubert[1] and C. Papusoi[1]
1. Western Digital, San Jose, CA, United States

Heat assisted magnetic recording (HAMR) is being developed to achieve recording densities well beyond 1 Tb/in^2. The technology uses a laser-coupled near-field transducer (NFT) to locally heat the recording layer, made of small high-anisotropy FePt grains, such that the grains' magnetization freezes in the direction of the head write field while the temperature cools just below their Curie temperature. Given the inherent variations of grains position, size and properties, the recording performance also relies on having a large temperature gradient at the freezing location. The temperature gradient requirement effectively replaces the field gradient requirement in conventional magnetic recording. The heat is provided by the local absorption of the laser light under the NFT and the resulting temperature profile stems from the medium thermal transport properties. As a result, both the optical characteristics and the thermal transport properties of the medium stack need to be properly designed. In addition, it has been shown that grain-to-grain temperature fluctuations can significantly contribute to transition jitter and limit HAMR performance [1, 2]. It is therefore important to identify all potential sources of temperature fluctuations and to evaluate their relative impact to HAMR performance. This work aims at understanding and quantifying the effect of spatial variations of the light absorption and spatial variations of the medium stack thermal properties on HAMR. Optical and thermal modeling is carried out to calculate temperature profiles in a simplified HAMR medium stack as a function of in-plane variations in the medium properties. The medium stack comprises a 5-nm-thick overcoat, a 10-nm-thick recording layer, a 5-nm-thick thermally resistive layer, a 100-nm-thick heatsink layer, and a glass substrate. To comprehend the relative contribution of each medium property, the spatial variations are first simplified to sinusoidal modulations with varying amplitude and period. These lead to sinusoidal variations of the location of the freezing point or sinusoidal transition jitter, whose amplitude δx_{max} is evaluated systematically for different optical absorption modulations and modulations of the thermal conductivities at each layer and interface. The main sources to transition jitter are found to be fluctuations of the absorption and of the thermal properties in the recording layer, in the thermally resistive layer and to a lesser extent in the overcoat. Absorption and thermal property fluctuations in the heatsink have significantly smaller impact on transition jitter. For all cases, δx_{max}, is proportional to the amplitude of the source fluctuation. δx_{max} is also strongly affected by the length scale of the source fluctuation. This is illustrated in Fig. 1, which shows δx_{max} as a function of the period for modulations of the optical absorption in the recording layer and for modulations of the effective thermal resistance between the recording layer and the heatsink. The trends at long periods are quantitatively understood with 1D heat flow considerations, while the reduction at low periods is explained by in-plane heat spreading in the HAMR stack. In addition, we note that contrary to what previous reports may suggest [1, 2], temperature fluctuations are quite different from the intrinsic Curie temperature fluctuations. The temperature fluctuations are proportional to the input laser power, which is also proportional to the downtrack thermal gradient. As illustrated in the Fig. 1, increasing thermal gradient does not reduce δx_{max}; the transition jitter associated with grain-to-grain temperature fluctuations does not improve with increasing the thermal gradients. The effect of roughness at the interfaces of the HAMR medium stack is also investigated. Roughness is source of combined optical absorption and thermal property spatial fluctuations. Interface roughness results similarly in grain-to-grain temperature fluctuations and therefore in sizeable transition jitter. The amplitude of the jitter is found to scale with the amplitude of the interface roughness and to also depend on the length scale of the roughness.

EF-03. A Split Pole and Gap-NFT Write Head Design for Transition Curvature Reduction in Heat Assisted Magnetic Recording.

C. Chow[1] and J.A. Bain[1]
1. Electrical and Computer Engineering, Carnegie Mellon University, Pittsburgh, PA, United States

Transition curvature poses a significant challenge to areal density capability in heat assisted magnetic recording (HAMR). Potential solutions include curvature correction through cross track (XT) write field gradient [1, 2] and engineering a flatter thermal contour using a crown-shaped near field transducer (NFT) [3]. We propose a head design aimed at curvature correction through XT magnetic field gradients using a split pole and with the potential for thermal contour flattening due to its gap NFT design. Our focus here will be an examination of the XT field profile. We use a finite element method (FEM) in COMSOL to model the final 100 nm of the pole/NFT tip in this work to assess how to get thermal and magnetic profiles close enough in the downtrack direction without excessive power absorption in the pole. A tapered low index dielectric separator (LIS) inserted between the NFT and the write poles is the key innovation to accomplish this proximity and is the focus of the analysis herein. Our write head design, shown in Fig. 1a, consists of split write poles which are magnetically driven in the same direction. The magnetic gap between these poles creates a XT field gradient inside the recording media. A gap-NFT, similar to that suggested in [4], is formed by a layer of Au on both poles, with the point of smallest separation between the Au layers being termed the optical gap. In simulation, we excite the surface plasmon mode confined in the optical gap, which propagates from the feed position to the air bearing surface (ABS). The optical feed structure to launch this mode is an important consideration in this design but is beyond the present analysis. Fig. 1b shows the reference media stack layers used in our model, including the magnetostatic boundary conditions. Media properties are taken from the 2015 ASTC reference media stack, except that the lubricant, head overcoat, and media overcoat layers are combined into a single air gap layer. The write poles are modeled to be FeCo and have a saturation magnetization of 2.4 T. They are driven to saturation at the distance of 100 nm from the ABS. A soft underlayer (SUL) beneath the heatsink layer in the media is modelled by a zero magnetic potential. For a 35 nm wide magnetic gap, we can achieve a difference of 2 kOe between the minimum and maximum write field in the XT direction inside the recording media. The temperature profile of the hotspot is computed through optical and thermal modelling with a free space wavelength λ_{fs} = 800 nm. The NFT material is assumed to be nanoscale Au (n = 0.2 - 5j, k_{th} = 100 Wm^{-1}K^{-1}), while the high index core is composed of SiN (n = 2, kth = 1 Wm^{-1}K^{-1}), and the low index cladding is SiO2 (n = 1.5, k_{th} = 1 Wm^{-1}K^{-1}). The pole material is assumed to have a combination of properties of Fe and Co (n = 2.8 – 4j, k_{th} = 80 Wm^{-1}K^{-1}). An LIS is inserted between the optical gap and the magnetic gap to reduce absorption in the poles due to proximity to the NFT and confine light to the optical gap. The LIS between the NFT and the poles provides optical isolation (reducing loss) which is desirable, but also increases the downtrack separation between the thermal and magnetic profiles, which is undesirable. We resolve this conflict by introducing a taper to the LIS with a thin section near the ABS to bring the write fields closer to the optical gap at the ABS without incurring the loss associated with a thin LIS over the entre pole tip. Fig 2a shows a side view of the taper. We hold total length constant at 100 nm and the length of the thin section near the ABS at 20 nm. The taper length and thick LIS input length are allowed to vary (producing different taper angles, as noted in the figure). Fig. 2b shows the ratio of power absorbed by the medium to total power absorbed by head and medium as a function of taper length, with both of the untapered cases shown for comparison. Fig 2c shows the location of the field profile relative to the hotspot for the two untapered cases and a representative tapered case. Together these figures show that the thick (35 nm) untapered LIS case gives the best efficiency of power delivered to the medium (31%) but creates a XT field gradient that is too far from the hotspot to be useful in curvature correction. Conversely, the thin (10 nm) untapered LIS gets good overlap of the hotspot and the magnetic field, but reduces power delivery efficiency by almost a factor of 3 down to 13%. The tapered LIS is a good compromise between the two untapered cases. It is able to achieve a field gradient sufficiently close to the hotspot to match the 10 nm thin LIS case, but it does so with a much more desirable power delivery efficiency of 25% for all taper lengths.

EF-04. Design of field generating layer in all-in-plane spin-torque-oscillator.

H. Sepehri-Amin[1], C. Abert[2], D. Suess[2] and K. Hono[1]
1. Research Center for Magnetic and Spintronic Materials, National Institute for Materials Science, Tsukuba, Japan; 2. Christian Doppler Laboratory, Advanced Magnetic Sensing and Materials, University of Vienna, 1090, Vienna, Austria

Microwave assisted magnetic recording (MAMR) is a promising technology to overcome the stagnated areal density increase of hard disk drives. However, its most essential part, spin-torque-oscillator (STO), has not been realized. The STO device for MAMR should have a size of 30-40 nm and be able to generate large $\mu_0 H_{ac} > 0.1$ T with a frequency over 20 GHz at a small current density $J<1.0\times10^8$ A/cm^2 [1]. In addition, large oscillation cone angle of free layer is desired to maximize the $\mu_0 H_{ac}$. Such a device has not been realized experimentally due to the lack of fundamental understandings on the desired materials and structure of the STO. We have recently demonstrated experimentally that mag-flip spin-torque-oscillator (STO) consisting of out-of-plane magnetized spin injecting layer (SIL) and in-plane magnetized field generating layer (FGL) with a diameter of 30-40 nm that can oscillate with resonance frequency of 21 -25.5 GHz and produced an ac magnetic field of 0.15 T [2,3]. However, the main disadvantage of the mag-flip STO device is its large thickness due to the need for ~10 nm out-of-plane magnetized FePt. In addition, the required bias current density of oscillation of mag-flip STO device is over 4.3×10^8 A/cm^2 that needs to be substantially educed for real application [3]. In order to reduce the total thickness of a STO device, in this work we propose all-in-plane STO device consisting in-plane magnetization SIL and FGL. In this study, we will show how design of materials in all-in-plane STO can lead to a STO that can generate large $\mu_0 H_{ac}$ with a frequency over 20 GHz in a small bias current density for MAMR. We employed a micromagnetic simulation code, *magnum.fe*, which solves the coupled dynamics of magnetization (*m*) and spin accumulations (*s*) simultaneously using the time dependent 3D spin diffusion equations and the Landau-Lifshitz-Gilbert (LLG) equation, respectively [4]. This will allow us to directly simulate the effect of locally varying spin accumulations on the magnetization dynamics. Based on the micromagnetic simulations, we propose desired spin polarization and saturation magnetization of FGL so that all-in-plane STO device can generate large $\mu_0 H_{ac}$ with a frequency over 20 GHz in a small bias current density. Figure 1 (a) shows our designed all-in-plane mag-flip STO device consisting a 3-nm-thick SIL and 14-nm-thick FGL separated by a 5-nm-thick Ag layer. An external magnetic field of 1 T is applied to saturate the magnetization of the SIL and FGL out-of-plane and electrons are pumped from bottom to top, and due to the reflection of electrons from FGL/Ag, the SIL switches and transmitted down-spin electrons lead to oscillation of FGL. Unlike the conventional mag-flip STO device, we found that the spin polarization of FGL play a very important role in J_c required for switching of SIL and OOP oscillation of FGL. As shown in Fig. 1, by increase of spin polarization of FGL, J_c can be substantially reduced. The underlying mechanism is shown in Fig. 2 (a). Fig. 2 (a) shows the STO device and 3D spin accumulation in Z direction in the model when all the layers are magnetized OOP under 1 T external magnetic field. Distribution of S_z from SIL toward FGL for different spin polarization of FGL is shown in Fig. 2 (a). It was found that by increase of β^{FGL}, we get more reflected negative spins from FGL/Ag interface that will be beneficial for switching of SIL and OOP oscillation of FGL, resulting in smaller J_c. However, highly spin-polarized materials such as Heusler alloys have limited saturation magnetization of below ~ 1.3 T. In order to increase the ac-field generated by STO, it is necessary to increase the saturation magnetization of FGL. In order to gain large spin polarization of FGL combined with large saturation magnetization in FGL, we propose all-in-plane STO with dual FGL as shown in Fig. 2 (b). By use of this model, we can gain large spin accumulation in SIL that is beneficial for the magnetization switching of SIL and second layer of FGL can have a large saturation magnetization with lower spin polarization desired for large ac magnetic field out-put of device. Acknowledgement: This work was supported by Grant-in-Aids for Young Scientific Research B (17K14802).

EF-05. Magnetization Switching of a Co/Pt-Multilayer Perpendicular Nanomagnet Assisted by a Microwave Field with Time-Varying Frequency. ***(Invited)***

H. Suto[1], T. Kanao[1], T. Nagasawa[1], K. Mizushima[1] and R. Sato[1]
1. Corporate Research & Development Center, Toshiba Corporation, Kawasaki, Japan

Microwave-assisted magnetization switching (MAS) has been studied as a candidate write method in next-generation high-density magnetic recording [1-3]. Although large switching field reduction by MAS has been theoretically and experimentally demonstrated, generating a large microwave field from a write head is a key challenge in developing MAS-based drives. In addition, the microwave field amplitude required for MAS will increase as the media anisotropy increases for further increasing recording density. One way to realize MAS by a smaller microwave field is to utilize a varying-frequency (VF) microwave field. Because the resonance frequency of a perpendicular nanomagnet is not constant and decreases as the magnetization excitation evolves, applying a VF microwave field that follows the resonance frequency can induce larger magnetization excitation and enhance the MAS effect [4-8]. In this presentation, we experimentally study MAS of a Co/Pt perpendicular nanomagnet by applying a VF microwave field. The microwave field is generated by introducing a microwave signal to a waveguide fabricated near the nanomagnet. Figure 1(a) and 1(b) show the waveforms of microwave signals used to generate a constant-frequency (CF) and VF microwave field. The frequency of the CF microwave field is 12 GHz, and that of the VF microwave field changes from 12 to 0.02 GHz in a 10-ns time period. The frequency is confirmed by estimating the instantaneous frequency from the zero-cross intervals of the waveforms [Figs. 1(c) and 1(d)]. Figure 2(a) shows the result of CF-MAS. The switching field decreases as the microwave field frequency increases and abruptly increases at the critical frequency, which is typical MAS behavior. Figure 2 (b) shows the switching field of VF-MAS as a function of the start frequency of the VF microwave field. The end frequency is fixed to 0.02 GHz. Similar to CF-MAS, the switching field decreases as the start frequency increases and continues to decrease when the start frequency exceeds the critical frequency. The switching field, thus, becomes smaller than that for CF-MAS, showing that the MAS effect is enhanced. As further increasing the start frequency, the switching field abruptly increases and becomes almost the same as the minimum switching field of CF-MAS, which indicates the following. When the start frequency becomes too high, the frequency change rate becomes so fast that the magnetization cannot follow the frequency change, and the enhancement of MAS disappears. In this case, MAS occurs in the same manner as CF-MAS when the frequency decreases to the frequency at which CF-MAS occurs. The MAS behavior in a VF microwave field is qualitatively explained by the theory based on the macrospin model [9]. This work is supported by Strategic Promotion of Innovative Research and Development from Japan Science and Technology Agency, JST.

Magnetic hard disk drives (HDDs) store over 90% of the world's digital data enabling the internet and economical access to data to power everything from social media to self-driving cars. Heat assisted magnetic recording (HAMR) is being developed as the next recording system for HDDs. HAMR will bring profound changes to the HDD components and architecture, incorporating laser diodes in an innovative plasmonic light delivery system into the recording heads, and novel nano-magnetic materials and layer architectures in the recording media [1]. Seagate demonstrated the promise of HAMR with a 1 -2 Tb/in^2 areal density demonstration [2,3] and the subsequent demonstration of a fully functional drive with more than 1000 write power-on hours [4, 5]. The significant progresses have been enabled by breakthroughs in media and head technology together with drive integration. With continuing development efforts in reliability and data density HAMR will serve the demand for economical hard disk drive storage solutions for the world's ever growing data. As announced in a recent blog, Seagate is now shipping HAMR units to select customers for integration tests, and will start shipping commercial HAMR products to key customers by the end of 2018 [6]. This paper will cover the key enablers for HAMR technology to support both high areal density and linear density, which will be critical for bringing a new "S" curve for the magnetic recording industry. It will also be discussed about the challenges and breakthroughs in fundamental magnetic properties for the recording layer and near field optical transducers, to support the extension of HAMR to around 4-5 Tbit/in^2.

Introduction: Energy assisted recording technologies have become indispensable for maintaining the continuous increase of the recording density of the hard disk drives. One of the promising candidates is the microwave assisted magnetic recording (MAMR). It allows us to record information on media with high magnetic anisotropy, by applying an additional ac magnetic field (h_{ac}) to induce the precessional motion of magnetic moments, which results in magnetization switching under a much smaller write head field. One critical component for MAMR is the spin torque oscillator (STO) that can generate large h_{ac}. The STO device consists of a perpendicularly magnetized spin-injection layer (SIL) and an in-plane field generating layer (FGL), mag-flip STO, was originally proposed for MAMR. [1] Previous studies using this design have shown the out-of-plane precession (OPP) mode of FGL for the generation of h_{ac}. [2, 3] However, some of the specifications of the STO device, *e.g.*, required currents, frequency and amplitude of h_{ac}, still do not fulfill the requirement for MAMR. Recently, another design for a STO device using an in-plane magnetized SIL with negligible magnetic anisotropy was proposed [4]. During the operation of the STO device, the trailing gap field is applied perpendicularly to the device to align the magnetization of SIL and FGL. As electrons flow from SIL to FGL, the spin torque scattered from FGL reverses the magnetization of SIL opposite to the trailing gap field, then an anti-damping torque can be applied to FGL to induce the OPP mode. In this study, we investigated the behavior of the STO device having an in-plane SIL with both experiment and micromagnetic simulation. We focused on the influence of the material of SIL to understand the SIL material parameters dependence on magnetization oscillation dynamics in FGL. Experimental procedures: The STO devices were microfabricated from epitaxial thin films grown on MgO (100) single crystalline substrates using magnetron sputtering. The stacking structures of the thin films were MgO (100) subs. // Cr (10 nm)/Ag (100 nm)/SIL (3 nm)/Ag (3 nm)/FGL (7 nm)/ Ag (5 nm)/Ru (8 nm), where full Heusler alloy $Co_2Fe(Al_{0.5}Si_{0.5})$ (CFAS) or $Fe_{67}Co_{33}$ (FeCo) were used as SIL while FeCo was used for FGL. Since CFAS has a half-metallic nature, it is interesting to compare the oscillation properties of STO with CFAS-SIL and FeCo-SIL to understand the effect of spin-polarization (β). Using electron-beam lithography and Ar ion milling, STO devices having a circular-shape pillar with the diameter of 100 nm were microfabricated. For characterization of the STO devices, electrical transport measurements were performed using a DC four-probe method. The STO devices were connected to a source meter and a nanovolt meter while placed in a Physical Properties Measurement System for field (H) and temperature control. Micromagnetic simulation was carried out using *magnum.fe*, [5] which can calculate the coupled dynamics of magnetization and the spin accumulation simultaneously. A 30 nm-diameter circular pillar with 3 nm SIL, 5 nm spacer and 14 nm FGL was modeled and calculated. Results: Under low current of 0.1 mA, the devices with SIL of CFAS and FeCo showed ordinary MR curves under perpendicular H, with MR ratio of 5.7% and 4.0%, respectively. Under large current above around 8 mA with electrons flowed from SIL to FGL, a clear increase of resistance into an intermediate resistance state (IRS) was observed for both devices under large H, where both SIL and FGL were aligned toward the direction of H under low current. The IRS was observed under positive and negative H, and expanded on both sides towards high and low H when the current increased (Fig. 1 (a)); however, the IRS was not observed when electrons flowed from FGL to SIL. Such behavior was qualitatively reproduced by micromagnetic simulation, which showed that the IRS was due to the reversal of SIL, while FGL underwent the OPP mode. Using micromagnetic simulation, we also investigated the influence of β of SIL, which showed higher β led to higher current for reaching IRS. To verify this, we carried out the electrical transport measurements at 10 K. The MR ratio of the device with SIL of CFAS increased up to 10.4%, which is attributable to the increase of β of CFAS. On the other hand, no IRS was observed until the current was increased up to around 18 mA (Fig. 1 (b)). This result is consistent with simulation, suggesting that materials with lower β as SIL lead to lower critical current density for SIL magnetization reversal.

Microwave Assisted Magnetic Recording (MAMR) is a type of energy assisted recording technology that uses microwaves to assist in the recording process. This allows for the use of high anisotropy media to maintain good thermal stability at high areal densities [1]. In MAMR, a spin torque oscillator (STO) is placed between the main pole and trailing shield to generate a magnetic field at microwave frequencies. The magnetic recording trilemma [2] is overcome by reducing the coercive field of the media via this microwave field, thereby aiding in the switching of media grains. Appropriate media stack configurations for MAMR and STO optimization have been investigated by both analytical theory and micromagnetic simulation [3], [4], [5]. In this paper, MAMR performance is evaluated on a reference design using our MAMR micro-magnetic model and the results are reported using EWSNR metrics [6]. In this study, we compare performance metrics for MAMR with other recording technologies such as Perpendicular Magnetic Recording (PMR) and Heat Assisted Magnetic Recording (HAMR). Recording media dynamics are modeled using the Landau-Lifshitz-Gilbert (LLG) equation for PMR and MAMR, and utilizing the renormalized LLG method for HAMR [7]. The DC magnetic write field is a current generation PMR writer design with 55 nm physical pole width and 1.0 T peak field strength. The STO stack has an optimized geometry that applies a 3D circularly polarized AC field to the media. STO field strength (~0.1Hk) and oscillating frequency (~35 GHz) are determined by the magnetic properties of the field generation layer (FGL) and the magnitude of the injected spin current. The magnetic head to media spacing (HMS) is fixed at 6.0 nm and head velocity is modeled to be 20 m/s. For MAMR, single layer media with varying anisotropy are considered. The PMR ECC multilayer media model, which is calibrated based on current PMR products, contains multiple magnetic layers and non-magnetic break layers that provide optimal exchange coupling. The HAMR media is a single layer $L1_0$ FePt media with a Curie temperature distribution of 3% and anisotropy field distribution of 10%. The down track thermal gradient used in the HAMR model is around 8K/nm, which is consistent with common near field transducer designs. The average media grain size is around 8.0 nm with 17% grain size distribution. A magnetoresistive reader with 30 nm width is used for obtaining the play back signal. Magnetic information is encoded using pseudo random bit sequences (PRBS), which mimic real user data. Figure 1 shows a comparison between PMR, HAMR and MAMR with thick free layer designs in terms of common performance metrics. Ensemble waveform analysis is used to calculate the total spatial SNR, the breakdown between transition and remanence SNR contributions, and the channel bit density (CBD) [6]. Bit error rate (BER) is calculated using a pattern dependent Viterbi detector [8]. The use of an NFT in HAMR allows the recording of much narrower tracks than PMR, with similar CBD and reasonable SNR and BER. In general, MAMR exhibits a large CBD, which may be related to intersymbol interference and track edge erasure caused by the demagnetization field. This high CBD results in much worse BER than both HAMR and PMR at all track width and linear density combinations considered. For the same ADC (shown in the last two table items in figure 1), SNR and BER are much better when the linear density is higher and the track width is larger. Since track edge demagnetization effects seem to have such a large effect in MAMR, this data suggests MAMR should aim to increase ADC via higher linear density and lower track density. For thick free layers, multi domains and multi-scattering contributions to electron's propagation can greatly deteriorate STO performance. Therefore, SNR versus recording media Hk for MAMR with thin free layer designs below 15 nm and STO width of 40 nm is shown in Figure 2. The figure suggests an optimal for MAMR media of around 25 kOe. MAMR SNR degradation at 20 kOe is due to erasure effects for low Hk material [9]. For high anisotropy media ~30 kOe, the transition SNR is reasonable (around 12 dB), but remanence noise is high, causing a 2 dB loss in total SNR.

EG-02. Fast Surrogate-Assisted Design of Multilayered Magnetic Shields.

H. Chen[1,2], Y. Du[2] and Q. Cheng[1]
1. Department of Electrical and Electronic Engineering, Southern University of Science and Technology, Shenzhen, China; 2. Department of Building Service Engineering, The Hong Kong Polytechnic University, Hong Kong, Hong Kong

Abstract — This paper presents a surrogate-assisted optimization process to design multilayer magnetic shields. The method builds the surrogate of the original problem to reduce the time consuming 3D calculation. Response surface approximation (RSA) is applied to construct a surrogate from a physics-based model. Evaluation time of the surrogate is negligible. The optimum design found by the surrogate is then refined using space mapping technique to give the location of the optimum design of the original model. The method is applied to optimize a double shield to demonstrate its efficiency. *Index Terms— magnetic shielding; surrogate; space mapping*. I. Introduction Planar multilayer shield is superior than the single-layer counterpart of equal thickness. Although the calculation of the shielding effectiveness of multilayered structures has been widely investigated, the problem of designing such shielding structures is not well addressed. Meanwhile, the high ratio of width to thickness of a planar shield leads to dense mesh in the calculation. The optimization process will be time consuming due to the fundamental challenge of the high computational cost of high-fidelity simulations on such 3D structures. Therefore, we present a surrogate based optimization (SBO) [1] to accelerate the design process of the planar multilayer shields. Its biggest advantage is the fact that because the surrogate embeds system-specific knowledge, usually a small number of high-fidelity simulations are sufficient to configure a reliable optimization. For demonstration of its efficiency, this approach is developed to optimize a double shield with aluminum and iron materials. II.Design Optimization Methodology The multilayered shield design problem R_f, here we call it a "fine model", can be formulated as a non-linear minimization problem of the form x_f = arg min $U(R_f(x))$ where U is a given objective function. $R_f : X_f \rightarrow R^m$, $X_f \subseteq R^n$, denotes the response vector of the fine model, x are designable variables. is the optimal solution to be determined. To accelerate the optimization process, an approximated physics-based "coarse model" R_c is constructed in the first step, where $R_c : X_c \rightarrow R^m$, $X_c \subseteq R^n$, denote the coarse model response vector. Thus, the optimization problem is approximated by x_c = arg min $U(R_c(x))$ However, it is still relatively expensive. Therefore, Instead of optimizing the coarse model directly, we built its surrogate for optimization. The process can be described as $x_c \approx x^{(i+1)}$ = arg min $U(s^i(x))$ where $x^{(i)}$, i = 0, 1,..., is a sequence of approximate solutions to the original problem, $s^{(i)}$ is the surrogate at the ith iteration. Response surface approximation (RSA) model (q) is then employed to build the surrogate. Its evaluation time is negligible. Obtained optimal design $x^{(i+1)}$ gives a good approximation of the location of the coarse model optimum. However, in order to include the unavoidable misalignment between and, the RSA model (surrogate) needs to be further refined using space mapping [2]. $q^{(i)}(x) = A^{(i)}R_c(B^{(i)}x+c)+d^{(i)}$ Thus, the surrogate is updated by solving. The optimum of the fine model then can be obtained using the updated surrogate. III.Numerical Simulation Results Consider a planar double shield with total thickness of 5 mm as shown in Fig. 1. The shield is composed of plates of aluminum and iron with thicknesses of d_1 and d_2, respectively. Both plates have the dimensions of 2 m × 2 m. A rectangular loop source is located 200 mm below the shield. The source loop carries a current of I_{rms} = 200 A and f = 50 Hz. The measured lines at the height of 300 mm above the shield. The design aims to find the optimal shield with the lowest magnetic field in the shielding area. The design variables are $x = [d_1, d_2]^T$ with the constrains $d_1 + d_2 \leqq 5$ mm. The fine model R_f is simulated in 3D ANSOFT MAXWELL. The coarse model R_c is also simulated in the same software, while, in a 2D solution. It is obvious that 2D simulation is more efficient while less accurate than 3D solution. The optimum of the surrogate = $[2.3, 1.1]^T$ was obtained using 24 evaluations of coarse model. The refined design = $[1.8, 1.0]^T$ was obtained by the refinement using SM. Only one evaluation of the fine model is needed through the whole process. In order to show the advantages of the proposed optimization procedure, the shield was designed with R_f directly using pattern search. However, direct optimization of the find model failed without finding the optimum. Acknowledgment The work was supported by grants from the RGC of HKSAR, No. 152038/15E, and NSF of China, No. 61471258.

I. INTRODUCTION In recent years, the switching performance of power devices have improved significantly, and the switching frequency of power inverter in pulse width modulated (PWM) motor system becomes higher and higher. As a result, the electromagnetic interference (EMI) problem in PWM motor system becomes more and more serious. In PWM motor system, EMI can be divided into two main parts: common mode current (CMC) and electromagnetic radiation (EMR). CMC is mainly caused by the large du/dt of common mode voltage (CMV) during inverter switching transition which will charge and discharge the distributed capacitance in motor system. The high frequency CMC will further generate EMR which is distributed around motor system. The CMC and EMR have long been known to cause a variety of problems. In order to reduce the CMC and EMR in motor system, lots of research work have been done in hardware topology modification and software control strategy optimization [1]-[5]. But very few papers have focused on the amplitude-frequency characteristic research of CMC and EMR. In this paper, the generation mechanism of CMC and EMR is illustrated, and the main influencing factors of CMC and EMR are theoretically analyzed and experimentally verified, which lays theoretical foundation for the CMC and EMR suppression in PWM motor system. II. GENERATION MECHANISM AND INFLUENCING FACTORS OF CMC AND EMR In PWM motor system, the outputted CMV of inverter is equal to the mean value of three-phase instantaneous voltage. For a two-level three-phase inverter, there are eight candidate vectors and the corresponding CMV are different. The CMV caused by zero vectors are higher than caused by active vectors, which is the reason why some papers propose nonzero vector PWM method to reduce CMV and CMC. The variation of CMV can charge and discharge the distributed capacitance, which results in the CMC and its complexity flowing paths. The RMS value of CMC can be roughly calculated according to the voltage-current equation of equivalent capacitance in motor system, and the value of CMC is related to three main factors: the value of equivalent capacitance, the DC bus voltage and the switching frequency of inverter. 1. The value of equivalent capacitance The capacitance impedance is inversely proportional to the capacitance value and the frequency of passed signal. So, the larger the capacitance value, the greater the CMC flowing through. In addition, under the same capacitance, the high frequency components of CMV are easier to pass through because of the corresponding smaller impedance, which result in that CMC contains lots of high frequency components. 2. The DC bus voltage According to the capacitance voltage-current equation, the CMC flow through distributed capacitance is proportional to the changing rate of CMV during a single switching operation of power device. In general, the duration of switch on or off of power device can be considered as fixed as several microseconds. So, the CMC passing through distributed capacitance is indirectly related to the value of DC bus voltage. 3. The switching frequency of inverter There is a certain amount of CMC passing through distributed capacitance in a single switching operation of power device. So, the RMS value of CMC in a certain duration is decided by the number of switching operations of power devices which is equivalent to the switching frequency of inverter. Theoretically speaking, the higher the switching frequency, the greater the CMC RMS value. The high frequency and high amplitude CMC can generate strong EMR. Within a certain distance, the motor system can be treated as a lumped parameter circuit, and the intensity of EMR can be approximated calculated by Biot-Savart law. In addition, according to the principle of equivalent circuit, the flowing path of CMC can be represented as an RLC circuit, the series resonant frequency of equivalent RLC circuit changes with the variation of distributed capacitance in motor system. III. EXPERIMENTAL RESULTS A PWM motor system experimental platform is built to test the CMC and EMR, and Capacitance with different values are artificially added between phase line and ground to simulate distributed capacitance. The CMC is measured by a leakage current sensor and the EMR is measured by a spectrum analyzer with built-in omnidirectional antenna. Fig. 1 is the CMC experimental waveforms under various values of the three main influencing factors. Fig. 2 is the experimental results of CMC, EMR and resonant frequency under various values of main influencing factors. It can be obviously seen from Fig. 1 and Fig. 2 that, the RMS values of CMC and EMR changes with the variation of DC bus voltage, switching frequency of inverter and distributed capacitance. The fitting curves of CMC and EMR RMS values shown in Fig. 2 further reveals that the RMS values of CMC and EMR change linearly with the variation of these three main influencing factors. In addition, the resonant frequency of CMC flowing path also changes with the variation of distributed capacitance as shown in Fig. 2(d), which are same with the calculation results of equation (5). In general, the experimental results are consistent with the above theoretical analysis, which verifies the correctness of theoretical analysis. Because of space limitation, more theoretical analysis and experimental results will be included in the full paper.

EG-04. Dual Mode Dual Stator Wound Rotor Synchronous Machine for Variable Speed Applications.

A. Hussain[1], M. Ayub[1], T. Yazdan[1] and B. Kwon[1]
1. Electronic Systems Engineering, Hanyang University, South Korea, Ansan, The Republic of Korea

1. Introduction Electric vehicles and hybrid electric vehicles are being developed as a means to extenuate the environmental concerns. Permanent magnet (PM) machines have been used for such applications due to their high torque density, robust structure and no need for an external excitation system. However, the limited supply and increasing price of PM material create a need to search the alternative solutions such as the brushless wound rotor synchronous machines (BL-WRSM). Several brushless topologies for WRSMs have been presented in [1-3]. In [1] and [2], the brushless operation of WRSM is achieved by utilizing sub-harmonic and third harmonic components of stator MMF, respectively. In [3], the sub-harmonic component of stator MMF is generated by dividing the stator winding into two sets of series connected windings, which are then supplied through a single inverter. In the brushless topologies, the stator current is the only source of excitation and the field current is induced from the harmonic component of MMF. When the machine operates below the rated speed, the induction process slows down and the magnitude of the field current is gradually decreased with the decrease in the speed of the machine. Therefore, the torque in the constant torque region cannot be maintained constant by the BL-WRSM. However, at or above the rated speed these machines work properly. In this paper, a dual mode dual stator wound rotor synchronous machine (DMDS-WRSM) for variable speed applications is proposed. Through the dual mode (DM) machine operation, the constant torque and the constant power are achieved in the constant torque and constant power region, respectively. However, the dual stator design has been chosen to improve the torque density of the machine as compared to the torque density of the single stator BL-WRSM presented in [3]. A 2-D finite element analysis is performed to validate the proposed DMDS-WRSM. 2. Proposed Topology and Operation Principle The topology for the proposed machine is shown in Fig.1(a). The winding of each stator is divided into two sets of series connected windings; winding ABC and a centrally tapped winding XYZ and both the windings have an equal number of turns. The winding of inner and outer stator is connected in series and supplied through a single inverter. The winding XYZ is tapped at the center point by using switches. There are two separate windings on the rotor i.e. harmonic winding and the field winding. Both windings are connected through a bridge rectifier mounted on the rotor periphery. The field winding is also connected to the slip rings so that it can be supplied through the external dc voltage source when needed. There are two modes of operation of the proposed topology as shown in Fig. 1(b) and 1(c). In mode-I: the switches S1 to S4 are in open state and the three-phase sinusoidal current is supplied to the stator winding through the inverter. The field winding is connected to the external dc supply by closing the switch S5. In this mode, the proposed topology is operating as a brushed WRSM. Mode-I is proposed to achieve the constant torque in the constant torque region. In mode-II, the proposed topology is operating as a BL-WRSM. The switches S1 and S3 are closed to tap the winding XYZ at the center point, such that the number of turns in winding XYZ becomes half compared to that of winding ABC. On the other hand, switch S4 is closed to connect the field winding in parallel with the harmonic winding through a bridge rectifier. Meanwhile, the switch S5 is opened to disconnect the field winding from the external dc supply. The difference in the number of the turns in both windings is responsible for the generation of the sub-harmonic component of stator MMF (SH-MMF). This SH-MMF induces the voltages in the harmonic winding, which is then rectified to supply the dc current to the field winding of the machine. The proposed topology is verified by designing an 8-pole, 48-slot machine. It has two stators and a sandwiched rotor. An 8-pole, double layer distributed winding is configured on both the stators. Both the stators have two windings; winding ABC and winding XYZ and these windings are connected in series. The machine model and winding configuration are shown in Fig. 1(d). Two separate windings are placed on the rotor; harmonic winding and field winding. The harmonic winding has 4 poles, while the field winding has 8 poles. The 4-pole SH-MMF generated in the airgap couples with the 4-pole harmonic winding and induces the voltages accordingly. 3. Simulation Analysis 2-D finite element analysis is performed on 8-pole 48-slot machine shown in Fig. 1(d). Fig. 1(e) shows the torque of the mode-I operation. The Fig. 2(a) shows the induced current in the harmonic winding and the rectified current in the field winding, during the mode-II. The average torque in mode-II of the proposed topology is shown in Fig. 2(b). The proposed topology is suitable for variable speed application due to its DM operation and it exhibits 20.24% higher torque density as compared to the BL-WRSM proposed in [3]. However, the use of switches makes this topology complex compared to the existing topologies. Figure 2(c) summarizes the performance comparison of the proposed DMDS-WRSM with the conventional WRSM. Detailed analysis of the proposed topology will be presented in the full paper.

EG-05. Radial Force and Vibration Calculation for Modular Permanent Magnet Synchronous Machine with Symmetrical and Asymmetrical Open-circuit Faults.

Y. Pei[1], Z. Song[1], *F. Chai*[1] and Y. Li[1]
1. Harbin Institute of Technology, Harbin, China

I. INTRODUCTION The vibration characteristic of Permanent Magnet Synchronous Machines (PMSMs) has become a research hotspot in recent years especially for those applied in demanding working situations with respect to fault tolerance [1, 2]. To reduce the possibility of failures, fault-tolerant topology such as modular three-phase structure is widely used [3]. For modular three-phase PMSM, there are special fault conditions such as symmetrical and asymmetrical open-circuit faults. Obviously, they will have a negative impact on the motor's vibration characteristic with additional harmonics and unbalanced magnetic pull to be significant due to structural and electrical asymmetries. Researches on this problem are quite limited. In this paper, the theoretical analysis of the air-gap magnetic field and radial force density under open-circuit fault is presented based on the modification of armature magnetomotive force (MMF). The simulation results under symmetrical and asymmetrical open-circuit faults by Finite Element Analysis (FEA) verify the theoretical ones. Multi-physics model for the stator system is built to determine the inherent properties and vibration characteristics. The investigations help analyze and mitigate the modular machine's vibration dealing with fault conditions in the engineering practice. II. THEORETICAL ANALYSIS The air-gap radial force, which is the main source of electromagnetic vibration, can be obtained from the air-gap magnetic fields. The difference of air-gap magnetic fields between normal and open-circuit fault conditions starts from the stator armature MMF. Suppose phase A winding is open. The resulting armature MMF harmonic of the three-phase winding can be expressed as (1). $f_v(\alpha, t) = F_{v1}\cos(\omega t\text{-}vp\alpha) + F_{v2}\cos(\omega t\text{+}vp\alpha)$ (1) For the harmonic orders $v = 6k+3 = 3, 9, 15,...$, $F_{v1} = F_{v2} = -F_{\Phi v}/2$; for the harmonic orders $v = 6k+1 = 1, 7, 13,...$, $F_{v1} = F_{\Phi v}$, $F_{v2} = -F_{\Phi v}/2$; for the harmonic orders $v = 6k-1 = 5, 11, 17,...$, $F_{v1} = -F_{\Phi v}/2$, $F_{v2} = F_{\Phi v}$. Here, $F_{\Phi v}$ is the magnitude of vth single-phase MMF; ω is the current angular frequency; α is the electrical degree. Note that there are no even harmonic orders in the MMF. To simplify the calculation, we consider only the average and the first tooth harmonic components of the air-gap permeance. Then the magnetic field and the radial force density along the air-gap can be derived according to the Maxwell stress tensor theory. During open-circuit condition, additional harmonic orders are (0,2*f*) generated by the armature magnetic fields, (2*p*, 0*f*) and (Z-2*p*, 0*f*) generated by the interaction of armature and PM fields. III. FEA SIMULATION The simulation results of the air-gap magnetic fields and the radial force density are obtained based on a 16p24s modular PMSM with four individual units. As is illustrated in Fig. 1, when two individual phase windings in non-adjacent units are open, it is called symmetrical fault; when two windings in adjacent units are open, it is called the asymmetrical fault. The radial force density distribution of the faulty unit is consistent with theoretical analysis. The radial force density harmonic contents under the two open faults are quite different, which is shown in Fig. 2. Secondary harmonics with frequencies of 0 and 2*f* appear in both the two fault conditions, and the low-order harmonic components of asymmetrical fault tend to be concentrated, while those of symmetrical fault tend to be dispersive. IV. VIBRATION CHARACTERISTICS Through 3-D model of stator system in structural field, including stator core, concentrated windings and frame, the inherent properties of the stator system can be analyzed through modal analysis. We take several test nodes on the frame circumference to get the instantaneous acceleration waveform and frequency response. The frequencies of acceleration peaks in the low frequency band mainly appear at 2*f* = 533Hz and 6*f* = 1600Hz. Open-circuit fault enlarges the acceleration amplitudes and asymmetrical fault makes the distribution more unbalanced. V. CONCLUSION This paper investigates the radial force and vibration for modular three-phase PMSM under symmetrical and asymmetrical open-circuit faults. The expressions of the MMF, air-gap magnetic fields and radial force density under open-circuit fault are first derived theoretically. The FEA simulation compares the radial force density under the two fault conditions. The results agree well with theoretical analysis. Acceleration response at low frequency band especially 2*f* is quite severe and asymmetrical fault makes the radial acceleration distribution more unbalanced.

EG-06. Weighted Average Efficiency Optimization for Permanent Magnet Synchronous Generators Used in Hybrid Electric Special Vehicles.

J. Gao[1], *L. Dai*[1] and W. Zhang[2]
1. College of Electrical and Information Engineering, Hunan University, Changsha, China; 2. Department of Electronic and Electrical Engineering, Changsha University, Changsha, China

I. Introduction In recent years, permanent magnet synchronous generators (PMSG) have been widely used in hybrid electric special vehicles (HESV) due to their high efficiency, power density and reliability [1]-[6]. But the output power of PMSG for HESV (H-PMSG) changes in a wide range with the different operating environment, such as normal driving, climbing and accelerating [1]. Therefore, the traditional rated efficiency (RE) optimization method (OM) for PMSG can no longer work well in this application. The efficiency optimization for PMSG has been discussed in many literatures. The efficiency characteristics of H-PMSG were analyzed under varied conditions [2]. In [3], the losses and efficiency in wide speed range for H-PMSG and switched reluctance generator were compared. The rotor structure of H-PMSG was optimized by Response Surface Methodology to reduce the vibration and noise under rated load [4]. The efficiency under rated load of H-PMSG were optimized by Particle Swarm Algorithm and Genetic Algorithm separately in [5] and [6]. This paper presents a new efficiency OM for H-PMSG with the weighted average efficiency (WAE) of the varied load ratios. The load ratio rule for H-PMSG in a driving cycle is investigated, and then the weighted coefficients for each load ratio (100%, 75%, 50% and 25%) are determined according to the operation time with the varied load ratios. Finally the optimization design by the genetic algorithm aiming at the weighted average efficiency is developed. Comparing with the traditional efficiency OM based on the rated load, the proposed method has significantly improved the global efficiency of H-PMSG and the overall fuel efficiency of HESV in the driving cycle. II. Model and Optimization The dimensions of the active parts can be obtained from the conventional magnetic circuit laws, which have been estimated to be sufficient for a preliminary generator design [7]. In this section, the analytic formulas for air-gap flux density B_g, no-load voltage E_0, stator currents I_1, losses p and efficiency η are deduced, which are made up of the analytic model of H-PMSG. In order to simplify the optimization process and save computation time, four typical load ratios of 100%, 75%, 50% and 25% are selected to match the whole load ratios in a drive period (an hour) of H-PMSG by the least square method. Therefore, the WAE for the four typical load ratios is defined as $\eta_{wa}=\alpha_1\eta_1+\alpha_2\eta_2+\alpha_3\eta_3+\alpha_4\eta_4/(\alpha_1+\alpha_2+\alpha_3+\alpha_4)$ (1) where η_1, η_2, η_3, and η_4 are the efficiency due to 100%, 75%, 50% and 25% load ratios separately, α_1, α_2, α_3 and α_4 are the weighted coefficients for the four typical load ratios. Seven variables are chosen to vary within a certain range, including the stator inner diameter, length of core, slot height, slot width, yoke height, length of air gap and PM thickness. The following constraints are used in the optimization program. The air-gap flux density is set to be 0.7-1.0*T*; the current density is limited to 5-7 A/mm^2; the current loading is limited to 60-70 *kA*/*m* due to the water cooling, and the slot filling factor is limited to 75%. The genetic algorithm is used for solving the efficiency optimization problems for H-PMSG. The objective function to maximize the WAE is as following maximize $\eta_{wa}(X)$ (2) where X is a vector of the optimal design variables. The feasibility of the design is guaranteed by adding a penalty to the objective function due to constraint violations. In each generation of the genetic algorithm, according to individual fitness value (i.e. the value of the objective function), referring to the transformation method of natural genetics to choose the individuals, the new individuals will be more adaptable to the environment than the original individuals, and then run over when the decision condition of the algorithm program is satisfied, Fig. 1(a) shows the block diagram of WAE optimization. III. Results and Prototype Verification A 500-*kW* H-PMSG with a constant speed of 4200 *r*/*min* has been chosen to demonstrate the developed electromagnetic design and the optimization models. The four weighted coefficients α_1, α_2, α_3 and α_4 are set to be 0.23, 0.32, 0.3 and 0.15 due to the actual operation conditions. It can be seen from Fig. 1(b) that the efficiency with WAE-OM are improved by 2.01%, 2.5% and 2.35% on 25%, 50% and 75% load ratios comparing to that with RE-OM, and is only decreased by 0.37% on full load ratio. The calculated input energy with WAE-OM is 340.9 *kWh*, which is reduced by 1.4% comparing to that of 345.8 *kWh* with RE-OM. Fig. 1 (c) shows that the active material weight with WAE-OM is 13.1% lower than that with RE-OM. In order to verify the results of the optimization, the prototype of 500kW-4200 *r*/*min* is manufactured. The experiment platform is shown in Fig. 2 (a). The prototype is dragged by an 800kW induction motor controlled on the constant rated speed, and the output power is consumed by a water resistance. The experimental and design efficiency on 25%, 50%, 75% and 100% load ratios of the prototype are shown in Fig. 2 (b), which shows that the experimental results are agreed well with those of the optimization design.

EG-07. Modeling Induction Motors under Mixed Radial-Axial Asymmetry of Air Gap Produced by Oil Whirl in a Sleeve Bearing.

M. Ojaghi[1] and R. Akhondi[1]
1. Electrical Engineering, University of Zanjan, Zanjan, The Islamic Republic of Iran

I. Introduction Squirrel cage induction motors (SCIMs) are widely used in modern industry due to their various merits; however, some faults may lead to their deterioration and economical losses. Several studies show that 40–50% of the motor failures are related to the bearing defects caused by many factors [1]. The SCIM bearings are of two main categories: rolling element bearings and sleeve bearings. Oil whirl fault (OWF) is a common faulty mode in the sleeve bearings and if not early detected and removed, leads to serious damage of the bearing [2-4]. The OWF usually happens in one bearing of the SCIM and introduces time-dependent mixed radial-axial asymmetry to the air gap distribution. This paper offers an analytical model for the SCIM with OWF in one of its sleeve bearings. Multiple coupled circuit model (MCCM) along with 2-D modified winding function theory (MWFT) are used for this purpose. The modeling and simulation results are in agreement with corresponding experimental results and show some harmonic components in the self-inductances of the stator windings. The most efficient harmonic is selected as the OWF index by further analysis performed using simulation under different fault severities, load levels and voltage unbalance conditions. II. Modeling Procedure Dynamic equations governing MCCM for Y-connected SCIMs are well defined in previous references [5]. Various self/mutual inductances of the SCIM are the main parameters of the equations. Due to rigid construction of the rotor, by happening oil whirl in a sleeve bearing, the OWF components will linearly change along the axial coordinate (z-axis) as follows: $OW_x(z) = (OW_x / L)z$ (1) $OW_y(z) = (OW_y / L)z$ (2) where OW_x and OW_y are the x and y components of the shaft vibration magnitude produced in the bearing location by the fault [2] and L is the distance between the two bearings of the motor. Using (1)-(2) and considering little inherent eccentricity as well, the coordinates of the rotor shaft center (C_x and Cy) versus the bearing center are determined as follows [2]: $C_x(\theta_r,z) = SE_x+DE\cos(\theta_r)+OW_x(z)\cos(k_{ow}\theta_r+\pi/6)$ (3) $C_y(\theta_r,z) = SE_y+DE\sin(\theta_r)+OW_y(z)\sin(k_{ow}\theta_r)$ (4) where k_{OW} is the oil whirl frequency ratio that is usually between 0.42 and 0.48 [3-4], θ_r is the rotor position angle, SE_x and SE_y are the inherent static eccentricity components in the x and y directions and DE is the inherent dynamic eccentricity degree. Then, the coordinates are changed to the polar form and used to define the air gap distribution function as follows: $R_c(\theta_r,z) = \sqrt{[C_x(\theta_r,z)^2 + C_y(\theta_r,z)^2]}$ (5) $\theta_c(\theta_r,z) = \tan^{-1}[C_y(\theta_r,z) / C_x(\theta_r,z)]$ (6) $g(\theta_s,\theta_r,z) = g_0 - R_c(\theta_r,z)\cos[\theta_s - \theta_c(\theta_r,z)]$ (7) where R_c and θ_c are the coordinates in the polar form, θ_s is the angle in the stator reference, $g(\theta_s,\theta_r, z)$ is the air gap distribution function and g_0 is the uniform air gap length in healthy condition. Using 2-D MWFT with this air gap function and ignoring the air gap mean radius variations, the mutual inductance between any x and y circuits of the SCIM is expressed as follows [5]: $L_{yx}(\theta_r) = \mu_0 r \iint[n_y(\theta_s,\theta_r) M_x(\theta_s,\theta_r,z) / g(\theta_s,\theta_r,z)]d\theta_s dz$ (8) where the inner and outer integrals are performed from 0 to 2π and along the stack length, respectuvely, $M_x(\theta_s,\theta_r,z)$ denotes 2-D modified winding function of circuit x, $n_y(\theta_s,\theta_r)$ denotes the turn function of circuit y, μ_0 is the air permeability and r is the air gap mean radius. Self-inductance of the circuit x is calculated by putting y=x in (8). Numerical techniques are used to solve the dynamic equations, where (8) is used to update the inductances values by varying the rotor position. III. Simulation Results A 510kW, 6kV, 50Hz, 2-pole SCIM is simulated under the healthy and OWF conditions. The simulation results, in accordance to the corresponding experimental results, approve the presence of the related harmonics in the stator line current due to the OWF [2]. However, the stator inductance fluctuation could be a more reliable index for the fault [6]. Fig. 1 shows time variation of the self-inductance of a stator phase winding (L_{aa}) during the motor startup in the healthy and OWF conditions. Inherent eccentricity is included in both cases. As seen, L_{aa} fluctuates slightly in the healthy condition due to the inherent eccentricity, while the OWF increases the magnitude and distorts the shape of the fluctuation. Fast Fourier transformation is applied to the time trend of L_{aa} during steady-state operation of the SCIM to show its harmonic content. Fig. 2 shows the attained results. As seen, in the healthy condition, L_{aa} includes a constant component at zero frequency and two harmonics at f_r (49.6 Hz) and $2f_r$ (99.2 Hz) frequencies produced by the inherent eccentricity (f_r is the rotor speed) [6]. The spectrum for the OWF condition includes new harmonics at $k_{ow}f_r$, $2k_{ow}f_r$ and $(1\pm k_{ow})f_r$ frequencies. Using an analytical approach, it is shown that the harmonics are introduced in the inductances by the air gap function (6). Therefore, the presence of $k_{ow}f_r$, $2k_{ow}f_r$ and $(1\pm k_{ow})f_r$ harmonics in the L_{aa} spectrum indicates the occurrence of the OWF. However, more detailed analysis show that $k_{ow}f_r$ harmonic is more robust against the load change and the voltage unbalance, while its magnitude is the highest and its frequency is the least, so, this harmonic is a more reliable index for diagnosing the OWF.

EG-08. PM Vernier Machine with Multiple Working Harmonics and Enhanced Flux Modulation Effect.

T. Zou[1], D. Li[1] and *R. Qu*[1]
1. School of Electrical and Electronic Engineering, Huazhong University of Science & Technology, Wuhan, China

I. Introduction With ever improving performance of rare earth permanent magnet (PM) material, PM machines have been widely used. In recent years, PM vernier (PMV) machines have gained increasing attentions due to their inherently high torque density [1-2], and have become promising candidates in low speed, high power applications such as wind power and ship propulsion. Researches on PMV machines have been mainly focused on proposing novel topologies [3-6], evaluating performances [7-8] and establishing analytical theories [9]. For non-overlapping winding PMV machines, it has been found that through changing the flux modulation pole (FMP) pitch, i.e., configuring non-uniformly distributed FMPs, additional working field harmonics can be introduced [10]. Based on this research work, a novel spoke type PMV machine with multiple working harmonics and enhanced flux modulation effect is further proposed in this paper. Section II will be devoted to introduction of the machine topology and working principle. In Section III, the production of multiple working airgap field harmonics involved torque production will be analyzed, and an enhanced flux modulation effect will be introduced for the fisrt time. Finally, in the full paper, electromagnetic performances of the proposed machine will be further investigated and compared with several existing PMV machine topologies to demonstrate its superiority in torque density. Experimental test results on several prototypes will also be provided. II. Machine Topology and Configuration Basically, the rotor pole pair number P_r, stator pole pair number P_s and FMP number P_f of a PMV machine should satisfy $P_f=nZ=P_r \pm P_s$ where Z is the stator slot number for embedding windings. Pole ratio (PR), defined as P_r/P_s, is a special design parameter for PMV machines. Generally, the higher PR is, the stronger flux modulation effect and higher torque density it will be. The exploded view of the proposed PMV machine is shown in Fig. 1(b). This machine is constructed with a spoke type PM rotor and a stator wound with non-overlapping windings. It can be seen that the stator is designed with auxiliary teeth, which work as FMPs. More specifically, the pitch angle θ of FMPs connected to one main tooth is set unequal to the slot opening angle. Essentially, the proposed machine topology is developed from a regular spoke-type PMV machine with uniformly distributed FMPs as illustrated in Fig. 1(a). The parameter k is defined as flux modulator pitch ratio and calculated as $k=\theta/(2\pi/P_f)$. The slot-pole combination of the proposed machine is carefully chosen, i.e., $Z=6$, $P_f=18$ and $P_r=14$. Then, P_s is supposed to be 4 and PR=3.5. III. Operation Principle of Multiple Field Harmonics with Enhanced Flux Modulation Effect Due to the existence of FMPs, the airgap field of a PMV machine cannot directly couple the stator windings. In order to reveal the nature of the proposed machine, a corresponding integrated magnetic geared (MG) machine is designed for evaluation, as shown in Fig. 2. When the additional outer airgap gets infinitely small, the two machines in Fig. 2 will become exactly equivalent. Field evaluation in the outer airgap of the MG machine can give a better insight into the harmonics which are actually involved in back-EMF and torque production of a PMV machine. Essentially, the variation of the flux modulator pitch k changes the airgap permeance distribution and enriches the permeance harmonics. Then, the main produced flux density harmonics including the newly induced ones are summarized in Table II. All these harmonics are with the same spatial electrical angular speed, and can induce back EMF with exactly the same frequency. The FEA-obtained outer airgap flux density harmonics for k=1.0 and 1.2 are illustrated in Fig. 3. It can be clearly seen that the 2^{nd}, 8^{th}, 10^{th}, 16^{th}, and 20^{th} harmonics are newly produced flux density terms for the proposed PMV machine, while the originally existed 4^{th} and 14^{th} harmonics are weakened. Fig. 4 gives the fundamental back-EMF contribution of these field harmonics. It can be seen that for the regular case with k=1, the back-EMF is induced by only the 4^{th}, 14^{th} and 22^{th} harmonics, in which the 22^{th} harmonic actually weakens the fundamental back-EMF. Nevertheless, for the proposed PMV machine with k=1.2, there are multiple harmonics which work together for the back-EMF production. With the same PM usage, the total back-EMF is increased significantly by ~40% compared with the regular case. Among these newly produced harmonics, it is interesting to find that the lowest harmonic order has been changed from 4 to 2. Since the winding pole pair number P_s is decided by the lowest order of working harmonics, it has been reduced to 2, and the pole ratio is in fact doubled to 7. Hence, the flux modulation effect has been enhanced compared with that in [10]. It will be verified in the full paper taht this newly found enhanced flux modulation effect can boost the torque capability of PMV machine much more significantly than that in [10]. IV. Conclusion In this paper, a spoke type, non-overlapping winding PMV machine with multiple working flux density harmonics and enhanced flux modulation effect has been proposed. The proposed PMV machine is supposed capable of improving the torque density by ~50% compared with its regular counterpart. The detailed comparison between the proposed machine and corresponding counterparts will be given in the full paper through both FEA and experimental results, and the advantage of the proposed machine will be verified.

INTRODUCTION Nowadays, dual-rotor motor is drawing more and more attention for wide application in drive for underwater and electric vehicles, as well as wind power generation due to the double mechanical port. Various types of dual-rotor motors have been studied in previous articles. The anti-directional-twin-rotary motor with a stator and a rotor is discussed [1]-[2].In [3], the four-quadrant transducer(4QT), consisting of two combined radial flux machines, one double rotor machine and one conventional machine, is presented for HEV applications. Professor Hoeijmakers put forward the electric variable transmission, which use the PMs to take place the winding of intermediate rotor of the 4QT [4]. In this paper, a novel dual-rotor motor -disk-type Single Stator Contra-rotating Rotors PMSM- is presented to improve machine efficiency and boost the torque density. The design principle and back electromotive force (EMF) characteristic are studied to validate the feasibility and evaluate the performance by means of 3D FEM and experiments taken from a machine prototype. Consequently, the results validates the correctness of design principle and shows good operating performances of the motor. DESIGN PRINCEPLE AND OPERATING CHARACTERISTIC ANALYSIS The principle of the motor is briefly introduced for better understanding this paper. The motor is mainly composed of one stator and two same rotors, all of them having a disk form. Dual rotors, which are mechanically independent, are set on the opposite side of the stator co-axially shown in Fig. 1a through a simplified 3D model. The most innovative part is that the stator windings is characteristic in a toroidal fashion as shown in Fig.1a. The windings terminal connection mode of one pole pair is shown in Fig.1c, which lead to the windings of rotor1 and rotor2 indicated by solid lines and dashed lines respectively. Hence, a pair of opposite rotating magnetic fields will be produced on both sides of the stator. The referential basis of magnetic circuit design is obtained by analyzing magnetic circuit variation. Compared with TORUS-NS PMSM [5], the motor's magnetic circuit of 3D FEM always changes from NN parallel magnetic circuit [6] to NS series [7]. Since the stator core of NN magnetic circuit is thicker than NS, the motor shall be designed according to NN magnetic circuit. The motor can be simply designed single stator single rotor structure, because dual rotors are symmetry with segmentation of the central plane stator core. In consideration of practical application, the main parameters is given in the Fig1.c. The detail will be presented in the full article. In view of the complexity of 3D analytical modeling and the accuracy of 2D simplified modeling [8-9], an approximate analytical formula from the simplified 2D model [10] has been applied to the motor to validate the feasibility of the motor. The influence of the dual rotors position variations on total back EMF should be considered to evaluate the performance of the motor through 3D FEM. Due to the structure of the motor, the total EMF of the motor can be deduced to be the sum of the dual rotors EMF. If the loads of dual rotors are balanced, the EMF waveforms is indicated in Fig.2b-c. It is suggested that the waveforms of dual rotors EMF are almost synchronous, thereby total EMF waveform is sinusoid with little harmonic, which is revealed that the motor with balanced load performances well. Considering the unbalanced case, Fig.2d intuitively shows peak value and phase variation of the total back EMF versus the absolute difference of dual rotors position angle through a line graph. It is provided that the peak total EMF decreases and the phase increases as the absolute difference of dual rotors position angle grows, which presents the distortion of total EMF waveform increases in the process. The fact indicated that the ripple will appear in the waveforms of speeds and torques when loads of dual rotors are unequal. PROTOTYPE VALIDATION AND EXPERIMENT RESULT The experiment was made to validate the machine operating principle using a constructed machine prototype. Fig.2a shows the physical picture of the motor prototype. To apply loads of dual rotors separately, the prototype's outer shafts are at two sides of the machine. Fig.2b-c presents the dual rotors EMF waveforms of 3D FEM and experiment results with rated loads, which are almost the same. The result is indicated that the ratio of the differences of EMF peak value are within 4% among the two situation. Therefore the correctness of prototype design is validated, and the motor performances with balanced loads are excellent to put into application. In the asynchronous case, the total EMF of the motor has a degree of distortion discussed in the paper. Thus, rotors' synchronous control strategy on a condition of the unbalanced load should be explored from the existing methods, which is very meaningful for drive of underwater vehicles. The specific solving of prototype machine parameter and operating characteristic analysis will be proposed in detail in the full article.

EG-10. Characteristics Verification of a Novel Motor with Two Controllable Rotors.

H. Suzuki[1], K. Hirata[1], N. Niguchi[1] and A. Kohara[1]
1. Graduate School of Engineering, Osaka University, Suita, Japan

1. Introduction The electrification of automobiles has been gaining momentum recently, and more and more automobiles are being fitted with electric motors and their inverters. In order to reduce the space of the motors and inverters, a motor with two controllable rotors was proposed [1-2]. This motor has two rotors and one stator. The two rotors can be independently controlled using 3- and 6-phase superimposed currents created by a 6-phase inverter. One rotor is driven by a 3-phase current and the other is driven by a 6-phase current. However, this motor has problems such as low heat dissipation and complicated support structure of the stator because the stator is sandwiched between the two rotors. In order to solve these problems, a motor with its stator on the outside of its rotors was proposed [3]. This motor has also two rotors and one stator, and the two rotors can be independently controlled using 3- and 6-phase superimposed currents. However, this motor has also a problem of a complicated support structure of the middle rotor. Therefore, we proposed a novel motor with two controllable rotors to solve above problems [4]. In this paper, 3D-FEM analysis coupled with vector control is conducted in order to verify that the two rotors can be independently controlled. 2. Structure and Operational Principle Fig. 1 shows the proposed motor with two controllable rotors. The proposed motor has two rotors and one stator as shown in Fig. 1. The 3-phase and 6-phase rotors have 12 and 6 poles, respectively, and the common stator has 18 slots with concentrated windings. This motor has a high heat dissipation because the stator is located outside. The two rotors can be easily supported because the two rotors are axially located with each other and the 6-phase rotor shaft is mounted in the 3-phase rotor shaft through bearings. The 3- and 6-phase rotors are driven as 3- and 6-phase permanent magnet synchronous motors, respectively, by using superimposed currents created by a 6-phase inverter, where the 3- and 6-phase currents do not interfere with each other [1]. 3. FEM Analysis 3D-FEM analysis coupled with vector control is conducted in order to verify that the two rotors can be independently controlled. In the analysis, a DC voltage of 12 V is used for 3- and 6-phase drives. The torque and rotation speed when the 3-phase rotor is rotated under a load of 2.4 Nm and the 3-phase voltage is applied is shown in Fig. 2, where the initial rotation speed of the 3-phase rotor is 660 rpm, and the 6-phase rotor is free. Similarly, the torque and rotation speed when the 6-phase rotor is rotated under a load of 1.2 Nm and the 6-phase voltage is applied is shown in Fig. 3, where the initial rotation speed of the 6-phase rotor is 660 rpm, and the 3-phase rotor is free. From Figs. 2 and 3, the driving current does not create any rotation torques on the free rotor. The torque and rotation speed when the 3- and 6-phase rotor are rotated under loads of 2.4 and1.2 Nm, respectively, and the superimposed voltage is applied are shown in Fig. 4, where the initial rotation speed of both rotors is 660 rpm. From Fig. 4, it is verified that the two rotors can be independently controlled because the both rotors are driven at a different rotation speed from each other. 4. Conclusion In this paper, 3D-FEM analysis coupled with vector control is conducted in order to verify that the two rotors can be independently controlled. From the analysis results, the driving current not create any rotation torques on the free rotor, and the two rotors can be independently controlled. In the final paper, the computed N-T curves of both rotors and the experimental results of a prototype will be shown.

EG-11. A New Structure of Stator Pole to Reduce Torque Ripple and Acoustic Noise in Switched Reluctance Motor.

M. Babaei[1] and A. Ahmarinejad[1]
1. Electrical Engineering Department, Yadegare Imam Khomeini (RAH) Shahr-e-Rey Branch, Islamic Azad University, Tehran, The Islamic Republic of Iran

Abstract—Radial forces are the main source of acoustic noise in Switched Reluctance Motors (SRMs). This paper presents new pole tip shape of SRMs for decreasing the torque ripple and reduces radial forces. By using time-stepping finite element analysis (TSFEA), this new structure is simulated numerically in case of single-phase and multiphase excitations to obtain electromagnetic torque characteristic of the motor. Then radial force that affected on stator of the motor calculated precisely from a new analytic proposed method. Simulation results show the high ability of the proposed structure to reduce the two main drawbacks of the motor. I. *Electromagnetic torque Calculation* An 8/6 SRM with new stator pole shape is simulated in Flux2d FE software for TSFEA. Rotor and stator pole angle are 23 and 21 degrees and motor rotates at 1500 rpm. Fig. 1 (a), shows the pieces of iron between stator poles. These pieces reduce the effect of salient structure of stator. Torque ripple is defined as the difference between maximum and minimum instantaneous torque dividing to average torque, as: Torque ripple=$(T_{ins}(max)-T_{ins}(min))/T_{ave}$ (1) Torque profile in normal form and new structures with various widths of iron pieces are shown in Fig. 1(b). Iron pieces widths in three models are 2, 2.5 and 3mm. As seen from Fig. 1(b), the average output torque and torque ripple of proposed structures decreased. Results are presented in Table 1. II. *Radial and tangential force calculation* The magnetic flux passes across the air gap in an approximate radial direction producing radial forces on stator and rotor, resulting in magnetic noise and vibration [1]-[3]. Assume that iron is infinitely permeable and has zero reluctance. The air gap flux density is given as: $B_g(\theta,l_g,i)=\phi/Lr\theta=\mu_0H_g=\mu_0T_{ph}i/l_g$ (2) and $T_{ph}i=l_g\phi/\mu_0rL\theta$ (3) where θ is the stator and rotor overlap angle, l_g is air gap length, consider equal to 0.35mm and r is the rotor radius that equal to 39.35mm. Also L, T_{ph}, i, H_g and ϕ are stach length, number of winding turns in one phase, winding current, magnetic field intensity in air gap and flux, respectively. The incremental electrical input energy is: $dW_e=id(T_{ph}\phi)=T_{ph}id\phi= (l_g\phi/\mu_0rL\theta)d\phi$ (4) and the stored energy in magnetic field is given by: $W_s=(l_gLr\theta/2\mu_0)Bg^2(\theta,l_g,i)=l_g\phi^2/2\mu_0Lr\theta$ (5) energy balance equation neglecting losses is: $dW_e=dW_m+dW_s$ (6) where dW_m is the incremental mechanical energy. To compute tangential force that is in direction of rotor pole arc and is a function of the varying rotor position, the incremental field energy is obtained from (7) as: $dW_s=-(l_g\phi^2/2\mu_0Lr\theta^2)d\theta+(l_g\phi/\mu_0Lr\theta)d\phi$ (7) Substituting (4) and (7) in (6), the incremental mechanical energy is obtained as: $dW_m= (l_g\phi^2/2\mu_0Lr\theta^2)d\theta$ (8) From the tangential torque that known as electromagnetic torque is obtained as: $T_e=dW_m/d\theta=(l_grL/2\mu_0)\ Bg^2(\theta,l_g,i)$ (9) Tangential force is obtained by dividing the tangential torque by the radius of the rotor pole, yielding: $F_t=T_e/r= (l_gL/2\mu_0)\ Bg^2(\theta,l_g,i)$ (10) Similarly, the normal force which is the radial force in the direction of the air gap is obtained as: $F_n=dW_m/dl_g=-(rL\theta/2\mu_0)\ Bg^2(\theta,l_g,i)$ (11) The ratio between tangential and radial force is: $F_n/F_t=-r\theta/l_g$ (12) Substituting (10) to (12), the radial force from electromagnetic torque is obtained as: $F_n=-T_e\theta/l_g$ (13) The rotor angle is equal to one phase conduction angle in terms of rotor and stator pole is given as: $\theta=4\pi/P_sP_r$ (14) where P_s and P_r are the number of stator and rotor poles. The radial force multiple times that of the tangential force in electrical machine. In SRMs, radial component of the force is the main source of radial vibration and acoustic noise. From TSFEA, electromagnetic torque obtained by single-phase excitation at unaligned to aligned position and the radial force can be calculated from (13) with considering nonlinearity. Fig. 1(c) showed the radial force of normal and proposed structures in one phase excitation from unaligned to aligned position of rotor and stator poles. According to this figure, radial force decreases and so acoustic noise will be reduced. III. *Conclusion* This paper presents the new pole shape of switched reluctance machine for decreasing the torque ripple and acoustic noise. This new structure of 8/6 SRM implemented by Flux2d for TSFEA. Multiphase excitations are used for obtaining actual and accurate electromagnetic torque performance such as average torque and torque ripple. It is shown that the proposed new structure will be able to decrease the torque ripple from 53% to 20%. For calculating radial force single-phase excitation is used. Radial force calculated from unaligned to aligned position with use the nonlinear electromagnetic torque characteristic and the analytical formula. Comparison between radial force characteristics shown that the new structure reduced the average and maximum force on stator. Therefore, acoustic noise will be reduced.

EH-01. Giant Magnetoelectric Effects in Multiferroic Hexaferrites.

Y. Sun[1], K. Zhai[1], J. Shen[1], D. Shang[1] and Y. Chai[1]
1. Institute of Physics, Chinese Academy of Sciences, Beijing, China

Multiferroics materials with coupled magnetic and electric orders have attracted tremendous research interest because of their potential in constructing next-generation multifunctional devices. The application of single-phase multiferroics is currently limited by their usually small magnetoelectric (ME) effects. Therefore, a major challenge for single-phase multiferroics is to explore new mechanisms that will significantly improve the ME coefficients. Hexaferrites with various tunable conical magnetic structures are among the most promising multiferroic materials for realizing large ME effects at low magnetic fields because the electric polarization is directly induced by magnetic ordering. Kimura et al. first reported magnetic-field-induced ferroelectricity in the Y-type hexaferrite $Ba_{0.5}Sr_{1.5}Zn_2Fe_{12}O_{22}$ [1]. Later, Ishiwata et al. demonstrated low magnetic field reversal of electric polarization in the Y-type hexaferrite $Ba_2Mg_2Fe_{12}O_{22}$ [2]. These discoveries have triggered considerable studies on hexaferrites. Here we report the realization of giant magnetoelectric effects in a Y-type hexaferrite $Ba_{0.4}Sr_{1.6}Mg_2Fe_{12}O_{22}$, which exhibits record-breaking direct and converse ME coefficients and a large electric-field-reversed magnetization at 10 K [3]. A systematic study in the Y-type hexaferrite $Ba_{2-x}Sr_xMg_2Fe_{12}O_{22}$ family with magnetization, spin-induced ferroelectricity and neutron diffraction measurements reveals that tuning the transverse spin cone symmetry is an effective route to enhance the ME effects in hexaferrites. Besides, we demonstrate a new type of nonvolatile memory device based on a single-phase multiferroic Z-type hexaferrite $Sr_3Co_2Fe_{24}O_{41}$ which exhibits nonlinear ME effects even at room temperature [4]. The principle of the memory is to store binary information by employing the states (magnitude and sign) of the ME coefficients, instead of using magnetization, electric polarization, and resistance [5,6]. Such kind of memory device using single-phase multiferroics pave a pathway towards practical applications of spin-driven multiferroics.

Three-dimensional topological insulators (TIs) are insulating bulk materials that carry a conducting surface state, arising from the intrinsically strong spin-orbital coupling (SOC) in the bulk band structure protected by time-reversal symmetry (TRS). While such unique systems offer nontrivial surface states that can be utilized to perform dissipationless spin transport, it is equally important to break the TRS of TIs to realize novel physical phenomena like quantum anomalous Hall (QAH) effect. [1-3] Within the growing family of TIs, ferromagnetism has been reported in V-, Cr-, and Mn-doped single crystals of Sb2Te3 [4] and Fe- and Mn-doped single crystals of Bi2Te3. [5] Both ferro- [6] and antiferromagnetism [7] have been reported in Cr-doped Bi2Se3, [10] and for Fe- doped Bi2Se3 observations are rather controversial. [8-9] So far, evidence for the detailed spin and orbital ordering of magnetically doped TIs are inconclusive. [1-8] In this regards, the synchrony-based X-ray absorption (XAS) / X-ray magnetic circularly dichroism (XMCD) technique can be an ideal tool as a valence-, site-, and symmetry-specific probe. Although XAS/XMCD has been intensively utilized in the determination of the impurity magnetism of diluted magnetic semiconductors (DMSs), to apply it to the 3d-metal-doped TIs emerged only very recently. [4-5] Here, we present a comprehensive study of the spin (mspin) and orbital (morb) magnetic moment of a prototype magnetic TI, i.e. Bi2Cr2- xSe3, in its ultrathin limit that is expected to give rise to QAH effect. The 10 nm Bi1.94Cr0.06Se3 thin film used in this study was grown by molecular beam epitaxy (MBE), whose ferromagnetism at low temperatures has been investigated by angular resolved photoemission spectroscopy (ARPES) and magnetotransport measurement as published elsewhere. [11] The XAS/XMCD experiments at the L2,3 Cr absorption edges were performed at the beamline I10 of the UK National Synchrotron Radiation Laboratory. XAS was performed at 3 K by total electron yield (TEY) in Faraday geometry and XMCD was taken as the difference spectrum by flipping the X-ray helicity at fixed magnetic field of 10 kOe. As presented in Fig.1., significant multiplet structure at each spin-orbit component of the 2p core was obtained, suggesting a mixed valance state of Cr and the peak asymmetry features of the dichroism point to a predominant contribution of trivalent Cr cations to the magnetization. By applying sum rules on the integrated XMCD and total XAS spectra,[10] we obtained a remarkable mspin = (1.54 ± 0.2) μB/Cr and a small negative morb = (-0.05 ± 0.02) μB/Cr at 3 K. The sum-rules derived value is considerably reduced from the Hund's rule value of 3 μB for the spin moment of substitutional Cr3+ onto Bi sites and that promoted us to investigate the possible scenarios. Simulations were performed based on first-principles density functional theory (DFT) within the Perdew-Burke- Ernzerhof generalized gradient approximation (GGA) and the SOC was included. The layered structure of Bi2Se3 allows the Cr dopants not only to enter the host substitutionally, but also in the van der Waals gap between the layers interstitially. Under the given growth conditions, the formation energies (ΔH) at various lattice positions including interstitial (CrI) and substitutional sites with Cr replacing Bi (CrBi), and Se (CrSe), as well as that of larger defect complexes containing pairs of Cr-atoms, such as the CrBi - CrSe and CrBi - CrI were calculated, as presented in Fig.2. In agreement with the ponieering reports by Zhang et al., [8] we also found that Bi substitutional sites are more stable than interstitial sites for Cr impurities. However, the CrBi - CrI bonding can significantly alter ΔH, leaving the (CrBi - CrI)3+ complex an energetically equally favorable defect. While both CrBi0 and CrI3+ have a magnetic moments of ~3 μB/atom, the CrBi-CrI pair is antiferromagnetic in nature with a nearly vanishing magnetic moment. Such spontenous coexsitance of ferro- and antiferromagnetic Cr in Bi2-xCrxSe3 can explain the observed suppressed magnetic moment and those reported by Haazen et al. [12] and Collins-McIntyre et al. [13]ours who consistently obtained magnetic moments of less that 2 μB/atom using different techniques. To summarize, we have presented a symmetric study of the mspin and morb of the Bi2Cr2-xSe3 thin film combining the XAS/XMCD and DFT methods. We quantitatively addressed the magnetic moment of Cr in the Bi2Cr2-xSe3 TI thin film and the results were well reproduced by DFT caculations. Our work provides valuable information of the fundemental quantities of the magnetic TI systems and has strong implications for the research of the interplay of magnetism with the topological states of matters.

EH-03. Role of R^{3+} ion on structural and magnetic properties of R_2NiMnO_6 double perovskites.

M. Nasir[1], S. Ayaz[2] and S. Sen[1,2]
1. Physics, IIT Indore, INDORE, India; 2. MEMS, IIT Indore, Indore, India

Double perovskites R_2NiMnO_6 (R = La, Pr, Tb) are ferromagnetic semiconductors that have received significant scientific attention[1, 2] because of their high magnetic Curie temperature which can be tuned by varying the size of rare-earth ions. From structural aspects, these systems adopt two different structures depending on the B-site ordering of Ni and Mn cations. A random distribution of B-site ions results in an orthorhombic *Pbnm* symmetry. While, an alternate regular arrangement leads to a monoclinic $P2_1/n$ symmetry[3, 4]. The replacement of La^{3+} by a smaller rare-earth ions modify the crystal structure which in turn influence magnetic properties. This is associated with the change of B-O-B' bond angles and exchange interactions. So by tuning their magnetic and electrical properties, these materials can be useful for variety of spintronic industry applications. Compared to La_2NiMnO_6, other R_2NiMnO_6 perovskites are relatively less studied. It is generally known that the entire series of R_2NiMnO_6 are ferromagnetic with Curie temperatures smaller than that of La_2NiMnO_6. Structure property relationship for R_2NiMnO_6 is not fully established. In the present work, R_2NiMnO_6 (R = La, Pr, Tb) perovskites have been prepared by means of a sol-gel assisted combustion method followed by high temperature sintering. R_2NiMnO_6 series has been examined by X-ray diffraction (XRD), magnetic measurements, and synchrotron based X-ray absorption near edge spectroscopy (XANES). Rietveld refinement was carried out using *FullProf* software with $P2_1/n$ space group as starting structural model. In all cases the crystal structure is defined in the monoclinic $P2_1/n$ space group, with an almost complete order between Ni^{2+} and Mn^{4+} ions. XANES measurements were employed at Ni and Mn K-edges to elucidate the oxidation sates of Ni and Mn ions which play an important role in magnetism [Figure 1]. XANES results are in well agreement with XRD data. Further, magnetic measurements show that there is a reduction in Curie temperature with smaller crystal radii of R^{3+} [Figure 2]. The Curie temperature is decreased to 104 K form 264 K with replacement of La^{3+} by Tb^{3+}. Infact, Curie temperature of R_2NiMnO_6 series is a linear function of the crystal radii of R. Thus, ferromagnetic ordering temperature of the R_2NiMnO_6 can be better correlated with the radius of R^{3+} atoms than with the average Ni– O–Mn angle. Our results which are presented here provide a detailed insight into the role of R^{3+} ions on the magnetic properties of the series.

EH-04. Enhancing the low-field magnetoresistance by ac current excitation in $La_{0.7}Sr_{0.3}MnO_3$.

P. Kumar[1], U. Chadhuri[1] and *R. Mahendiran*[1]
1. Physics Department, 2 Science Drive 3, National University of Singapore, Singapore

Among the oxides possessing perovksite (ABO_3) structure, $La_{0.7}Sr_{0.3}MnO_3$ is widely known because it is a rare example of ferromagnetic metal with ferromagnetic transition above room temperature (T_C = 382 K) and exhibits colossal negative magnetoresistance (-$\Delta R/R \approx$ 50-60 % in a dc magnetic field of 6 Tesla) near T_C.[1,2] However, the dc magnetoresistance (measured with direct current passing through the sample) is small in low magnetic fields, typically less than 1% in H = 1 kOe. Surprisingly, magnetoresistance of this compound in response to an alternating current driving current through the sample or exposing the sample to an oscillating magnetic field has been overlooked so far except by a few researchers[3]. Few years ago, we reported [4] that the resistive component of the ac impedance (Z = R+iX) of a bulk $La_{0.7}Sr_{0.3}MnO_3$ sample showed a remarkable decrease (ΔR/R(H= 0) ~ 45 % for f = 1 MHz, where f is the frequency of alternating current through the sample) in a dc magnetic field of 1 kOe at room temperature. Here, we extend the frequency of measurement from 1 MHz to 3GHz. We measured both resistive (R) and reactive (X) components of the ac impedance using a shorted-coaxial cable and an Agilent Impedance Analyzer (model E4991A RF) $R(H)$ shows a single peak centered around H = 0 for 1 < f < 30 MHz but it transforms into a dip at H = 0 accompanied by double peaks at H = $\pm H_p$ for higher frequencies. The position of the double peak shifts towards higher field with increasing frequency. Ac magnetoresistance changes sign from positive to negative with increasing frequency ($\Delta R/R$ = -0.07%, -20.2%, and +27.5%) for f = 1, 50 MHz and 3 GHz, respectively. The transition from a single to double peak is also seen in $X(H)$ with additional features developing near zero field for f > 2 GHz. We suggest that transverse magnetic permeability and ferromagnetic resonance govern the high frequency magnetotransport in this oxide. Our findings indicate that this ferromagnetic manganite could be used for sensing low magnetic field by properly exploiting its high frequency magnetic property. Our simple experimental technique can be also used to study magnetization dynamics in metallic ferromagnets Acknowledgement: R. EH-05. Suppression of charge and antiferromagnetic ordering in Ru substituted $Bi_{0.5}Ca_{0.5}MnO_3$ probed by electrical, magnetic and thermoelectric transport.

M. Kumari[1], A. Chanda[1] and R. Mahendiran[1]
1. Physics, National University of Singapore, Singapore

Half-doped manganites of general formula $R_{0.5}A_{0.5}MnO_3$ (R = rare-earth, A= alkaline earths) are known to undergo charge ordering (ordering of electrons and holes in a regular pattern) and e_g-orbital ordering.[1] These systems are normally antiferromagnetic insulators at low temperatures and charge ordering occurs in the paramagnetic state, well below room temperature (T_{CO} = 240 K-270 K for various rare earth ions).[2] However, Bi based systems *i.e.,* $Bi_{0.5}A_{0.5}MnO_3$ (A = Ca and Sr) show some interesting peculiarities that differ from the general behavior of previously studied rare-earth based manganites. For instance, these systems show a charge ordering far above room temperature (T_{CO} = 325 K for Ca and 550 K for Sr system).[3-4]. The charge ordering in these systems is reported to be so robust that remains stable even at fields as high as 60 T. Also, the substitution at Mn-site with other transition metal ions (Cr^{3+} or Ni^{2+}) fails to induce a ferromagnetic metallic state.[5] In this work, we are demonstrating that a systematic substitution of Ru at Mn site in $Bi_{0.5}A_{0.5}MnO_3$ samples suppress the charge-ordering and transforms the antiferromagnetic insulating ground state into ferromagnetic conducting state even in the absence of an external magnetic field. Here, we report the magnetization, electrical resistivity and thermopower in $Bi_{0.5}Ca_{0.5}Mn_{1-x}Ru_xO_3$ (x = 0.00, 0.01, 0.03 and 0.05) system for the first time. In pure $Bi_{0.5}Ca_{0.5}MnO_3$ (x = 0), on cooling from 400 K, charge ordering takes place at $T= T_{CO}$ ~325 K and on further lowering the temperature, an antiferromagnetic ordering of Mn-spins takes place, showing a second peak at T_N~130 K. In 5% Ru doped sample (x = 0.05), both the charge and antiferromagnetic ordering are suppressed and the magnetic moment increases gradually below CO temperature for this sample. Resistivity decreases with increasing Ru content and falls by two orders of magnitude for x = 0.05 in comparison to the pure compound. Thermopower increases gradually and shows a temperature independent behaviour above 230 K due to polaronic conduction. We will discuss the connection between magnetism, electrical resistivity, magneresistance and thermopower as a function of Ru content in this series.

EH-06. Anisotropic Electronic Transport Properties in Low-Temperature Phase Fe_3O_4 Epitaxial Films.

X. Liu[1], *W. Mi*[1], Q. Zhang[2] and X. Zhang[2]
1. Department of Applied Physics, Tianjin University, Tianjin, China;
2. PSE Division, King Abdullah University of Science and Technology (KAUST), Thuwal, Saudi Arabia

Magnetite (Fe_3O_4) has attracted tremendous attention due to its unique electrical and magnetic properties including high Curie temperature (~858 K), large net magnetic moment (~4 μ_B/f.u.) and theoretical -100% spin polarization. As the first known phase transition in oxides accompanied with charge ordering, Verwey transition at 125 K (T_V) in Fe_3O_4 is being actively investigated. At T_V, physical properties of Fe_3O_4 show distinct changes where conductivity and magnetization show abrupt decrease and the specific heat shows an anomalous maximum.[1] Although the Verwey transition has been found nearly eighty years, the underlying physics of Verwey transition is still unclear. The detailed electronic transport properties around T_V are rarely, especially the anisotropy magnetoresistance (AMR). AMR is considered as a consequence of spin-orbital interaction in magnets and has relation with the easy axis. In Fe_3O_4, the easy axis undergoes a transition from <111> to (001) as temperature cools down to 130 K where the cubic magnetocrystalline anisotropy (MCA) transforms to a uniaxial one.[2] In previous studies AMR of Fe_3O_4 films shows fourfold symmetry below T_V which is contradictory to the uniaxial MCA. This work investigated the detailed structural properties and AMR across T_V based on high quality Fe_3O_4(100)/MgO(100) and Fe_3O_4(111)/Al_2O_3(0001) films. The configuration of sample, current and magnetic field is shown in Fig. 1(a). In Fe_3O_4(100) film, the symmetry of AMR shows a fourfold to twofold transition as the temperature cools below T_V. At temperature $T<T_V$-15 K, the twofold AMR gradually evolves to a fourfold one. Considering the sharp Verwey transition in our Fe_3O_4 sample, the evolvement of AMR has no correlation with the charge ordering. Then, the novel microstructure of trimeron[3] inspires us. The distribution of in-plane trimeron in monoclinic Fe_3O_4(100) and (111) samples are compared together with their AMR curves as shown in Figs. 1(b) and 1(c). It is found that the AMR shows maximum when external magnetic field is parallel to trimeron. The evolvement of fourfold symmetry in Fe_3O_4(100) film below T_V may also have relation with the formation of trimeron. From this perspective, the temperature gap between Verwey transition and lattice distortion detected by Raman spectroscopy is easy to understand. So, two significant outcomes of the analysis are (a) the Verwey transition contains two steps including the formation of charge ordering together with cubic-monoclinic transition at temperature just below T_V and the formation of trimerons at a lower temperature, (b) the fourfold symmetry of AMR in Fe_3O_4 below T_V derives from the in-plane trimerons. Although the fourfold AMR has been found for many years, the mechanism is not clear yet. Our work not only explains the anomalous magnetotransport behavior in monoclinic Fe_3O_4 but also looks into the Verwey transition at temperature just below T_V, which push forward the understanding of Verwey transition in structural and electronic aspects. EH-07. Effect of $CaCO_3$ and V_2O_5 on the microstructure and magnetic property of MnZn ferrites.

G. Wu[1], Z. Yu[1], Z. Tang[2], K. Sun[1], R. Guo[1], X. Zou[1], X. Jiang[1] and Z. Lan[1]
1. University of Electronic Science and Technology of China, Chengdu, China; 2. China Aerospace Components Engineering Center, Beijing, China

Manganese-zinc (MnZn) ferrites have been widely applied in convertors and switching mode power supplies, on account of its high saturation magnetic induction B_s, initial permeability μ_i and low core losses P_L [1-3]. With the development of miniaturization and integration of electronic devices, the application frequency of MnZn ferrite core has been raised from tens of kilohertz to several megahertz (2~4MHz). Thus, MnZn ferrites with low core losses especially at high frequency (~3MHz) are urgently demanded. Aiming at this goal, many efforts have been done to investigate the factors that may influence core losses, such as the main compositions, fabrication processes of powders and additives [4-6]. K. Praveena [4] et al investigated the effect of Zn^{2+} content on the core losses for $Mn_{1-x}Zn_xFe_2O_4$ and found that optimized Zn^{2+} content could reduce the core losses from 358kW/m^3 (x=0) to 163kW/m^3 (x=0.9) at 1MHz. Haining Ji [5] et al studied the effect of second milling time on the loss characteristics of MnZn ferrites. The results showed that when the second milling time is 2h, the core losses achieved its minimum value of 430kW/m^3 at 100kHz and 200mT. A low-loss MnZn ferrite material DMR508, sintered in precisely controlled oxygen partial, has been developed through optimized additives of CaO, SiO_2, Nb_2O_5, TiO_2 and ZrO_2 [6]. The core losses of this material were only 200kW/m^3 at 3MHz and 10mT. To sum up, it is a feasible way to unify these factors harmoniously for the realization of even lower losses at 3MHz. In this work, $Mn_{0.67}Zn_{0.21}Fe_{2.12}O_4$ ferrites doped with $CaCO_3$ (0~0.3wt%) and V_2O_5 (0~0.03wt%) have been prepared by solid-state reaction method, and ultra-low core losses at 3MHz 10mT and 30mT were achieved through the combinative doping of $CaCO_3$ and V_2O_5, as well as other additives (TiO_2, Co_2O_3 and SnO_2). The effect of $CaCO_3$ and V_2O_5 on the microstructure and electromagnetic properties of MnZn ferrites have been investigated in detail, such as initial permeability μ_i, saturation magnetic induction B_s, coercivity H_c and resistivity ρ. In addition, based on core losses separation method, the core losses mechanism has been discussed. Core losses are divided into three parts: hysteresis loss P_h, eddy current loss P_e and residual loss P_r through following equation: $P_L/f = K_hB^3+K_eB^2f/\rho+P_r/f$ (1), where K_h and K_e are constants, B is the magnetic flux density, f is the frequency and ρ is the resistivity. In view of the relationship curve between P_L/f and f, P_h/f, P_e/f and P_r/f could be obtained from the interception part, slope of linear part and nonlinear part, respectively. The SEM micrographs of MnZn ferrites are shown in Fig. 1. Remarkably, the average grain size decreased with the increase of $CaCO_3$ content via the refinement grain growth as shown in Fig. 1(a)-(b). Besides, small and even grains were obtained with 0.1wt% $CaCO_3$ and 0.01wt% V_2O_5 co-doping in Fig. 1(c). Fig. 2(a) shows the P_L variation of MnZn ferrites with different $CaCO_3$ contents at room temperature. With the increase of $CaCO_3$ content, the core losses at 3MHz 10mT and 30mT showed a tendency of decreasing then increasing with the minimum of 56kW/m^3 and 859kW/m^3 for 0.1wt% $CaCO_3$ doping. Furthermore, on the basis of 0.1wt% $CaCO_3$ doping, the core losses were furtherly reduced with 0.01wt% V_2O_5 doping. The core losses at 3MHz 10mT and 30mT were only 33kW/m^3 and 598kW/m^3, respectively, as shown in Fig. 2(b). The excellent properties of MnZn ferrite core with ultra-low core losses make it a candidate for the application of high frequency of 3MHz.

EH-08. Magnetically driven insulating behavior in monoclinic antiferromagnetic Ni-Mn-In Heusler alloys.

H. Yang[1,2], B. Wang[1,2] and R. Li[1,2]
1. Key Laboratory of Magnetic Materials and Devices, Ningbo Institute of Materials Technology and Engineering, Chinese Academy of Sciences, Ningbo, China; 2. Laboratory of Magnetic Materials and Application Technology, Ningbo Institute of Materials Technology and Engineering, Chinese Academy of Sciences, Ningbo, China

In solid state matters, the electrons are confined in a potential that is constructed by atomic networks. As electrons have both charge and spin characters, the potential can be separated into charge potential and spin potential. In most cases, the charge potential plays a decisive role in determining the electronic structures in solids [1]. However, in some cases, the spin potential cannot be ignored, as it could split the electronic structure into two spin dependent channel and result in spin-polarized conducting electrons. A unique case has been pointed out by J. C. Slater in the 1950s [2], where he suggested that in certain antiferromagnets, an insulator could be purely induced by spin potential. In recent years, it has been suggested that some 5d transition-metal oxides could be Slater-type insulators. However, their insulating nature as being Slater-type or Mott type has been frequently debated [3-6]. Therefore, it is still unclear if there are purely magnetically driven insulating behaviors. Here we report an anomalous insulating behavior in the monoclinic $Ni_{50}Mn_{50-x}In_x$ bulk alloys. The alloys show low resistivity (~ 10^{-4} Ω cm) and high carrier density (~ 10^{22} per cm^3) that are comparable to those of common alloys, yet, an insulating behavior was identified. The insulating behavior was found in the doping range of roughly $10 < x < 16$ [Fig. 1]. By comparing the electrical transportation with magnetism, a correlation between antiferromagnetic order and the insulating behavior is revealed: both the high temperature paramagnetic phase and the low temperature super-spin glass phase are metallic, and the insulating behavior is observed when long range AFM order is established [Fig. 2]. Furthermore, applying magnetic fields tend to destroy the AFM state, thus the temperatures at which MIT occurs (Tp) increase as the applied magnetic field is increased. Neutron results indicate that in our case, the spin order doubles the lattice periodicity no longer holds, manifesting that the alloys do not belong to Slater-type insulator. Our results indicate that the insulating behavior could be ascribed to certain peculiar spin dependent scattering process.

EH-09. Valley polarized tunneling through magnetic and electrical barriers in Weyl semimetals.

C. Yesilyurt[1], Z. Siu[1], S. Tan[1], G. Liang[1] and M.B. Jalil[1]
1. Electrical and Computer Engineering, National University of Singapore, Singapore

Recently, valley polarized tunneling has been predicted in Weyl semimetals with tilted energy dispersion in the presence of magnetic and electrical barriers [1]. It has been shown that Weyl electrons that encounter an electrical potential barrier experience a valley dependent transverse momentum shift, which originates from the coupling of the tilted energy dispersion and electrical potential difference. Despite the electrons being valley-polarized in angle-space, the contribution of each valley to the total conductance remains constant. Additional magnetic barrier breaks the angular transmission symmetry and leads to valley dependent conductance at the barrier interface. Here, we delve deeper into the physics of magnetic barrier structure and provide a detailed quantitative analysis based on more realistic model. We focus on the simplest Weyl semimetal case, where two Weyl fermions emerge with opposite chirality, and reversed tilt vector, whose low energy characteristics can be described by $H_{K,K'} = \eta h(v_F k.\sigma + w.k)$, where the σ is the vector of Pauli matrices in three dimensions, w is the tilt vector, $\eta = \pm 1$ and represents the chirality of the Weyl node. The system consists of a one-dimensional rectangular electrical potential [Fig. 1 (b)], and magnetic gauge potential [Fig. 1 (c)] induced by the ferromagnetic layer deposited on the Weyl semimetal, as illustrated in Fig. 1 (a). The ferromagnetic layer induces two asymmetric spike-like magnetic fields at the interface of the barrier as shown in Fig. 1 (c). The realistic magnetic field profile can be analytically described by $B_{z(x)}$ that is plotted in Fig. 2 (a), where the *z* is the distance along *z*-direction [2]. The strongest magnetic field strength $B_{max(z)}$ (i.e., the peak value of $B_{z(x)}$) is experienced by electrons at the Weyl semimetal region that is closest to the top ferromagnetic layer. $B_{max(z)}$ decreases along *z*, and the field profile spreads out over wider extent in *x*. We note that the integral of $B_{z(x)}$ over *x* is constant at all depth *z* even though the peak value of $B_{z(x)}$ reduces along *z* [i.e., shown in Fig. 2 (c)]. Therefore, the magnetic gauge profiles at different depths exhibit similar characteristics, such that the maximum height of the gauge potential is independent of the field variations along *z* [i.e., shown in Fig. 2 (b)]. We perform numerical calculations by considering tunneling conductance of Weyl electrons and dividing the whole device into short segments where the magnetic gauge potential is spatially varying along *x*. The valley dependent conductance profiles are shown in Fig. 2 (d), which exhibit almost the same characteristic at different depths *z*. Our results revealed that the valley-dependent conductance profile is mostly determined by the maximum point of the magnetic gauge potential, and not sensitive to field variations along the transmission direction, as well as the direction along the B-field.

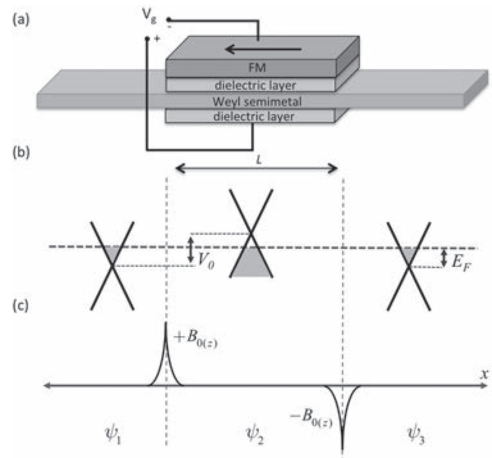

Fig. 1. Weyl semimetal with one-dimensional rectangular, square electrical potential (b) and magnetic barrier (c) induced by ferromagnetic (FM) layer deposited on the central region of the p-n-p junction.

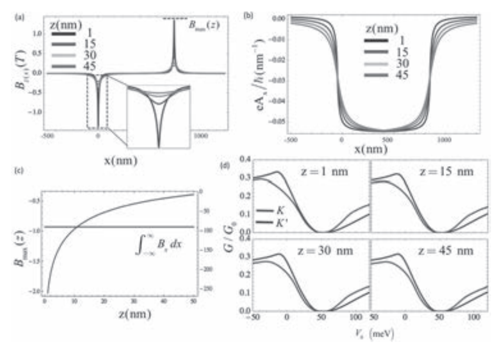

Fig. 2. Realistic magnetic barrier configuration. (a) shows magnetic field profile with two asymmetric peaks, induced at the edges of the ferromagnetic layer shown in Fig. 1. Different colors represent the field profile at different points in the z-direction. (b) shows the shift of the k_y due to the gauge potential $A_{(x)}$ induced by the magnetic fields shown in (a). The maximum magnetic field strength $B_{max(z)}$ shown in (a) reduces with increasing distance along *z*, of which characteristic calculated for continuous distance in (c), while the integration of the magnetic field over *x* is constant as shown at the right axis in (c). Since the maximum height of the $A_{(x)}$ does not depend on the field profile, the valley resolved conductance shows very similar profiles at varying depth of the device, as shown in (d).

Magnetic skyrmions are topologically protected spin textures with great technological potential for high-density, low-power electronics in the form of magnetic storage as well as for magnonic devices [1]. The time-varying magnetic field experienced by an electron passing through a topologically non-trivial spin texture such as a skyrmion generates an emergent magnetic field that in turn exerts an additional Lorentz force on the electron [2]. This appears as an additional transverse voltage in the Hall effect, known as the topological Hall effect, allowing skyrmions to be detected electrically. A class of magnetic materials that is particularly interesting for a wide range of magnetoelectronic technologies are the Heusler alloys - many are ferromagnetic with high Curie temperatures and highly spin polarized band structures [3]. However, there have been very few efforts to explore the possible use of Heusler alloys for stabilising skyrmions at room temperature [4-6] – a critical aspect for developing a practical skyrmionic device. Recently, we have shown that perpendicularly magnetised thin films of Heusler alloy Mn_2CoAl show the electrical characteristics of skyrmions up to ambient temperature [7]. Thin films were grown by DC magnetron sputtering as multilayer stacks in the sequence MgO(2)/Mn_2CoAl(t)/Pd(2.5), where the number in parentheses is the nominal layer thickness in nanometres and t=1.3-2.6 nm. Samples were grown at ambient temperature and post-growth annealed in-situ for 1 hour at 300 °C in such a way as to induce a perpendicular magnetic anisotropy [8,9]. Hall effect measurements were made on samples patterned into Hall bars using photolithography and dry etching or lift-off, and on unpatterned samples in a Van der Pauw geometry. Figure 1 shows Hall resistivity measurements for a trilayer at different temperatures. On top of the typical anomalous Hall effect signal seen for magnetic materials, the topological Hall effect is clearly seen as a peak, appearing near the coercive field. At 3 K, where the anomalous Hall effect dominates, the topological Hall effect persists as a shoulder in (a) and (b). The topological Hall effect peaks are clearer at higher temperatures as shown in (c) and (d), indicating skyrmions exist to above 275 K. In Figure 2, we demonstrate a novel method to explore the magnetisation and skyrmion nucleation processes by studying minor loops of the Hall effect. The measurements were done at 225 K where both anomalous and topological Hall effect components are obvious. The full field sweep starts at +300 Oe, above the saturation field of the topological and anomalous Hall effects, is swept to the desired negative field and back to positive saturation at +300 Oe. This minor loop, explained with cartoons, implies that opposite skyrmion polarities can coexist in a carefully conditioned sample. The sweep to negative field is stopped just at the start of the rise in Hall resistivity (position 4) showing that the film magnetization is being reversed and some skyrmions are being annihilated. Upon sweeping the field in the positive direction, the Hall resistivity is more negative than the saturation value reached at large positive fields. This is a clear sign that, during the up sweep through zero field, some skyrmions still exist in the film. Between positions 4 and 5 there is a positive contribution to the Hall resistivity that comes from the nucleation of opposite polarity skyrmions, taking the total Hall value back to that of the positive saturated state. Conclusions: We have shown the topological Hall effect in ultrathin layers of Heusler alloy Mn_2CoAl, implying the existence of skyrmions to ~ 280 K. As shown by Hall effect minor loops, we can controllably nucleate and annihilate skyrmions of opposite polarity as well as induce a state where skyrmions of both polarities coexist.

3. UGC-DAE Consortium for Scientific Research, Indore, India

Co_2FeSi thin films with different disorder states are prepared in order to tune the longitudinal resistivity (ρ_{xx}) in a wide range and investigate the scaling with anomalous Hall resistivity (ρ_{xy}). The thin films of 50 nm thickness are grown on Si (111) substrate using ultra-high vacuum dc magnetron sputtering at different substrate temperature ranging from room temperature (RT) to 600°C. The films, deposited at RT, 200°C are amorphous in nature, crystallinity improved with increase in deposition temperature. A2, B2 disorder is found in the films deposited at 450°C and 550°C respectively. 'Zero-field resistivity', ρ_{xx} (*T, H=0 Oe*), and 'in-field resistivity', ρ_{xx} (*T, H=80 Oe*), of all the thin films go through a minimum at a temperature, T_{min} and exhibit a metallic behaviour for $T > T_{min}$ as shown in fig. 1. T_{min} is maximum for the RT samples with the value of 115 K and systematically decreases with increase in deposition temperature. T_{min} is lowest (~ 12 K) for the most ordered film (550°C). In crystalline film enhanced electron-electron interaction (EEI) is the responsible mechanism for the resistivity minima wherein diffusons and weak localization give rise to resistivity minima in amorphous films. Temperature dependence of Hall resistivity isotherms are shown in fig.2 for the RT film. At any temperature, anomalous Hall resistivity (ρ_{xy}) is maximum for the RT deposited film and lowest for the ordered film (550°C). Like longitudinal resistivity, low temperature upturn is observed in Hall resistivity for the RT, 200 and 300 films [inset of fig. 2 for RT film]. In the amorphous films, upturn at low temperature is observed in ρ_{xy}, suggesting that effect of diffusons reflect in anomalous Hall resistivity ρ_{xy}. The effect of EEI is absent in ρ_{xy} for the crystalline samples, resulting no upturn in ρ_{xy} at low temperature [1]. In clean region ($10^4 < \sigma_{xx} < 10^6$ S/cm, σ_{xx} = longitudinal conductivity) side jump plays major role for the scattering mechanism of ρ_{xy} along with skew and intrinsic contributions [2]. In amorphous films (dirty region, $\sigma_{xx} < 10^4$ S/cm), anomalous Hall coefficient (R_A) scales with intrinsic resistivity, ρ_{xxT}, only when ρ_{xx} and ρ_{xy} are corrected for quantum correction of diffusons.

EI-01. Magnetic Nanoparticles for Theranostics. ***(Invited)***

Y. Ichiyanagi[1], H. Takeuchi[1], K. Fujiwara[1], T. Ide[1] and A. Oshima[1]
1. Yokohama National University, Yokohama, Japan

Magnetic nanoparticles have attracted attention for biomedical applications. One of the author reported original preparation method of magnetic nanoparticles (MNPs), and the way of functionalization by amino-silane coupling procedure [1]. We tried to introduce these functional particles into the living cells, and these particles were localized by the external magnetic field. Then cancer cell selective NPs were further developed by conjugating with folic acid [2]. We have also suggested that these magnetic nanoparticles can be utilized in biomedical applications, such as hyperthermia treatment [3] or MRI agent [4], for producing functional magnetic nanoparticles. These magnetic nanoparticles are expected as agents for future theranostics, namely, performing therapy and diagnostics simultaneously [5]. Effective heat dissipation for magnetic hyperthermia treatment in AC field depends on the magnetic relaxation parameters. Several kinds of ferrite NPs were prepared and AC magnetic measurements were performed in order to improve heating effect of MNPs for hyperthermia treatment. The relationship between imaginary part of AC magnetic susceptibility χ" and increase in temperature in the AC field was estimated. The particle size and composition of the samples were varied and examined. Fig.1 shows temperature dependence of imaginary part of AC magnetic susceptibility χ" for various particle size of $Co_{0.3}Fe_{2.7}O_4$ nanoparticles in a 1 Oe, 100 Hz field. The temperature rise of this sample upon an alternative field was measured, and it was found that the temperature increased by about 20 K under AC frequency of 15 kHz and field of 210 Oe. From the result of the temperature increase rate, heat dissipation was evaluated quantitatively according to Néel relaxation theory. An AC field was found to cause an increase in temperature, with the 7.5 nm particles exhibiting the highest temperature increase as expected. Therefore, finally *in vitro* experiments to study the hyperthermia effects of $Co_{0.3}Fe_{2.7}O_4$ particles on cancerous cells were carried out. Drastic effect of magnetic hyperthermia was observed. (Fig.2) Imaging methods are one of the effective tools for diagnostics. Specifically, magnetic resonance imaging (MRI) and mass spectrometric imaging (MSI) [6], and MNPs can be used to improve these imaging methods. Currently, main components of γ-Fe_2O_3 and Fe_3O_4 have been used for MRI contrast agents to emphasize the relaxation time of T_2 in the clinical scene. We synthesized Co-ferrite nanoparticles surrounded by amorphous SiO_2, and the relationship between these MR relaxivity and physical properties was investigated by spin echo sequence. The T_2 relaxation curves of $CoFe_2O_4 \cdot nSiO_2$ (n = 1,3,6 and removed Si) and other sample γ-Fe_2O_3, Fe_3O_4 and agarose for comparison were measured. These samples also had larger R_2 compared with conventional materials such as γ-Fe_2O_3, Fe_3O_4 and background. The parameters of T2 and R2 varied depending on only Si composition even same metal compositions, same particle size. It is considered that distance between nanoparticle and proton would be increased as the thickness of SiO_2 shell increased. Furthermore, dispersibility of nanoparticles was improved under the influence of negative charge carried SiO_2 layer. Magnetic particle imaging (MPI) and CT (X-ray tomography) imaging using our particles are in progress. Our metal oxide nanoparticles and their hybrid materials with organic compounds are anticipated to find use in the area of multifunctional nanomedicine such as magnetic hyperthermia and MRI contrast agents, called "Theranostics"

Magnetite (Fe_3O_4) is a favorite material to be used in biomedical applications owing to its remarkable magnetic properties and suitable biocompatibility & biodegradability. It has been widely studies as a material of choice for magnetic hyperthermia therapy, controlled drug delivery, magnetic separation and as a magnetic resonance imaging contrast agent [1-2]. Under an oscillating magnetic field magnetite nanoparticles generate heat due to Néel losses and Brownian rotations in physiological fluids [3]. Magnetite nanoparticles also respond to certain visible light wavelengths near infrared region and are excited upon irradiation. During de-excitation it releases extra energy into molecular vibration modes that transform into thermal energy [4]. Current study is about combining the magnetic hyperthermia and photothermal therapies into a single bimodal system for cancer therapy. The synthesized magnetite nanoparticles were superparamagnetic having appropriate colloidal stability due to being coated with polyethylene glycol. Cell viability and cytotoxicity were studied on HeLa cells using MTT assay and proteome apoptosis kit. They were subjected to an oscillating magnetic field of 375 kHz & 170 Oe for hyperthermia. For photothermal therapy, the system was irradiated with a laser emitting 808 nm wavelength which is a near infrared regime in electromagnetic spectrum. The two treatments were performed separately as well as in combination and the combined treatment was multifold more effective in treating the cancer cells as compared to separate sessions.

Magnetic dots in vortex state have been intensively studied due to their attractive properties for emerging multidisciplinary applications such as magnetic information storage, spintronics and biomedicine. In the vortex ground state, the magnetic moments are curled in the dot plane and only at the center the core of the vortex points perpendicularly to the plane. This configuration gives rise to a characteristic magnetic behavior as a function of the in-plane applied magnetic field, displaying hysteresis loops with no remanence or coercive field and open lobes at high field [1]. Apart from the intrinsic interest that this peculiar magnetic structure offers from a fundamental point of view, some appealing applications for this type of particles have been proposed, such as the magneto-mechanical actuation for cancer cell destruction [2]. This therapy employs disc-shaped particles with vortex magnetic configuration that, under an low amplitude (about 10 mT) and low frequency (tens of Hertz) AC fields, are made to oscillate, hitting and damaging the integrity of cancer cells to which they were attached. Since this actuation does not imply heat generation, in principle, the magneto-mechanical actuation avoids the risk of damaging the surrounding healthy tissue as it can occur in magnetic hyperthermia. Additionally, it is thought that the magneto-mechanical actuation leads to the apoptosis of the cells instead of the necrotic pathway caused by heating, avoiding cell-leakage in the surrounding extracellular environment and inflammatory reactions caused by necrosis [3]. In this work, we present the results obtained in Permalloy circular dots fabricated by hole mask colloidal lithography (HCL) with diameters ranging from 60 to 140 nm, and different thicknesses from 20 to 60 nm. HCL is a bottom-up fabrication technique that basically uses a monolayer of self-assembled polystyrene nanospheres to create a template of holes in a polymer film deposited over a substrate. The holes are filled with sputtered Permalloy and the polymeric template removed to produce a dense pattern of dots on the substrate [4]. For their use in the *in vitro* experiments, the nanostructures are prepared on top of a sacrificial layer that is later removed to release the discs. In this case, the discs are prepared with a thin (4 nm) gold layer on both sides. The nanodiscs on the substrate are magnetically characterized by SQUID and MOKE magnetometries, and Magnetic Force Microscopy (MFM). Additional micromagnetic simulations and analytic calculations have been performed to clarify the magnetization configuration in the dots with different diameter to thickness ratios [5]. In the dots with a diameter of 140 nm, the MFM images reveal that the vortex core occupies about half the size of the dots. This vortex core diameter is approximately equal to the dot diameter for the smaller dots (60 nm). Micromagnetic calculations confirms that, in this case, the size of the core can be even greater that the dot size. Nevertheless, this does not prevent the existence of a clear magnetic vortex behavior as demonstrated by the measured hysteresis loops. The suitability of nanodiscs for cancer cell treatment using the magneto-mechanical actuation is evaluated using lung carcinoma cells for the *in vitro* experiments. For comparing with previous studies, we simultaneously perform the experiments using Permalloy discs with a diameter of 2 μm fabricated by photolithography. The internalization process in cancer cells, along with the cytotoxic effect, and the influence of a low magnetic field on the viability of the cells are studied. We observe that the discs do not disrupt the viability of the cells, but they seem to inhibit their proliferation. The application of an alternating magnetic field to produce the magneto-mechanical actuation seems to have a scarce impact on the cell viability when using large discs (2 um in diameter) but, with the use of nanodiscs, the destroyed cell rate is increased to 30 % among the cells that have internalized discs. Figure 2 show an example of cell death by the treatment. We must stress that these results are obtained in a small number of experiments, and that we have used manual counting of cells under the microscopy (no cytometers used). In any case, although the percentages may not be statistically sound, the results prove the ability of the nanodiscs to produce irreparable changes in cancer cell integrity. Computer simulations (*in silico*) have helped in vitro and in vivo experiments to develop new therapies in medicine, reducing time and costs to produce the tests. In the particular case of healthcare, in silico trials can predict the effectiveness of a treatment and optimize it to get the best benefit/risk ratio. In turn, this improvement will allow for adjusting the treatment to each patient following into high-performance, precision therapies. Magnetic hyperthermia is one of the nanotechnology-driven cancer treatments benefiting from computer simulations as the prime component of its planning platform [1]. When addressing localised tumours, magnetic hyperthermia relies on the intratumoral injection of magnetic nanoparticles that are excited by an external alternating magnetic field. The nanoparticles then release heat through hysteresis losses, eventually killing tumour cells. Magnetic hyperthermia has already been trialled in clinical settings as coadjuvant to chemotherapy and radiotherapy to successfully treat several types of tumours [2-3]. The specialised instrumental development is moving forward, and commercial systems are being deployed throughout Europe and USA [4]; nevertheless, research on safety, dosimetry, and treatment planning does not progress to the same pace. The therapy has to be adapted to each patient and tumour as well as to the evolution of the tumour along the process. Due to the complexity in programming the therapy plan for each patient, we intend to achieve a semiautomatic means to get the optimum number and placement of injections points of the nanoparticles into the tumour. The present work encompasses results obtained by jointly considering both the tumour vasculature and nanoparticle distribution inside a virtual tumour model (Fig. 1a) when simulating the power deposition in tissues. The resulting temperature distributions (Fig. 1b) generated by changing the vasculature branching and the nanoparticle distribution are discussed. In addition, in this presentation we report on our dedicated research program aimed to accelerate the pre-clinical and clinical testing of MH based on *in silico* methods.

EI-05. Magnetic hysteresis, cellular uptake and cytoxicity of submicron magnetic nanodisks for biomedical applications.

P. Tiberto[1], G. Barrera[1], F. Celegato[1], M. Coisson[1], C. Divieto[1] and M. Sassi[1]
1. INRIM, Torino, Italy

Progress in nanotechnology-based fabrication process have boosted the quest to exploit magnetic nanostructures in nanomedicine (i.e. magnetic resonance imaging, controlled target-drug delivery and magnetic hyperthermia). High-aspect ratio nanoparticles (i.e. nanodisks) allow an easy remote vehiculation by magnetic fields and limit agglomeration as they display high saturation magnetisation and zero remanence values [1]. Au-layers allow an easy functionalisation for target controlled released. Magnetic $Ni_{80}Fe_{20}$ nanodisks (30 nm thickness and diameter ranging in the interval 200 – 650 nm) having disc shape have been fabricated and directly coated by a Au layer by means of a bottom-up self-assembling nanolithography process assisted by polystyrene nanospheres [2]. The room-temperature magnetic behavior of the two systems dispersed in liquid is reported in Fig. 1a (disks diameter having diameter 650 nm). In both cases, the typical shape of magnetization vortex nucleation is observed. In fact, the loops exhibit a magnetic remanence close to zero and an almost linear behaviour at low fields followed by an increase of hysteresis at fields preceding the magnetic saturation. In particular, the low-field reversible linear behaviour corresponds to the movement of magnetic vortex perpendicular to the applied field across the nanodisk In addition, the Au-layer is seen not substantially alter the magnetic behavior being the annihilation and nucleation vortex field practically the same for the two systems. Despite their multifunctionality, two major issues prevent the application of magnetic nanostructures in nanomedicine as biocompatibility and cellular uptake for submicron nanoparticles. To this aim, in-vitro toxicity assessment of the nanodisks will be here discussed together with the evaluation of cellular uptake. To assess the cell viability, PT-45 cells (human lung cancer) have been exposed to varying concentrations of nanodisks with and without the protective gold layer (from 0.12 to 58 μg/ml) in order to investigate their cytotoxicity. Generally, a considerable fraction of cells remains alive and proliferate at all nanodisks concentration. The metabolic activity value is similar to the one obtained in absence of magnetic nanoparticles. As expected, lower cytotoxicity has been observed over time when cells were exposed to Au- covered nanodisks compared with bare nanodisks Electron microscopy images have been acquired with a FEI Inspect-F scanning electron microscope (SEM) equipped with three different detectors: secondary electrons (SE), backscattered electrons (BSE) and transmitted electrons (STEM). The results are reported in Fig. 1 b, c and d after dispersing 58 μg/ml in PT-45 cells. After careful washing they were transferred to a TEM holey carbon grid. The combination of the three different detectors allows, by comparing the images, to clearly distinguish le presence of several nanodisks in the cells or in their membrane. The effectiveness of the washing procedure is demonstrated by the fact that there no nanodisks can be observed neither on the holey carbon structure nor on the copper grid. The remaining nanodisks have therefore become part of the cells, having adhered to their membrane or having being internalised making magnetic submicron nanodisks good and realistic candidate for application in nanomedicine and theranostics.

Magnetic particles (MPs) were found useful in different cancer treatment applications such as magnetic hyperthermia, magnetic controlled delivery and release of antitumoral drugs at the targeted site of a tumour [1-3]. Lately, cancer cell destruction techniques involving the movement of magnetic particles in alternative magnetic fields (MFs) came to the fore [4, 5]. Once the destruction effect of moving MPs on cancer cells was demonstrated, researches focused on the study of magnetic materials appropriate for this application and their magnetic properties in order to achieve a larger mechanic torque of MPs under the alternative MFs action. In this work, we aimed to find proper MPs for this type of application – MPs that can be produced by a controllable process in a large amount without involving costly technologies. For this experiments we used a new type of particles developed by us, with the nominal composition Fe79.7-xETMxNb0.3B20 (ETM = Cr, Ti, Mn; x = 12÷20 at.%), which exhibit high saturation magnetization, characteristic that leads to an increased magnetic torque and force of action on cellular membrane and high magnetic susceptibility that make the actuation of the particles possible even in low magnetic fields and low Curie temperature. These particles are suitable for self-controlled hyperthermia application [6], and were obtained by high energy ball milling of FeCrNbB amorphous ribbons prepared by rapid quenching from the melt. The size of the particles is ranging between 20 – 200 nm, depending on the milling conditions and they present a particular non-spherical and irregular shape which leads to an improved amplitude of the movement in the rotating alternative MFs caused by the shape anisotropy. We have applied linear and rotating alternative magnetic fields and studied the influence of the intensity of the field, its frequency, and the time of exposure on cellular viability. The MPs were dispersed in calcium gluconate prior adding in cell culture media. In order to set up the experiments, we designed a system consisting of four coils placed in cross which can be supplied either to produce a MFs variable in time providing a high gradient moving from one coil to another or to produce a rotating MFs and a special electronic system which allows us setting of the MFs intensity, its frequency and the time of exposure. In the centre of the coils system there is a space of about 20 cm^3 where the MFs is uniform, where cell culture plates containing cells to be studied can be placed. A device which allows temperature variation can be inserted in order to modify and maintain the desired temperature of the cell plates. We have first evaluated the cytotoxicity of the FeCrNbB ferrofluid for concentrations of MPs in cell culture media ranging between 0.5 – 5 mg/ml and we observed that there is no cytotoxic effect even at high concentration rates such as 5 mg/ml. A systematic experimental setup was then performed by analysing one by one the parameters involved in the MFs– cells – MPs interaction, such as frequency and intensity of the field, time of exposure and magnetic particle concentration. We have observed that the concentration of MPs in cell culture media, when the cells are exposed in rotating magnetic field, has an important influence on cellular viability, as shown in figure 1. The higher concentration of MPs is, the lower the viability of cells after treatment becomes, reaching 14% cellular viability at a concentration of 5 mg/ml for a time of treatment of 10 minutes and a field intensity of 1 mT. The influence of time of exposure on cellular viability was also tested by applying the rotating MFs for 5, 10, 15 and 20 minutes on osteosarcoma cells, at a field intensity of 1 mT and a frequency of 20 Hz. The results show that, when we increase the time of cells exposure in MFs cellular viability is decreasing sharply. Following the same experimental setup we have tested the influence of field intensity and its frequency and observed that in both cases the cellular viability decreases with the increase of the frequency or of the field, but only to specific values. In an additional experiment, we sought to check if a simultaneous overlapping of hyperthermia treatment with rotating magnetic fields could boost the cytotoxicity. The heating effect was induced by a laboratory-made incubation system with the walls heated by water recirculated by a thermostated bath. Temperature of the cell culture well was raised from 37°C to about 46°C and the magneto-mechanical treatment was applied for 3 minutes from the moment temperature reached 45°C in the well. The results showed that the viability of osteosarcoma cells was reduced to about 80% when a conventional hyperthermic regime was applied and decreased to 73 % when hyperthermia was conjugated with rotating magnetic field. While the applied treatments were efficient for killing the human cancer cells, normal cells (fibroblasts) were not affected by the hyperthermia or rotating MFs combined with hyperthermia. EI-07. Twin Coil Design Considerations for Depth and Focality in Transcranial Magnetic Stimulation.

S. Chang[1], X. Wei[1], Z. Zhang[1], S. Li[1], J. Wang[1] and G. Yi[1]
1. School of Electrical and Information Engineering, Tianjin University, Tianjin, China

INTRODUCTION As a non-invasive stimulation treatment, the transcranial magnetic stimulation (TMS) utilizes the magnetic pulses to modulate neural activities via the induced electric field inside brain. The corresponding stimulation depth and focality determines the locus of activation in the brain, which is the most technical concern for the design of stimulating coils of TMS systems. Previous studies have shown that the twin coil can offer an enhanced stimulation performance, whereas the relationship between electric field spatial features and twin coil geometry has nearly unexplored before. Accordingly, this paper carries out a comprehensive analysis for the impact of the coil size and the angle on the stimulation depth and focality, which aims to provide theoretical basis on the optimal design and contribution of twin coils for TMS researchers and clinicians. METHODS The exemplified model are set up based on the finite element method, where the human head is modelled as a homogeneous sphere with the 170 mm diameter and the isotropic conductivity of 0.33 S/m. The distance between the stimulation coil and the surface of the head is 5 mm. In order to reveal the impact of the coil size and angle on the stimulation performance, as depicted in Fig. 1(a), the coil diameter and the opening angle are adjusted from 102 mm to 162 mm and from 60° to 180°, respectively. Fig. 1(b) shows the corresponding distribution of twin-coil-induced electric field on the surface of the human brain. By choosing the depth and the focality as the performance indicators of TMS systems, the penetration of the electric field can be quantified as the half-value depth ($d_{1/2}$). It is the distance between the head surface and the deepest position with the half value of the maximum electric field strength. In addition, denote the half-value volume as $V_{1/2}$, which is the volume of area where the strength of the electric field is stronger than the half of the maximum value. Besides, the focality is quantified by the tangential spread ($S_{1/2}$), which is the ratio of the half-value volume to the half-value depth, namely $S_{1/2}=V_{1/2}/d_{1/2}$. RESULTS As shown in Fig. 2(a), the exemplified twin coils with the diameter of 102mm, 122mm, 142mm and 162mm have the maximum electric field half-value depth $d_{1/2}$ when the opening angle is 100°, 120°, 140°, and 160°, respectively. Fig. 2 graphically shows that $d_{1/2}$ has a peak value along with the increases of the opening angle, while the electric field spread $S_{1/2}$ increases monotonically with respect to the opening angle. In addition, Fig 2(c) depicts the electric field $S_{1/2}$-$d_{1/2}$ locus with the coil size and opening angle change. The corresponding deepest half-value depth values of exemplified four twin coils are 23.7mm, 26.3mm, 29.6mm and 31.5mm, respectively. When $d_{1/2}$=29.6 mm, the values of $S_{1/2}$ of 142-mm coil and 162-mm coil are 188cm^2 and 151 cm^2. It shows that the coil size determines the maximum half-value depth value, namely the larger coil the deeper half-value depth. Furthermore, for the identical stimulation half-value depth, the increased size of the simulation coil can also enhance the electric field focality. Thus, the optimal design of the coil size can offer salient advantages of the depth and the focality of the induced electric field, thus effectively improve the stimulation performance for TMS systems. CONCLUSION This paper carried out a comprehensive analysis on the impact of the coil size and the opening angle of twin coils on the stimulation depth and the focality. According to the computational simulation, the main result can be summarize as: (i) there is a deepest stimulation depth when the opening angle is adjusted, (ii) the coil size limits the maximum stimulation depth, (iii) the large coil has salient advantages of the depth and the focality. The presented results shows significant meanings for researchers and clinicians to design or configure the optimal twin coil for TMS systems. Besides, the detailed parameters, theoretical analysis, simulated results, and experiment results will be presented in the full manuscript.

Department of Neuromodulation and Neurosurgery, Graduate School of Medicine, Osaka University, Osaka, Japan

Recent studies show that transcranial magnetic stimulation (TMS) is effective for the treatment of neurological and psychiatric diseases, however, the therapeutic effect varies significantly among patients. The distribution of the electric fields induced by TMS is affected by individual variability in the shape of the human head and by the targeted area of the brain, thus, the efficiency of the existing magnetic stimulators or coils varies considerably among patients because of their fixed geometries. Moreover, all existing coils are subjected to a depth focality tradeoff limiting their use to narrow area of TMS application. In this study, we try to create a universal coil with a variable geometry by employing figure-of-eight coil with bending wings, as shown in Figure 1. A novel rotary mechanism is proposed to realize this coil and we name it as Angular coil or Acoil. In numerical simulations with a human brain model, we found that its optimal angular degree is markedly different between not only subjects but also stimulation positions. We define the efficiency of the coils by the value of the induced eddy current density in the targeted area of the brain for the same driving current intensity. Numerical simulations through scalar potential finite difference (SPFD) method were conducted on a conductive sphere model to study the depth and focality characteristics of the stimulation induced by Acoil for bending angles ranging from 90 to 180 (figure of eight coil configuration) degrees. Then, using the same numerical method on real brain models constructed from MR images of 5 healthy human subjects, we measured the induced eddy current in the motor cortex left hand, foot and face areas by the Acoil for different bending angles. The positions of the coil were defined by medical doctors using a neuronavigation system. For the study of the coil stimulation characteristics. we calculated the magnetic flux density for different distances from the center of the coil revealed that by bending the coil, we could obtain a stronger magnetic field with a higher field penetration and the highest values were obtained in the case of 90 degrees bending which is the most acute angle for this study. We found through the study on the conductive sphere model that for a range of 30 degrees bending from a figure of eight coil configuration (180 degrees), we could obtain a focused stimulation with a higher efficiency the more we bend the coil. For bending angles ranging from 120 to 150 degrees, the stimulation was deeper and more efficient but much less focalized compared to figure eight-coil. Thus, we could conclude that the bending angle that had the best depth-focality tradeoff for the case of Acoil was 150 degrees. Finally, for 90 to 120 bending angles, The stimulation was neither deep nor focalized because the angle becomes largely acute so we are obliged to elevate considerably the coil center from the sphere surface to avoid the penetration of the wings in the model, losing the efficiency of the coil. The results with brain models show that the efficiency of the stimulation varies considerably among the subjects and for the different brain areas, as shown in Figure 2. However, because of the variable geometry of the Acoil, we could adapt its shape to obtain the most efficient stimulation defining the best bending angle in each case, with an increase in efficiency of an average 30% compared to baseline figure of eight coil for all the cases. Furthermore, we found that the stimulation is the most efficient for the bending angles for which the coil fits the head geometry and has a maximum contact with the scalp. In fact, we demonstrated through the study of the stimulation characteristic that Acoil can be used to provide efficient focused stimulations and deep stimulations depending on the bending angle covering a wide area of TMS applications (nTMS, dTMS, rTMS among others).

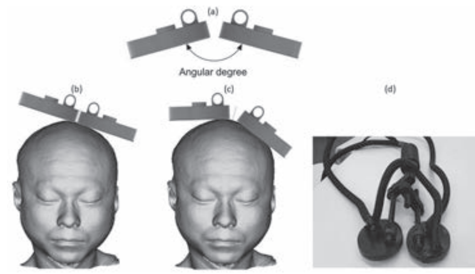

Fig. 1. (a) Acoil model. (b) Head model constructed form MR mages and Acoil with 180 degrees bending angle in the position defined by medical doctors for the stimulation of the foot area of the brain. (c) Same head model and Acoil with 140 degrees bending angle. (d) Prototype of Acoil.

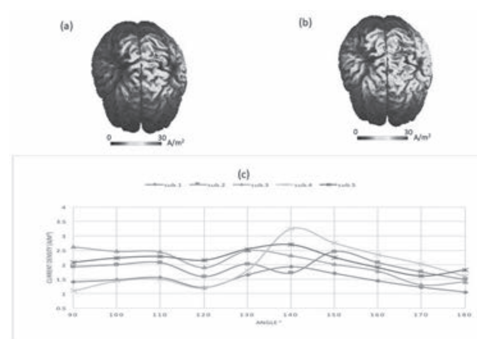

Fig. 2. Study of the efficiency of Acoil for the stimulation of the foot area of the brain for different bending angles considering 5 human subjects. (a) Distribution of the eddy current induced in subject 4 brain after the stimulation by Acoil with 180 degrees angle. (b) Distribution of the eddy current induced in subject 4 brain after the stimulation by Acoil with 140 degrees angle which is the most efficient bending angle for the stimulation of subject 4 foot area. (c) Evolution of the eddy current density induced by Acoil for different bending angles in the foot areas of 5 human subjects brains. From this graph, we can conclude that the most efficient angle for subject 4 is 140 degrees.

EI-09. Flexibility of Micro-magnetic Flagella in the Presence of an Oscillating Field.

Y. Li[1] and C. Yen[1]
1. Department of Mechanical and Aerospace Engineering, National Defense University, Taoyuan, Taiwan

Magnetic microbeads have recently been the subject of much study because of their potential applications in microfluidic systems which facilitate mixing[1], labeling[2], separation[3] and transport[4] in lab-on-a-chip devices. It has been proposed that rotating superparamagnetic beads chains can enhance the mixing efficiency in microfluidic devices[5] and the magnetic micro-bead chain that is subjected to an oscillating field can be used to design a micro-swimmer[6]. To manipulate the micro-beads chain swimming in the low-Reynolds number environment, various magnetic actuation methods have been employed to obtain the higher propulsive efficiency for the locomotion in the viscous fluid. A flexible flagellum is arguably the simplest mechanism to duplicate as it is a one-dimensional structure. However, a challenge to create the stable planar beating motion for propulsion generation is to fabricate the magnetic flagellum simultaneously flexible and stable structure at a microscale. In order to effectively use an oscillating magnetic flagellum as a tail of a microswimmer, the measurement of the bending rigidity for the flexible micro-chains is essential. In this study, the curvatures and the bending rigidity of distorted chains with different lengths subjected to an external field with various controlling parameters (such as the field intensity and frequency) were probed to evaluate the flexibility of the magnetic flagellum. The magnetic flagellum is obtained by combining the self-assembling ability of micro-sized superparamagnetic particles composed the iron oxide magnetite (Fe_3O_4) embedded in polystyrene microspheres suspended in distilled water. Properties of the commercially available micro-beads are density ρ=1500 kg/m^3, diameter $d = 4.5$ μm, initial magnetic susceptibility $\chi = 1.6$, and without magnetic hysteresis or remanence, which could be magnetized under an applying external field and completely demagnetized when the field is removed. Firstly, the magnetic beads magnetized by a homogeneous static field H_d tended to aggregate and form the linear flagellum, and a dynamical sinusoidal field H_y with a maximum amplitude H_p and an adjustable frequency f, that is, $H_y = H_p \sin(2\pi ft)$, were then applied in a direction perpendicular to H_d. Thus, the planar beating motion is created to form the dynamic flexible flagellum. In order to accurately obtain the chain flexibility and bending rigidity, we model the waggling chains as continuous elastic flagella and analytically derive their curvatures as a function of magnetic field strength. The maximum dimensionless curvature (denoted as C_{max}) of the chain is given as $C_{max}=d/R$, R represents the flagellum's radius of curvature. The bending rigidity κ of the waggling chain is measured from the S-shape of the chain by using the equation given as[4]: $C_{max}=(Bd/4)(\pi/3\kappa\mu_0)^{0.5}$ Where the μ_0 represents the vacuum permeability, B is the overall magnetic field strength. Figure 1 shows the most significant deformed shapes for the flexible flagella of various lengths subjected to the increasing field strength. It can be seen that all the chains bend to S-shape for all values of applying field strength, and the deformation increases slightly with an increase in the perpendicular dynamic field intensity H_p for each flagellum. On the other hand, the influences of flagellum strengths are not consistent. By examining figure 1 carefully, we found the increase of the length doesn't enhance the deformation significantly. On the contrary, the longer length as flagellum consisting of 16 particles (denoted as P16) behaves more insignificant S-shape than the counterpart of the P15 chain because of the more significant constraint from the stronger hydrodynamic drag acting on a longer chain. The further inspection of the interesting finding can be done by the examination of figure 2, which shows the geometrical relation between the flagellum's radius of curvature R and the diameter d of the magnetic bead. It can be seen that for all lengths of flagella the maximum curvature of the flagellum increases linearly with the intensity of the applied field. In addition, the value of C_{max} of the flagellum firstly gets higher then declines with the increase of the length, which indicates the magnetic flagellum subjected to an oscillating field would have the most flexible structure at the certain length. The further discussions are shown in full paper demonstrating the effects of the other controlling parameters on C_{max} and the bending rigidity κ.

EI-10. Novel Electromagnetic Targeting System for Navigating Surgery in Endobronchoscopy.

C. Chen[1], C. Lin[1,2], Y. Cheng[1], T. Chung[1], C. Chang[1], S. Tsai[1], J. Chen[1] and X. Lin[1]
1. National Chiao Tung University, Hsinchu, Taiwan; 2. National Taiwan University Hospital, Taipei, Taiwan

I. INTRODUCTION Nowadays, lung cancer is one of common cancers around the world. To increase the survival rate of the patient, early diagnosis is necessary. To achieve this, bronchoscopists usually use endobronchial ultrasound for navigating surgery in endobronchoscopy. However, because the bronchoscopist has to continuously re-navigate/re-target the bronchoscope to collect specimens from the same tumor, the whole navigating/targeting process has to be repeated many times in one surgery. Due to this, navigating/targeting the bronchoscope to correct/same tumor is still a time-consuming process. Therefore, a more accurately tumor-targeting approach is needed to significantly save time in navigating surgery. To address this issue, recently researchers combined electromagnetic (magnetic-sensor-based) targeting technology with conventional endobronchial ultrasound as a hybrid targeting approach to achieve a more accurate real-time tumor-targeting in endobronchoscopy [1]. However, when comparing conventional bronchoscopes, the bronchoscope with magnetic sensor is more expensive and less compatible. Thus, a cheaper and compatible electromagnetic targeting technology is required. Recently, some researchers demonstrated electromagnetic-induction/magnetic-interaction approaches to target distal screw-hole in intramedullary interlocking-nail surgery [2]-[5]. We think that these targeting approaches can be modified to develop as a new, cheaper, and compatible electromagnetic targeting technology for general endobronchoscopy. Hence, in this paper, we demonstrate the electromagnetic targeting system for endobronchoscopy. II. DESIGN The system is illustrated in figure 1(a). The system consists of an emitting electromagnets-array, a receiving electromagnets-array, a 2D model of bronchial tree, and a high-permeable silicon-steel collar fixed on an endobronchoscopic guide sheath. The targeting principle of the system is shown in figure 1 (b)(c). As shown in figure 1(b), an AC current is applied to the emitting electromagnets-array to produce AC magnetic flux. Consequently, the magnetic flux is received by the receiving electromagnets-array. Due to the electromagnetic-induction, each receiving electromagnet produces a corresponding voltage output. When the guide sheath with the collar travels through the air gap between the emitting and receiving electromagnets no. 1, the collar concentrates the magnetic flux and thereby the magnetic flux received by the receiving electromagnet no. 1 is increased. Thus, the voltage output of receiving electromagnet no. 1 is increased. However, at this moment, the magnetic flux in the other air gaps is not concentrated. Thus, the voltage outputs of the other receiving electromagnets are not changed. By analyzing these voltage changes of receiving electromagnets, the location of the collar/guide-sheath is targeted. III. FABRICATION Figure 1(d) shows fabrication result of the system. We used AWG 25 enameled wires and silicon-steel stack to fabricate an electromagnet. 12 electromagnets are arranged on a print-circuit-board as the emitting electromagnets-array (note: same fabrication-process for the receiving electromagnets-array). The 2D model of bronchial tree is produced from PMMA plate by laser machining. We used aluminum extrusion beams and PMMA plates to fabricate the mechanical frame. The silicon-steel collar is attached on the guild sheath. Finally, we assembled the electromagnets-arrays, 2D model, mechanical frame, and emitting/receiving-electronics (i.e., switches, function generator, and lock-in amplifier) as the system. IV. TESTING AND RESULTS The testing procedure, shown in figure 2(a), is guiding the guide sheath (silicon-steel collar) to insert into right primary bronchus and sequentially travels above the receiving electromagnet no. 2, 7, and 12. While the sheath/collar is traveling, we use the lock-in amplifier with the switch to sequentially measure voltage output of each receiving electromagnet. The voltage outputs are shown in figure 2(b)-(d). When the collar is above the electromagnet no. 2, the voltage output of the electromagnet no. 2 becomes relatively large. When the collar travels away from electromagnet no. 2 toward no. 7, the voltage output of the electromagnet no. 2 and 7 gradually decreases and increases, respectively. When the collar is above the electromagnet no. 7, the voltage outputs of electromagnet number 7 is relatively large. Similarly, the change of voltage output of the electromagnet no. 12 is similar as the electromagnet no. 7. By analyzing the changes of the voltage outputs of the electromagnets, the location of the collar (with the guide sheath) in the 2D model of bronchial tree is successfully targeted. V. CONCLUSION We demonstrated a novel electromagnetic targeting system for navigating surgery in endobronchoscopy. Experimental results show that the system successfully targeted the guide sheath traveling in bronchial-tree model. This means the system can navigate the bronchoscope and forceps for surgery. In the future, we will continuously improve the system and apply the system to clinical test. VI. ACKNOWLEDGEMENT Chin-Chung Chen and Chin-Kai Lin are equal contribution (co-first author). EP-01. Thickness dependence of spin polarization in Co_2FeAl thin films.

X. Zhang[1], L. He[1], Y. Xu[1,2] and W. Liu[2]
1. Nanjing Unversity, Nanjing, China; 2. University of York, York, United Kingdom

Half-metallic ferromagnets (HMFs) have only one spin channel for conduction at the Fermi level, while they have a band gap at the other spin channel. Therefore, in principle this kind of material has 100% spin polarization for high efficient spin dependent transport, which is perfect for spin injection, spin filtering, and spin transfer torque devices. We have studied the half-metallic Co_2FeAl thin films with different thicknesses epitaxially grown on GaAs (001) by molecular beam epitaxy. The magnetic properties and spin polarization of the films were investigated by *in-situ* magneto-optic Kerr effect (MOKE) measurement and spin-resolved angle-resolved photoemission spectroscopy (spin-ARPES), respectively. We have found that the films possess an in-plane uniaxial anisotropy with the easy axis of [-1 1 0]. Along the easy axis, the field dependent MOKE signals of various thicknesses are presented in Fig. 1a. Square hysteresis loops can be observed. As the film thickness increases, both MOKE intensity and the coercivity increases. The coercivity saturates after the film thickness is beyond 4 uc. The magnetization of all the films demonstrates a linear relationship with the thickness and a kink at 4 uc (Fig. 1), above which it reaches the bulk value of 1000 emu/cm^3. For the film thickness below 4 uc, a linear relationship cross zero suggests that there are no magnetic dead layers. The magnetization and coercivity imply that the films thicker than 4 uc are bulk-like, while films thinner than 4 uc are mostly affected by the interface. The magnitude of spin polarization of ferromagnetic materials is a key property for their application in spintronic devices, especially at room temperature. To investigate the spin polarization of the Co_2FeAl films, samples were transferred under ultra-high vacuum to the ARPES chamber upon the growth is finished. Figure 2 exhibits the representative spin-resolved photoemission spectra and the corresponding spin polarization at room temperature. A broad peak at ~1.0 eV in Fig. 2a comes from the combination of Co and Fe's 3d electronic states. As shown in Fig. 2b-2e, the spin polarization of Co_2FeAl films exhibits a peak at the Fermi energy (E_F), then decreases slowly with the binding energy increasing, and reaches zero beyond 1 eV. A high spin polarization of ~ 65% has been observed for the Co_2FeAl film of 21 uc (Fig. 2), for the first time in this system. As the thickness decreases, the spin polarization stays roughly constant until it drops down to 37% at 2.5 uc. For the film of 2.5 uc, the peak value is much lower than the thicker films, and also the spin polarization goes to a negative value at higher binding energies, suggesting the swap of spin direction of the majority and the minority band. The strong attenuation of the spin polarization at 2.5 uc may be due to the interface bonding or the site disorder, resulting the spin polarization much less than the bulk. Both the *in-situ* MOKE and *in-situ* spin-resolved ARPES indicate that the Co_2FeAl films is suitable for the fabrication of MTJs after about 4-6 uc. Our results show that the intrinsic spin polarization is still rather high and doesn't limit the TMR value. It is the interface, where the sharp decrease of spin polarization happens, that leads to a relatively smaller TMR in the epitaxial Co_2FeAl based MTJ.

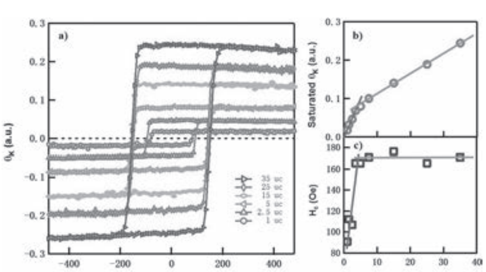

Fig. 1. Thickness-dependent *in-situ* MOKE measurements of the Co_2FeAl films. (a) In-plane magnetization measured at 300 K along [-1 1 0] (easy axis direction) by a longitudinal-mode MOKE set up. Both thickness dependent (b) Kerr rotation & (c) coercive field estimated from (a) show a turning point at ~ 4 uc.

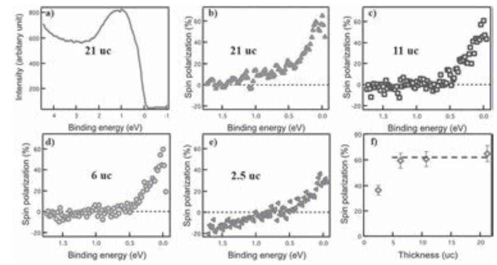

Fig. 2. *In situ* spin-resolved ARPES measurements. (a) Spin-resolved photoemission spectra of the 21-uc-thick Co_2FeAl film, probed by 21.2 eV photons at 300 K. (b)-(e) Spin polarizations of Co_2FeAl films with thicknesses of 21 uc, 11 uc, 6 uc and 2.5 uc, respectively. (f) Spin polarizations at the Fermi level versus film thicknesses. It is almost constant of 60 - 65% with film thicknesses more than 6 uc, and it then decreases to 37% at 2.5 uc.

EP-02. Levitation Force Computation of HTS/PM system by H-formulation.

W. Chen[1], J. Shi[1] and Y. Xu[1]
1. Huazhong University of Science & Technology, Wuhan, China

Abstract—This paper presents a model to predict the electromagnetic behavior of HTS/PM system which based on finite element method and H-formulation combining with E-J characteristics and J-B relationship. And the model is suitable for axial symmetric problems. The axial levitation force of the HTS/PM system is calculated considering the nonlinear and anisotropic properties of HTS bulks. In order to validate the model, experimental results of the system are obtained and compared with simulation results. The comparison shows experimental and simulation results match well. Keywords— HTS/PM system; H-formulation; levitation force; finite element method I. Introduction The superconducting magnetic levitation system has great advantages due to its passive levitation stability comparing to permanent and active magnetic levitation system. Hence, it has lots of applications such as flywheel energy storage system, motor, maglev vehicles [1-3] etc. And the system usually consists of HTS bulks and permanent magnets (PM). Besides, it's important to be able to predict its electromagnetic behavior in order to optimize its performance in the processing of designing the superconducting magnetic levitation system. But it's difficult to predict the electromagnetic behavior of SMB because of inhomogeneous, nonlinear and anisotropic properties of HTS bulks. So in order to explore the levitation properties of the system, a model is presented to predict its electromagnetic behavior combining with E-J characteristics and J-B relationship of the HTS bulk. This model is suitable for 2-D axial symmetry system, but the hysteresis effect is not considered for the sake of the simplification. The computation is based on finite element method and H-formulation which is evaluated by COMSOL Multiphysics. II. The H-Formulation The Maxwell equations can describe macroscopic electromagnetic phenomena. And the H-formulation can be obtained from Maxwell equation. Besides, H-formulation can be applied to the entire region and only has one variable *H*. Meanwhile, in 2-D axial symmetry problem, the variable *H* only has 2 components *Hr* and *Hz*. The electromagnetic behavior of HTS bulk can be represented by E-J power law relationship, KIM model for J-B relationship and linear B-H relationship [4]. And the levitation force between HTS and PM can be obtained by Lorentz force equation. III. Modelling and Computation of HTS/PM System A. HTS/PM System Model Fig.1(a) presents the HTS/PM system which consist of a cylindrical permanent magnet above a HTS bulk. The magnet and HTS bulk are made of rare earth material and melt textured yttrium barium copper oxide (YBCO) respectively. According to Fig.1(a), the corresponding 2-D model can be obtained due to the symmetry of the system, which shows in Fig.1(b). More importantly, the 2-D model can reduce the computation time comparing to its 3-D counterpart without accuracy loss. B. Computation of the Levitation force The levitation force computation of HTS/PM system is based on finite element method combining with the H-formulation. And the simulation process is implemented by COMSOL Multiphysics. In this paper, we focus on the 2-D symmetry model, and only the movement along the z-axis is considered. And the computation is to simulate the process of experiment scenario of levitation force measurement. In the initial position, the HTS bulk and PM are coaxial with a fixed gap and the HTS bulk is cooled at 77K in zero field condition. After that, the PM is brought down to the HTS bulk until reaching the previously fixed minimum gap. Then the PM is brought back to the initial position. When the gap between HTS and PM varies, during the movement, the HTS bulk generates induced persistent current to resist the movement, hence the levitation force can be calculated by using Lorentz force equation. IV. Simulation Results To evaluate the interaction between HTS bulk and PM, the simulation is carried out by COMSOL Multiphysics. The simulation result of axial levitation force is shown in Fig.2(a). In order to verify the accuracy of the simulation result, the comparison of the simulation result and its experiment counterpart [5] is shown in Fig.2(b). From Fig. 2(b), the simulation and experiment results match well, especially when PM approaches HTS bulk, hence the simulation verifies the validity and accuracy of the model. V. Conclusions This paper presents a model to predict the electromagnetic behavior of HTS/PM system which based on finite element method and H-formulation combining with E-J characteristics and J-B relationship. In the meantime, the levitation force alone the z-axis is calculated. The comparison of simulation and experiment results matches well. Meanwhile, the results verifies the accuracy and validity of the model.

In this study, we investigate both experimentally and theoretically the holmium doped rare-earth langasite $Ho_{0.09}La_{2.91}Ga_5SiO_{14}$. The magnetic and magnetoelectric behavior in single crystalline $Ho_{0.09}La_{2.91}Ga_5SiO_{14}$ along the main crystallographic directions has been studied in broad magnetic field and temperature ranges. To explain the observed properties we applied a theoretical approach successfully used previously for rare-earth borates [1-4]. Here we extend the quantum theory of magnetoelectric effect in rare-earth langasites to the holmium doped compound. From the comparison to the experiment we evaluate the parameters of the crystal field and of the magnetoelectric Hamiltonian. Both magnetic and magnetoelectric properties of the Ho-doped langasite can be successfully explained by the suggested model. Figure 1: Experimental (solid lines) magnetization curves along two crystallographic axes in $Ho_{0.09}La_{2.91}Ga_5SiO_{14}$ as compared to the theoretical model (dotted lines). EP-04. Anomalous magnetic and Electrical properties of $Fe_2V_{2-x}Al_x$ (x=0-1) alloys.

S. Hari[1] and V. Srinivas[1]
1. Department of Physics, IIT Madras, Chennai, India

Intriguing correlated electronic structure is revealed when vanadium is substituted in place of iron in ferromagnetic DO_3-Fe_3Al intermetallic alloy and transforms it into a Fe_2VAl Heusler alloy with $L2_1$ crystal structure. This particular composition exhibits nonmagnetic semi-metallic character [1], [2]. Both DFT calculations and experiments revealed the existence of pseudogap or gap ranging up to 0.5 eV. The origin of the gap and the role of hybridization in these alloys is still debated[3]. These studies reveal that the vanadium reduces the moment, yet the role of aluminium in altering the electronic properties is still need to be investigated. Therefore, in the present investigation, we have studied the structural and magnetic properties of $Fe_2V_{2-x}Al_x$ alloys with x varying from 0 to1 to unravel the role of Al in Fe_2VAl which is known to be exhibiting the features similar to that of equiatomic FeV. Alloy ingots were synthesized by arc melting the elemental constituents and subsequent annealing at 1273 K for 3 days. From X-Ray Diffraction studies it is observed that x=0 composition (FeV) stabilized in σ-phase, while a mixed phase (σ+cubic) is obtained for x=0.2. It is observed that as the Al-composition varies from 0.4 to 1 it exhibits a cubic phase. DC magnetic measurements were performed for all samples, which revealed that the magnetic character decreases with Al concentration. The extreme compositions (well ordered) of this series namely, FeV (with σ-phase) and Fe_2VAl ($L2_1$-phase) are found to be paramagnetic down to lowest temperature. The temperature dependence of magnetization curves shown in Fig.1 for composition x=0.2 suggest ferromagnetic character with Curie temperature (T_c) close to 240 K and for x=0.4 with T_c~ 130K, while the compositions x=0.8, 1 exhibit nonmagnetic behavior down to 5K (Fig.1). The magnetic isotherms of these compositions exhibit anomalous magnetic character i.e., exhibit higher coercivity at 300K compared to 5K (except for Fe_2VAl), with lower saturation magnetization. The existence of hysteresis behavior above T_c indicates the possibility of the presence of ferromagnetic clusters in intermediate compositions. Analysis of magnetic data suggests that disorder plays a significant role in addition to the composition. To see whether the magnetic anomalies affect the electrical transport, we carried out electrical resistivity measurements in the low temperature range, shown in Fig.2. The electrical resistivity shows a positive temperature coefficient of resistivity (TCR) for x=0 to x=0.8 and the resistivity at temperatures below 250K decreases with Al concentration which indicates the presence of Al improves the metallic nature of these samples. But the sample with highest Al concentration i.e Fe_2VAl shows negative TCR which also exhibits high values of resistivity compared to other compositions of the series. This kind of behavior can be attributed to band structure formed due to structural disorder in samples, x=0.2, 0.4, 0.8, and pseudo band gap formed in Fe_2VAl near Fermi level[4], [5]. From above studies, it is quite evident that the material going from metallic state to semi-metallic state with a small variation in Al concentration. The resistivity increased by two orders of magnitude from $Fe_2V_{1.2}Al_{0.8}$ to Fe_2VAl, whereas both the samples were paramagnetic down to 5K. An inflection point in resistivity curve near the magnetic transition temperature T_c is observed, which suggests a correlation between transport and magnetic properties. These magnetic and electrical transport anomalies show even non-magnetic aluminum plays a significant role in electronic properties and will be discussed in detail.

EP-05. Spinterface Properties and Magnetic Coupling of Tris(8-hydroxyquinoline)iron(III) on Cobalt Surface.

L. Yu[1], J. Lin[1,2], Y. Lai[1], H. Shiu[1] and Y. Hsu[1]
1. National Synchrotron Radiation Research Center, Hsinchu, Taiwan;
2. Program for Science and Technology of Accelerator Light Source, National Chiao Tung Universoty, Hsinchu, Taiwan

Tris(8-hydroxyquinoline)aluminium (Alq_3) has been successfully sandwiched between two ferromagnetic electrodes as a buffer layer in organic spin-valve (OSV) devices to exhibit prominent magnetoresistance (MR) values [1]. Compare with inorganic spintronics, organic/molecular spintronics use the chemical versatility of molecules to own charming properties, such as paramagnetic behaviour of metal ions, and tuneable electronic structure [2-8]. The tris(8-hydroxyquinoline)iron(III) (Feq_3) containing the paramagnetic iron centre has the similar structure with Alq_3, that implies that Feq_3 has the potential for promising organic/molecular spintronics. Here we report that Feq_3 was synthesized and deposited on cobalt for investigating the electronic and magnetic interplay between Feq_3 and ferromagnetic Co surface. Feq_3 was synthesized by the recipe described as bellow. Iron(III) chloride (367 mg, 2.3 mmol) and 8-hydroxyquinoline (1.09 g, 6.9 mmol) were dissolved in 80 ml methanol. The solution was then heated to reflux for 20 minutes. Triethylamine (698 mg, 6.9 mmol) was added, and the resulting mixture was heated for 20 minutes. The deep green crystal Feq_3 was precipitated and filtered (842 mg, 75%). All thin films were fabricated and characterized under ultra-high vacuum (UHV) conditions without air exposure to avoid surface contamination during deposition and spectroscopy measurements. The Co/Feq_3 film was evaporated on Si(100)/Au near 295 K. The Co and Feq_3 films were sequentially deposited in two separate deposition chambers which are also detached from the analysis chamber. After complete fabrication, samples were transferred to the analysis chamber for x-ray photoelectron spectroscopy (XPS), near-edge x-ray absorption fine structure spectroscopy (NEXAFS). The powder x-ray diffraction were measured to identify the crystalline structure. The chemical states, electronic structures and magnetic properties were recorded at beam lines (BL) 09A2 U5 for spectroscopy, 17A for powder x-ray diffraction and 11A Dragon for XMCD at National Synchrotron Radiation Research Center (NSRRC) in Taiwan. XPS was used to examine the interfacial chemical and electronic properties at Co/Feq_3 interface. At the bottom contact interface for Feq_3 atop Co surafce, three N peak features are observed at binding energy (BE) 399.8, 398.8 and 397.5 eV for a sub-monolayer of Feq_3 adsorbed on Co. The BE at 399.8 eV is corresponding to the molecular state, the lower BE at 398.8 eV and 397.5 eV are attributed to the hybridized states of N atoms in Feq_3 with underneath Co. On the other hand, the O peak features of the Co/Feq_3 interface express negative shift in the low coverage of Feq_3, but shift back to the position of molecular state in high coverage of Feq_3, that implied the oxygen atoms in Feq_3 are also involved in the hybridization with Co. The XPS results indicate that the interface interaction between Feq_3 and cobalt is similar to Alq_3 on Co [9-10]. The nitrogen atoms of pyridyl ring and oxygen atoms of phenoxide ring in Feq_3 show strong hybridization with cobalt by XPS. The chemical states and electronic structure of central iron are also influenced by thermal evaporation and the hybridization. Two absorption peaks of Fe *L*3-edge at 709.2 and 710.8 eV corresponding to iron(II) and iron(III), respectively are observed for 10 nm Feq_3 adsorbed on Au. Nevertheless, a sub-monolayer of Feq_3 adsorbed on Co only shows the iron(II) absorption peak at 709.2 eV. The iron(III) of Feq_3 was reduced to iron(II) when sub-monolayer Feq_3 deposited on Co. XMCD spectra reveal the magnetic interaction between Fe ion and Co in the Co/Feq_3 interface as depicted in Fig. 1. The Au/Feq_3 film shows slight XMCD dichorism at Fe *L*3-edge in Fig. 1(a), meaning the intrinsic paramagnetism of Fe ion in Feq_3 is observed in the magnetic field [11-12]. However, in Fig. 1(b), the more evident XMCD dichorism is obtained when a sub-monolayer of Feq_3 deposited on Co, and the negative dichroism is found in Co *L*3-edge as well (Fig. 1(c)). As a result, the spin-polarization of Fe ion is enhanced by the magnetic coupling with Co. The magnetic hysteresis loops of XMCD measured at the Fe and Co *L3*-edge in the sample of Co/Feq_3 is depicted in Fig. 1(d). The same magnetization direction and coercivity (H_c) are found in the MH loops that corresponding to the ferromagnetic interaction between Feq_3 and Co. Feq3 containing the paramagnetic metal center was synthesized and deposited on Co surface. The interfacial characterization of nitrogen and oxygen in Feq3 on Co display similar behaviour to Alq3 on Co that all show strong hybridization with Co. The chemical states and electronic structure of central iron are also strongly influenced by the interfacial hybridization. Measurements of XMCD at Fe and Co L-edge illustrate that central iron metal of Feq3 exhibiting apparent spin-polarization after contact with cobalt that is the ferromagnetic interaction between central iron ion and cobalt.

EP-06. Observation of superconductivity in $LaNiO_3/La_{0.7}Sr_{0.3}MnO_3$ superlattice.

G. Zhou[1], Z. Quan[1] and X. Xu[1]
1. Shanxi Normal University, Linfen, China

School of Chemistry and Materials Science, Key Laboratory of Magnetic Molecules and Magnetic Information Materials, Ministry of Education, Shanxi Normal University, Linfen 041004, China Atomic scale control of the hetero-interfaces in transition metal oxides has attracted significant attention due to the possibility of observing novel phenomena[1,2]. The cuprate- and ferrite-based interfacial superconductors have been investigated extensively, while the research of nickelate-based heterostructure is quite rare[3,4]. Recently Chaloupka and Khaliullin theoretically predicted that antiferromagnetism and high temperature superconductivity (SC) may be stabilized in LNO-based superlattices[5]. However, the superconductivity state in LNO-based heterostructure has not yet been experimentally reported. In this work, we investigate the properties of a superlattice (SL) composed of an ultrathin $LaNiO_3$ layer, with a ferromagnetic insulating $La_{0.7}Sr_{0.3}MnO_3$ (LSMO) layer. Zero resistance and Meissner effect are observed by resistive and magnetic measurements on the superlattice, which gives experimental indication of superconductivity in new kinds of superconductors. X-ray linear dichroism causes the NiO_2 planes to develop electron occupied x^2-y^2 orbital order similar to a cuprate-based superconductor. Our findings demonstrate that artificial interface engineering is a useful way to realize novel physical phenomena, such as superconductivity. Typical x-ray diffraction scans through (002) symmetric reflections of the LNO/LSMO superlattice are shown in Fig. 1a. The main peak of the superlattice and satellite peaks of SL-1 and SL+1 are observed, suggesting sharp interfaces in this superlattice. The coherent epitaxial growth and the absence of secondary phases or dislocations in LNO/LSMO superlattice are both confirmed by high resolution high-angle annular dark field scanning transmission electron microscopy, as shown in Fig. 1b. Because the A site is similar to the superlattice, and the atomic number of B site is contrasted in this image, the LNO layers appear brighter than the LSMO layers The high quality epitaxial $[(LNO)_2/(LSMO)_3]_{20}$ superlattice was measured with a current of $5E10^{-3}$ mA in a Van der Pauw geometry. In order to directly observe the superconducting property at low temperatures, the temperature dependence of resistivity was measured, as shown in the inset of Fig. 2a. The superlattice displays metallic behavior with the temperature below 10 K and the resistivity abruptly drops around 3.7 K, clearly indicating superconductivity. To further verify the superlattice nature of the observed superconductivity, we measure the magnetic susceptibility (χ) as a function of temperature at magnetic field (H) strength of 10 Oe. As shown in Fig. 2b, the zero field cooled (ZFC) and field cooled (FC) susceptibility are essentially temperature independent at low temperatures. A sharp drop of magnetic susceptibility is observed for both ZFC and FC processes, indicating that the magnetic onset of superconductivity appears around 3.5 K, which is the same as the zero-resistivity temperature. Further confirmation of superconductivity in the superlattice is shown in the inset of Fig. 2b, displaying the typical magnetic hysteresis curve for a superconductor at 2 K after zero-field cooled process. The characteristic M-H loop indicates that the present superlattice is a superconductor of the second kind with a lower critical field of 50 Oe. The work was supported by National Key R&D Program of China (No. 2017YFB0405703), NSFC (Nos. 61434002, 51571136, 11274214), and the Special Funds of Sanjin Scholars Program.

The closely related interplay between magnetism and superconductivity has been an intriguing phenomenon in high-T_C superconductors for several decades and was heavily explored in the case of bulk single crystals. Superconductivity in bulk Fe based materials, similar to cuprates, emerges upon the suppression of the magnetic order in the parent compounds via doping, signifying an intimate relation between magnetism and superconductivity [1, 2, 3]. The parent compound FeTe of the high-T_C Fe-chalcogenide family exhibits a bi-collinear antiferromagnetic (AFM) diagonal double-stripe (DDS) order [4,5,6]. Recently, it was shown that ultrathin films of Fe-based superconductors can have transition temperatures approaching the highest values that have been reported for cuprates, which boosted the interest in these materials even further. However, an understanding of the relevant mechanisms on the atomic scale, in particular, related to the spin degree of freedom, is still lacking and calls for an in-depth investigation of the phase transitions in these systems. A real-space visualization of spin-dependent phenomena on the atomic scale independence of the doping and temperature can thus provide a new dimension towards an understanding of high-T_C superconductivity. A suitable technique for this purpose is spin-polarized scanning tunneling microscopy (SP-STM) which has widely been utilized in studying magnetic nanostructures and spin-dependent phenomena of metallic materials on the atomic scale [7]. While superconductivity in chalcogenide materials such as $Fe_{1+y}Te_xSe_{1-x}$ has been extensively investigated by spin-averaging STM in the past few years [8,9,10], there are only a few results using SP-STM for these materials [11,12,13,14,15]. The DDS spin order in the parent compound $Fe_{1+y}Te$, emerging around the Néel temperature (T_N~65K) from the paramagnetic state [5,6,16,17,18], has been recently confirmed by SP-STM at low temperatures (T) [11,12,13,15]. In the regime of low excess Fe content y, T_N generally strongly increases with decreasing y [16], with reported maximum values of T_N of 72K [17,18], which is limited by the lowest achievable values of y=0.02 in conventional bulk crystal growth [19]. Here, the successful growth of well-defined one and two unit cell (UC) thin FeTe films of high stoichiometric quality on the topological insulator Bi_2Te_3 is demonstrated. The sample surface after the growth procedure probed by STM is displayed in Fig. 1 (a). The line profile in (b) plots the height information along the line in (a) and illustrates the corresponding sample composition. Since the investigated FeTe thin films do not exhibit any excess Fe, they are an ideal model system to study the pure stoichiometric composition of $Fe_{1+y}Te$ (y=0). On this system, we performed the first atomic-scale real-space observation of the evolution of spin order of the parent compound of a Fe-based superconductor with temperature. The spin order on the FeTe films persists up to temperatures which are higher than the transition temperature reported for bulk $Fe_{1+y}Te$ with lowest possible excess Fe content y. The STM images displayed in Fig. 2 (a,c,e,g) show the surface of one UC thin FeTe islands within the temperature range from 30K to 78K. The AFM DDS spin order is clearly visible in the STM images (a,c,e) as a bi-collinear surface modulation along the crystallographic axes a (red arrow) up to 73K. Further evidence gives the corresponding Fourier peaks associated with the DDS order marked in the fast Fourier transformations (FFTs) displayed in Fig. 2 (b,d,f). At 78K, in Fig. 2 (f), the atomic lattice is clearly visible, but the DDS order has vanished in accordance to the lack of Fourier spots in the corresponding FFT shown in (g). For two UC thin FeTe islands, the SP-STM investigation reveals the DDS order even up to 79K. The enhanced spin order stability is assigned to a strongly decreased y with respect to the lowest values achievable in bulk crystal growth, and effects due to the interface between the FeTe and the topological insulator substrate. The result is relevant for understanding the recent observation of a coexistence of superconducting correlations and spin-order at the interface of the two materials [14] and highlights the significance of magnetism and interfacial doping in the realm of unconventional superconductivity. This work is submitted for publication in a peer-reviewed journal and available as a preprint [20].

EP-08. The long-range exchange bias in ultrathin paramagnetic $LaNiO_3$-based heterostructure.

X. Xu[1], G. Zhou[1] and Z. Quan[1]
1. Shanxi Normal University, Linfen, China

With the rapid development of synthesis techniques, it has become possible to control transition metal oxide heterostructures by manipulating atomic flatness.[1] In the nickelate family, $LaNiO_3$ (LNO), is an exception since it exhibits metallic paramagnetic behavior over all temperatures.[2] Recently, the antiferromagnetic (AFM) state in ultrathin LNO layers has been theoretically predicted.[3] However, as far as we know, this has not yet been experimentally realized. The long-range exchange bias effect[4], where a non-magnetic material is inserted into ferromagnetic/AFM heterostructure, is a useful way to exclude the contribution of exchange bias by the interfacial coupling between Ni and Mn ions.[5,6] In this work, high quality LNO/STO(n)/LSMO superlattices are grown using a pulse laser deposition system. Both the exchange bias and coercive fields decrease monotonically with the spacer thickness. The role of antiferromagnetic behavior in the ultrathin LNO layer is essential for understanding the behavior of this exchange bias system. Hopefully, this work reveals new perspectives for simplifying the behavior of confusing systems. Fig. 1a shows the configuration of the investigated LNO/STO(n)/LSMO superlattices, which consists of a non-magnetic STO layer. The STO layer changed from 1 u.c. to 7 u.c. and inserted in every interface between the LNO and LSMO layers. Typical x-ray diffraction patterns measured with Cu-K_α radiation around the (002) STO Bragg peak of the investigated specimens are shown in Fig. 1b. Satellite peaks SL+1 and SL+2 are observed, indicating smooth interfaces in the LNO/STO/LSMO superlattices.[25] To support of the claims of coherent and epitaxial heterostructure growth and the absence of secondary phases, an atomically resolved high-angle annular dark field scanning transmission electron microscopy image of the LNO(2)/STO(2)/LSMO(5) superlattice is shown in Figure 1c. The good layering with atomically flat interfaces is readily identified from this image. Typical in-plane magnetic loops at 5 K in the LNO(2)/LSMO(5) superlattice after positive field cooling (FC) and negative field cooling processes are shown in Figure 2a. In this field-cooling magnetic loop, the exchange field and coercivity are 603 Oe and 1999 Oe, respectively.[8] In Figure 2b, the H_{EB} and H_C decrease to 230 Oe and 1181 Oe for the LNO(2)/STO(2)/LSMO(5), respectively. In Figure 2c, when the thickness of the inserted STO spacer layer is 6 u.c., the negative coercive field and positive coercive field values after the ±5 kOe FC procedures are consistent with each other. This indicates that the exchange bias effect is absent. The dependence of the exchange bias field and coercivity on the LNO/STO(n)/LSMO system STO spacer layer thickness is shown in Figure 2d. As the spacer layer thickness increases, the exchange bias field decreases monotonically and smoothly. At a maximum thickness of 6 u.c., the exchange coupling vanishes. According to these magnetic measurements, long-range exchange coupling can be confirmed in the LNO/STO(n)/LSMO system. The work was supported by National Key R&D Program of China (No. 2017YFB0405703), NSFC (Nos. 61434002, 51571136, 11274214), and the Special Funds of Sanjin Scholars Program.

Nanostructured materials consisting of metal and magnetic layers have been studied widely in order to obtain enhanced magneto-optical effects- a research activity known as magneto-plasmonics [1]. In this study, the magnetic properties of nano-dot arrays and thin films were investigated. The Ag (~ 30 nm)/Fe (~ 50 nm) bilayers were prepared on amorphous SiO_2 substrates by using a dual ion-beam sputtering deposition technique [2]. Ag/Fe nano-dot arrays (diameter ~ 200 nm, center-to-center distance ~ 400 nm) were fabricated by using electron beam lithography and followed by Ar-ion etching techniques [3]. Continuous Ag/Fe thin film exhibits a smooth surface with an average roughness of R_a ~ 0.9 nm, as measured by atomic force microscopy, and grain sizes ranged from ~ 10 to ~15 nm, as characterized by transmission electron microscopy. Grazing incidence x-ray diffraction identified that both Fe and Ag of the reference Ag/Fe bilayer were crystallized in their fcc phase (space group: F*m*-3*m*), and the lattice parameters are 4.16 and 4.31 Å for Ag and Fe, respectively. The reference Ag/Fe thin film exhibits soft magnetic properties with a coercivity (H_c) of ~ 20 Oe. By contrast, the Ag/Fe nano-dot arrays present half of that H_c at 300 K, with H_c (T) increasing with cooling (H_c~ 100 Oe at 2 K). In addition, asymmetric hysteresis loops observed at temperatures below 100 K signify different domain reversal modes and their associated energetics in positive and negative fields, in contrast to the reference film that presents symmetric hysteresis loops. The impact of magnetic coupling between dots (Fig. 1) is also observable from the difference in the temperature dependent DC susceptibilities of the reference film and the nano-dot arrays (e.g. $\Delta\chi_{FC-ZFC}$ (T > 50 K) = 0 for the film and $\Delta\chi_{FC-ZFC}$ (T > 50 K) ~ 10^{-5} emu for the nano-dot arrays). Numerical simulations analysis will be used to elucidate the nature and strength of different coupling energies. Research was supported by MOST of Taiwan and NSERC of Canada.

Magnetization reversal process of a Fe/GaAs/GaMnAs hybrid structure has been investigated by using planar Hall resistance (PHR) measurement. The transitions of magnetization in the Fe and GaMnAs layers are clearly observed as abrupt change in the PHR value during the magnetization reversal process. Interestingly, the hysteresis observed in the field scan PHR measurement with low sensing current of 0.5 mA at temperature of 3 K was asymmetric indicating presence of additional effective field. The asymmetry in the PHR hysteresis, however, becomes weaken as the current increases and it disappears at 3.36 mA of current. The asymmetry in the PHR hysteresis of the Fe/GaAs/GaMnAs structure was assigned to the exchange bias effect arising from the antiferromagnetic FeO, which forms on the surface of Fe layer by oxidation. The exchange bias effect of FeO on Fe film is known to be very sensitive to the temperature and it appears only very low temperature below 20 K.[1] The disappearance of asymmetry in the PHR hysteresis with increasing current is due to the Joule heating effect that increases the sample temperature up to 52 K at 3.36 mA.[2] The magnetization reversal process of the Fe/GaAs/GaMnAs hybrid structure was carefully analyzed by considering such exchange bias effect on the Fe layer.

The Center for Micromagnetics and Information Technologies (MINT) and Department of Electrical and Computer Engineering, University of Minnesota, 200 Union St SE, Minneapolis, Minnesota 55455, MN, United States

The phenomenon of exchange coupling has become major research area since its discovery [1] and was extensively studied in various ferrromagnet (FM) - antiferromagnet (AFM) systems in the presence of spintronics [2-4], which usually occurs in a FM/AFM bilayer [1-4]. A large exchange bias field (H_{ex}) at room temperature is preferred, but perpendicular magnetic anisotropy is found to be more desirable due to a high thermal stability for various spintronic devices. In our work [5], we report a giant perpendicular exchange bias H_{ex}^{per} exhibited in the *R-H* curves of an inverted $(Co/Pt)_n$/Co/IrMn multilayer and an inverted $(Co/Pt)_n/Co/Cu/(Co/Pt)_4$/Co /IrMn spin valve structure, in which the Pt layers are only 1/4 nm in thickness and less than Co layers. H_{ex}^{per} has an unusual linear scaling with the repetition n+1 of the $(Co/Pt)_n$/Co free layer, with its maximum value near the order of 1000 Oe for n+1 = 9. The in-plane exchange bias H_{ex}^{in} is almost constant. The origin of exchange bias in inverted spin valve structure is due to Co/IrMn interfacial magnetic coupling in inverted $(Co/ Pt)_4$/Co/IrMn reference layer, which is magnified by the exchange coupling between the interface Co layer and the multilayer $(Co/ Pt)_n$ (n = 4 for the spin valve structures) in the reference stack. As shown Figure 1, giant conventional and pseudo H_{ex}^{per} in the perpendicular inverted $(Co/Pt)_n$/Co spin valves enhances their roles in perpendicular spintronic devices.

Exchange bias has long been the focus of scientific attention due to its tremendous applications in various spintronics devices although underlying physics of the misalignment anisotropies and dynamic magnetization relaxation still remain unclear.[1] Herein, we investigate the exchange bias field, noncollinear magnetic anisotropies and unidirectional damping in a series of $[Fe_{70}Co_{30}/(Ir_{25}Mn_{75})_{1-x}(MgO)_x]_3$ multilayer exchange bias system with nonmagnetic MgO-dilution in the antiferromagnetic. Fig. 1(a)-(g) shows the in-plane angular dependent resonance field in diluted-AFM $[Fe_{70}Co_{30}/(Ir_{25}Mn_{75})_{1-x}(MgO)_x]_3$ (x £ 0.09) exchange bias multilayers by using the following expression:[2] $H_{res}= H_0-H_{eb}\cos(\phi_H)-H_k\cos2(\phi_H-\beta)$ where H_0 is the angular-independent, isotropic term. H_{res}, H_{eb}, and H_k denote the resonance, exchange-bias, and in-plane uniaxial anisotropy fields, respectively. ϕ_H, β is respectively the azimuthal angle of the external magnetic field applied in the film plane and misalignment angle between unidirectional anisotropy and the uniaxial anisotropy. We plot the doping concentration dependence x of fitted misalignment angle β in Fig. 1(h). β first decreases at small doping concentration (x<0.019) from 5° to 1° then increases up to 15° at high doping concentration (x=0.09). And the fitted exchange bias field H_{eb} is shown in Fig.2 (a). H_{eb} first increases from 185 Oe to 300 Oe at low doping concentration (x<0.019) then decreases to 80 Oe at high doping concentration. The enhancement of H_{eb} has been successfully interpreted by the domain state theory.[3] It is favored by the doping of nonmagnetic impurities and gives rise to the increase of excess magnetization, thereby increases the H_{eb}. For the higher dilution concentrations, the AFM bonds will be broken by the excess impurities. It leads to the connectivity loss of the AFM spin lattice and thus the decrease of H_{eb}. Hence, the H_{eb} of an exchange bias system with diluted AFM layers is determined by the competition between the dilution induced additional net magnetization and the decrease of connectivities in the AFM lattice. We notice that the misalignment angle β shows exactly opposite variation trend to that of H_{eb}, suggesting the noncollinear magnetic anisotropy in the diluted-AFM exchange bias multilayers may be related to the dilution in the AFM layers. Small nonmagnetic dilution will be in favor of the formation of volume domain wall. The driving force for the domain formation is a statistical imbalance of the number of impurities of the two antiferromagnetic sublattices within the dilution region. The imbalance leads to a net magnetization within that region which couples to the external field. During the spin reversal of the region, a domain wall will be created to lower the energy of the system. The necessary energy increase due to the formation of a domain wall can be minimized if the domain wall passes preferentially through nonmagnetic defects at a minimum cost of exchange energy. The domain wall may increase the AFM anisotropy thus β decreases. For larger dilution, it leads to the connectivity loss of the AFM spin lattice and isolated spin clusters appears which do not contribute to AFM anisotropy on longer-time scales leading to a increase of β. In Fig. 2(b), we show the in-plane angular dependence of effective Gilbert damping α for all samples. A cosine dependence of on the in-plane angle was observed, indicating that the dissipation rate depends upon the projection of the magnetization along the bias field. Our study reveals a misalignment of unidirectional and uniaxial anisotropy in the exchange bias system, and the misalignment angle β can be quantified by in-plane angular dependent FMR measurements. We are able to show that misalignment angle can be effectively tuned by the dilution concentration, which is in part caused by the change of AF anisotropy caused by dilution. Also, a very strong unidirectional magnetization relaxation in this system has been observed. The result is beneficial for the understanding of the dilution effect and EB mechanism, and it will contribute to the realization of high-speed spintronics devices with low-energy consumptions.

R. China [f] Department of Micro-nano Fabrication Technology, Institute of Electrical Engineering, Chinese Academy of Sciences, Beijing 100190, P.R. China Perovskite transition-metal oxide $LaMnO_3$ has been studied extensively due to its interesting physical properties. Bulk $LaMnO_3$ is an A-type antiferromagnetic insulator and is typically found to be ferromagnetic and semiconducting from various doping. Besides, even without extrinsic doping, $LaMnO_3$ itself has very rich phases induced by its nonstoichiometry [1]. For example, as-grown $LaMnO_3$ films usually exhibit ferromagnetism rather than antiferromagnetism, because the cation vacancies derived from oxygen nonstoichiometry lead to a mixed valence state for Mn ions. Ferromagnetic double-exchange and antiferromagnetic super-exchange interaction compete in the as-grown $LaMnO_3$ films. The exchange bias (EB) effect is observed in systems exhibiting the exchange interaction at the interface between a ferromagnetic material and an antiferromagnet, ferrimagnet, or a spin glass [2, 3, 4]. It has been widely used in spintronic devices, such as giant magneto resistance (GMR) read heads and magnetic random access memory (MRAM) [2, 5]. The EB effect was mostly found in the heterogeneous interface between two separately materials [6]. However, the electronic phase separation (PS) in mixed-valence manganites, namely the coexistence of FM metal and AFM insulator, provides a unique opportunity to construct a "homo-interface" in a chemically uniform material, which may exhibit exchange bias effect and metal-insulator transition [7]. In this paper, we reported the exchange bias effect in the $LaMnO_3$ film by using electron beam irradiation technology, which can provide not only thermal effect but also reduction characteristics to control the Mn valance state. $LaMnO_3$ films (13 nm) were first fabricated on $SrTiO_3$ (001) substrates by pulsed laser deposition technique (PLD), and the as-grown films were treated by electron beam irradiation process (the EBI films). The X-ray diffraction (Figure 1(a)) shows that the as-grown $LaMnO_3$ films and the EBI films all present only the (00*l*) peaks, confirming that all samples were grown epitaxially oriented with respect to the substrate. Figure 1(b) indicates that the EBI film shows a pronounced peak with an increased *c*-axis lattice constant which can be explained by the valence state of the Mn ions. The dominant mechanism for ferromagnetism in as-grown $LaMnO_3$ films is the ferromagnetic double-exchange interaction induced by the mixed valence of Mn^{3+}-Mn^{4+}. After electron beam irradiation process, Mn^{4+} transformed into Mn^{3+} partly owing to reduction characteristics, which corresponds to the increase of *c*-axis lattice constant. Fig 2(a) shows the magnetic moments as the function of temperature, and figure 2(b) exhibits magnetization versus applied magnetic field at 10 K. The Curie temperature (T_C) of the EBI films is lower than the Curie temperature of the as-grown films, and the magnetic moments also decrease in lower temperature. In particular, figure 2(b) shows that the EBI film exhibits unexpected exchange bias in 10 K. As the amount of the Mn^{3+} ions in EBI films increases, the antiferromagnetic super-exchange interaction becomes stronger and meanwhile the ferromagnetic double-exchange interaction is weakened. Therefore, the Curie temperature (T_C) and the magnetic moments all decrease in EBI films. Besides, with the amount of the Mn^{3+} ions in EBI films increasing, the exchange coupling between the ferromagnetic phases and the antiferromagnetic phases enhanced, which induce the exchange bias in EBI films. This explanation also corresponds to the XRD results.

The exchange bias effect is investigated in CoFeB / MnIr multilayers system with perpendicular magnetic anisotropy. An interlayer of Pt (0.5nm) between CoFeB and MnIr layer enhanced both the perpendicular anisotropy and the exchange bias. Both the exchange bias and the coercivity field depend on the thickness of the MnIr layer, the largest exchange bias field of 201.7 Oe was obtained in a 5nm MnIr thickness samples which had been annealed at 573 K in external magnetic field. The exchange bias becomes weaker when the thickness of the Cu or Pd underlayer increases in [Pd / CoFeB]$_4$ / MnIr multilayer system. The Gilbert damping constant obtained from the Kerr effect (TR-MOKE) measurement increases as the thickness of Cu or Pd underlayer increases. However, in the pump-probe measurement, the exchange bias fields decreased before the Kerr signal starts change and restored when the change of the Kerr signal reaches its maxima, the total time of this process is about 1 ps. The loss of the exchange bias is probably attributed to the electron temperature. The relation between the exchange bias and the Gilbert damping constant is detail discussed.

The interfacial coupling between ferromagnetic and antiferromagnetic thin films displays noticeable features such as an enhancement of the coercivity and an offset of the magnetic hysteresis loop from zero, known as exchange bias field (H_{EB}). Since its discovery [1], the phenomenon of exchange bias has been studied thoroughly, although a complete connection between the static and dynamic properties of exchange-biased systems is still lacking [2]. In this study, a series of [NiFe/FeMn] bilayer films with varying thicknesses (t_{AF}) of the antiferromagnetic layers (3 nm ≤ t_{AF}≤ 15 nm) and constant thickness of the ferromagnet (50 nm) were deposited on silicon (100) substrates through magnetron sputtering. The exchange bias properties in these samples were evaluated through angular-dependent ferromagnetic resonance (FMR) measurements conducted at room temperature in the plane of the sample. The saturation fields were determined through the major hysteresis loop. It has been shown that the switching peaks obtained through reversible susceptibility measurements performed for different orientations of the applied magnetic field can be used to construct a critical curve [3]. In this work, the high frequency properties of the material were studied in a way reminiscent of this static critical curve, as has been done for other systems [4]. The microwave absorption of the exchange bias systems was investigated through vector network analyzer ferromagnetic resonance (VNA-FMR) spectroscopy. The sample was coupled to the signal line of a coplanar waveguide, which was connected to the VNA. The dc magnetic field was created in the plane of the sample by an electromagnet on a rotation stage capable of 360° rotation. For a fixed frequency, the S_{21} transmission coefficient was recorded as a function of applied field for different orientations of the applied field with respect to exchange bias axis to construct a dynamic critical curve for different frequencies. This therefore gives a fingerprint of the high frequencies properties of the sample. Analogous to the static critical curve, H_{EB} can be determined from the opposite branches of a single dynamic critical curve. Noncolinear anisotropy axes were observed for t_{AF} ≥ 6 nm. The magnitude and direction of exchange anisotropy can be determined using this dynamic critical curve. Our results show a reasonable agreement between the value of H_{EB} obtained through static measurements as well as other FMR studies for these samples including broadband and X-band measurements.

I. INTRODUCTION The extraordinary optical transmission (EOT) of light through nanostructured metallic films with sub-wavelength metallic grating has got a lot of researchers attention attracted who work in the areas of nanooptics and plasmonic applications[1] Many research shows that the EOT phenomenon of the metal sub-wavelength slit array is mainly due to the resonance coupling of the incident wave with the SPPs excited by the free electron oscillation of the metal surface. SPPs was found to be responsible for enhanced transmission[2,3]. At the same time, it was found that the EOT phenomenon is also affected by LSP resonance within the metal slit[4]. Both of which play an important role in the generation of EOT phenomena, but only when the two energy is similar, it is most conducive to enhanced transmission[5]. In addition, the study also found that the spectrum of the EOT caused by the main role of LSP is narrow and its application is limited[6]. Therefore, it is significant to study the broadband enhanced optical transmission caused by non-LSP. In 2011, G.Subramania et al. Designed a rectangular array of connected holes, and found that the structure can achieve a non-resonant wide band enhanced transmission[7]; then in 2012, Shen HH and others use the transmission line theory to design a wedge-shaped slit grating structure from the entrance to the exit port, whose the characteristic impedance is gradually changed. The resonant condition of the FP cavity is destroyed, and the enhanced transmission of the non - resonant wide band is realized[8]. In 2013, Qin Yan designed the embedded rectangular cavity wedge-shaped metal slit array, which further promoted the enhanced projection of the metal sub-wavelength slit[9]. In 2016, Xiao Gongli et al proposed an array of symmetrical rectangular cavity wedge-shaped metal slit array. Dimensional structure is extended to three-dimensional structure, on the basis of improving the transmittance, while achieving a short wavelength range transmission band gap and long wavelength range of transmittance[10]. However, the study found that, in some cases, the wedge-shaped slit has a better transmission than the straight slit, so there was less research on the study of the straight-slit EOT phenomenon of the embedded mirror symmetric rectangular cavity. So we present a novel periodic sub-wavelength metallic grating on the silica substrate. This is compound structure of the rectangular metallic slit embedded with mirror symmetric rectangular cavity, as shown in figure 1a, and with finite difference time domain (FDTD) method simulation. The effects of length, width and position of embedded rectangular cavities on transmission property of metallic slits array were studied. The result shown that the grating not only can achieve higher transmission efficiency, but also the band gap can be adjusted through change the geometric parameter of the structure. Meanwhile it has enhanced optical transmission in long-wavelength range and showing double peaks, the transmission efficiency can reach even over 99%. We find that the transmission properties of the proposed grating strongly depend on the geometric parameters including the period. The transmission spectra can be manipulated by tuning the parameters of the structure. II. Modeling and Simulation The structure was characterized by the thickness h, the period P, the slit width W, the rectangular cavity width a, the rectangular cavity depth b, the distance between two rectangular cavities d, and the rectangular wall thickness c. the thickness of silica substrate was 100nm. The metal film material was silver, Both electrolytes in Metal slits and rectangular cavities are air, the perfectly matched layers (PML) boundary condition was used in the Z direction, and the period boundary condition was used in the X direction and Y direction. The light source was set to a plane wave placed on the upper surface of the silver film at 200 nm incident normally onto the metallic slit array from the air side. As shown in fig 2d, we can clearly observed that enhanced optical transmission in long-wavelength range and showing double peaks, the transmission efficiency can reach even over 99% at l=. Furthermore, the full width at half maximum (FWHM,T>50%) is over. To understand the physical mechanism of the optical properties observed above, the normalized electric field intensity distributions in the yoz plane at corresponding peak and trough wavelength as shown in fig 2 a b and c.

NiCuZn ferrites have important application in the microwave magnetic devices. The energy cost, reliability and working range of these devices mainly depends on the ferromagnetic resonance (FMR) linewidth (ΔH) of ferrite materials [1]. Therefore, the study about the contribution of FMR linewidth of NiCuZn ferrites is significant and meaningful. The polycrystalline ferrites $Ni_{0.5-x}Cu_{0.12}Zn_{0.4}Co_xFe_{1.98}O_4$-δ with different cobalt-substituted contents (x=0.000~0.015) have been synthetized via the solid-state reaction method. All samples exhibit single phase of cubic spinel structure. The lattice parameter (a) increases while the amount of cobalt substitution increases. The main reason for this phenomenon is that Co^{2+} ions intend to occupy the position of Ni^{2+} ions on the octahedral site (B sublattice) and Co^{2+} ion (0.78 Å) has a larger radius than Ni^{2+} ion (0.74 Å) [2]. As the amount of cobalt substitution increases, both grain size and porosity rise. Meanwhile, remanence ratio (B_r/B_s) increases and the saturation magnetization (M_s) has little change. The ΔH of polycrystalline ferrites is the sum of three parts [3]: (1) the anisotropy linewidth broadening (ΔH_a), (2) the porosity linewidth broadening (ΔH_p) and (3) the intrinsic linewidth broadening (ΔH_i). However, ΔH_i can be ignored in polycrystalline ferrites owing to their less value that is smaller than 1 kA/m. Meanwhile, ΔH_a and ΔH_p are attributed to magnetocrystalline anisotropy constant (K_1) and porosity, respectively. Based on the law of approach to saturation, the magnetocrystalline anisotropy constant (K_1) of samples have been calculated and the results are shown in Fig. 1, the sign change of K_1 was caused by positive K_1 value of Co^{2+} ions. The addition of cobalt compensates the negative K_1 value of NiCuZn ferrites. While the amount of cobalt substitution is 0.003, the K_1 represents the minimum absolute value of 1.77kJ/m^3. With the previous data of K_1 and porosity, an approximate calculation for the separation of ΔH has been done by adopting dipolar narrowing theory [4]. As shown by the calculated results (see in Fig. 2), the porosity linewidth broadening contribution (ΔH_p) is larger than the anisotropy linewidth broadening (ΔH_a). Thus, the uniform and dense microstructure is effective to reduce the ferromagnetic resonance linewidth. Far more important is that proper amount of cobalt substitution can reduce the value of anisotropy linewidth broadening.

Magnetic ultrafine particles-insulator composite films including Fe-Ni ultrafine particles and insulating epoxy films used for electromagnetic wave absorbing films were synthesized by a newly developed electrochemical method termed the “LbL assisted composite plating method”. The reaction solution containing 40 ml / L water-solve epoxy resin prepared by NIPPON PAINT Co., LTD and 0-3 g / L Fe-Ni ultrafine particles 60 nm in diameter manufactured by the Nilaco corporation were used for film fabrication. Cu substrates and Ti / Pt plates were used as the cathode and anode, respectively. Epoxy films were deposited by the following schemes: $O_2 + 2H_2O + 4e^- \rightarrow 4OH^-$ $(Resin)_3NH^+ + OH^- \rightarrow (Resin)_3N + H_2O$ In LbL assisted composite plating, charged Fe-Ni ultrafine particles are attracted to the cathode by electrostatic force simultaneously with insulator epoxy film electrodeposition. LbL treatment was performed using 1 wt.% PSS (Poly (sodium 4-styrenesulfonate)) and 0.5 mM NaCl solution, and 1 wt.% PDDA (poly (diallyl dimethyl ammonium chloride)) and 0.5 mM NaCl solution. Fe-Ni ultrafine particles were alternately immersed in PSS solution and PDDA solution. In water Fe-Ni ultrafine particles before LbL treatment have 20 mV zeta potential. After immersion in PSS solution, Fe-Ni ultrafine particles have -40 mV zeta potential, and after immersion in PDDA solution, Fe-Ni zeta potential increases to 60 mV. This increase of zeta potential means that the amount of charged electrons on the ultrafine particles surface were increased through a layer by layer structure of cationic and anionic polyelectrolytes formed on the particles. The Fe-Ni ultrafine particles not treated with LbL precipitated in the reaction solution within 30 minutes, while the particles subjected to the LbL treatment were stable in the reaction solution over 16 days. Figure 1 shows the particle size distribution of Fe-Ni ultrafine particles with LbL treatment and without LbL treatment in water. The peak diameters of the distribution curves with LbL treatment and without LbL treatment were 35 nm and 52 nm, respectively. LbL treatment using PSS and PDDA were effective for increasing the charging electrons on Fe-Ni ultrafine particles and for enhancing the dispersibility of ultrafine particles in the reaction solution. At electrophoresis of only Fe-Ni ultrafine particles without epoxy film on Cu substrate, the 4.3-fold increase in the mass of deposited particles with LbL treatment was observed compared with no LbL treatment, as a result of the increase of charging electrons on Fe-Ni particles. Electrodeposition of Fe-Ni ultrafine particle-epoxy composite films was conducted under a constant current density of 4 mA / cm^2, and 5-minute deposition time using the LbL assisted composite plating method. The film thickness was measured from the cross-section SEM image of the films. The film thickness of the deposited film prepared from the reaction solution containing 3 g / L Fe-Ni fine particles without LbL treatment is about 30μm, whereas that prepared from the reaction solution containing 3 g / L Fe-Ni particles with LbL treatment is about 80 μm. From the EDX mapping image of the film prepared using Fe-Ni particles without LbL treatment, the agglomerates of Fe-Ni particles were observed. On the other hand, there are no agglomerates in the film prepared using Fe-Ni particles with LbL treatment. These aggregates of Fe-Ni particles not treated with LbL were generated due to less electron charging on the particle surface than particles having LbL treatment, and act as the growth inhibiter of the epoxy film. Therefore, the film thickness of the films prepared using Fe-Ni particles not treated with LbL was less than that of the film prepared using Fe-Ni particles having LbL treatment. Figure 2 shows the Fe-Ni content in the films dependence on the concentration of Fe-Ni ultrafine particles in the reaction solution. The Fe-Ni content in the films increased in proportion to the Fe-Ni concentration in the reaction solution. Using LbL treatment, the Fe-Ni content in the films increased 1.6 times compared to that without LbL treatment. Over 22 vol. % Fe-Ni ultrafine particles included in epoxy films were successfully obtained using LbL assisted composite plating from the 3 g / L Fe-Ni content reaction solution. The experimental results clearly show the dispersibility in the reaction solution could be greatly improved using LbL treatment for Fe-Ni ultrafine particles, and Fe-Ni ultrafine particles uniformly dispersed in epoxy film could be fabricated using our newly developed electrochemical method.

I.Introduction Modeling the rotational magnetic hysteresis phenomenon based on the physical mechanism is particularly challenging for magnetic research [1, 2]. Among various approaches proposed, a typical one is the Stoner-Wohlfarth (S-W) model, which has been investigated for many decades primarily due to its strong appeal to physical intuition and vectorial nature. The S-W model assumes that a magnetic material is composed of a great number of single-domain particles with uniaxial crystal anisotropy. This assumption, however, is inconsistent with the phenomena in cubic textured magnetic materials which have biaxial anisotropy in each crystal plane. Also, the numerical implementation is very inconvenient for its incorporation in magnetic field analysis software packages. Many improvements and extensions have been presented based on the conventional S-W model. The asteroid rule was introduced to directly determine the orientation of magnetization based on the graphical interpretation. However, these phenomena-based methods are lack of physical background and difficult to directly apply in the practical engineering calculation. In this paper, in the framework of biaxial operator and wind-rose method, the magnetic properties of a soft magnetic composite under rotational magnetization are predicted and compared with the experimental results. II.Model Description Most magnetic materials are polycrystalline, composed of microscopic crystalline grains. In the ferromagnetic material, such as iron, each crystal lattice has multi-easy-axes and multi-hard-axes [3]. In this paper, magnetization process in the (100) plane, which has two easy axes, is studied. Similar to the determination method of S-W particle, the stable orientation of the magnetization vector in the crystal structure can be obtained by minimizing the energy of the elemental operator. Thus the wind-rose curve, which with two orthogonal easy axes and two orthogonal hard axes and separates the regions with different energy minimum, can be determined. With this wind–rose curve, graphical interpretation can be given for the magnetization process of this biaxial elemental operator. In this H_x-H_y plane, four regions can be separated by the wind–rose curve, and different region corresponding to different number of the energy minima exists, as shown in Fig.1 [4]. The determination of the actual energy minimum is related to the magnetization history. When the magnetic field applies inside the wind–rose shape, with the increase of magnetic field, four, three and two energy minima may exist corresponding to different magnetic field magnitudes. When the magnetic field applies outside the wind–rose curve, the magnetization only has one stable orientation as there is only one energy minimum. When the loci of the rotational magnetic field is outside the wind-rose curve, the magnetization rotates with the magnetic field. The magnetic field and the magnetization cross simultaneously the easy axes and the hard axes, but elsewhere the magnetization is shifted more or less forward or backward depending on the orientation of magnetic field. III.Numerical Implementation To simulate the magnetic properties of different materials by this model, the different distribution functions and parameters are needed. Each magnetic material has an optimal distribution function and parameters, which deliver the best results. This model utilizes the concept of distribution function density in order to consider the interaction field and the coercive force of each elemental operator, which is similar to the method in the traditional Preisach model. The implementation of the Preisach model can be used for reference. In the Preisach model, the distribution can be produced by combing some well-known continuous statistical distributions, such as Gaussian-Cauchy distribution, Gaussian-Lognormal distribution, Cauchy-Lognormal distribution [5]. IV. Experimental Verification To verify the proposed model, the magnetic hysteresis of a soft magnetic composite material, SOMALOY 500, under rotational excitations has been simulated and compared with the experimental results. In the measurement process, the magnetic materials always be controlled to work under the circularly rotational flux B, hence, to verify the introduced method, the corresponding magnetic field should be predicted and measured, respectively [6]. Fig.2 shows the comparison of a series of B and H loci while the magnetic flux densities with magnitudes of 0.3, 0.6, 0.9, 1.2, 1.5 T at 50Hz. As shown, the simulated results agree well with the experiment results in both major and minor rotational hysteresis loops under different rotational magnetization. V.Conclusion In this paper, the rotational magnetic properties have been presented based on the elemental operator and wind-rose method. By adopting the concept of distribution function in Preisach model, the effects of the elemental operators can be integrated to simulate the magnetic hysteresis phenomenon. It has shown that this method features strong physical background, easy software implementation, and acceptable precision.

1. Background- Recently, magnetoelectric (ME) gallium ferrite ($GaFeO_3$, denoted as GFO), which exhibits ferrimagnetism and piezoelectricity, has gained a considerable attention from the scientific community in the context of multiferroics [1,2]. Site-disorder in GFO is reported to be induced by adopting different preparation conditions and methods, such as quenching, ball milling, and chemical routes, which are shown to affect the magnetic properties significantly [3,4]. In addition, all the metal cations in GFO are trivalent, similar to those of rare earth orthoferrites which enhance their magnetic property for isovalent substitution. Acharya et al. [5] reported that magnetization of $LaFeO_3$ was highly enhanced by doping with Al^{3+} ions. Furthermore, the doping of Al^{3+} ions in GFO will be isovalent substitution because of which there will be no charge imbalance. In this work, therefore, we prepare a series of $Ga_{1-x}Al_xFeO_3$ (GAFOx, $0 \le x \le 0.5$) nanoparticles by a modified Pechini method to systematically study the effect of Al doping on their structural, magnetic, and magnetodielectric (MD) properties. In particular, the simultaneous enhancement of magnetization, magnetic transition temperature, and MD effect of the Al-doped GFO samples will be quite interesting for applications in electronic and memory devices. *2. Experimental Methods*- The $Ga_{1-x}Al_xFeO_3$ (GAFOx, $0 \le x \le 0.5$) nanoparticles were synthesized through a modified Pechini method using nitrates as starting materials. First, stoichiometric amounts of gallium nitrate, iron nitrate, and aluminum nitrate were dissolved in distilled water. And then, citric acid ($C_6H_8O_7$) in a 1:1 molar ratio, with respect to the metal nitrates, was added to the solution as a complexant. The mixture was dried 120 ^oC to form a gel, and then the obtained gel was burned until the combustion process was completed. Finally, the precursory powders were reground and sintered at 800 ^oC for 2 h. The crystalline structure and the phase purity of the samples were examined with a typical x-ray diffraction (XRD) system of Cu K_a radiation. The temperature- and field-dependent magnetizations were measured with a Quantum Design superconducting quantum interference device (SQUID) magnetometer. For the magnetodielectric measurements, the powders were pressed into the disk (5 mm in diameter and 1 mm in thickness) under a pressure of 1.5 GPa and then coated with 100 nm thick silver layers on both the top and the bottom sides of the disk as electrodes. A capacitance bridge (Agilent E4980A Precision LCR meter) hooked to a probe station was used. The dielectric constant of the samples was measured in absence and presence of magnetic field at RT. *3. Results*- Based on the standard reference, all the observed XRD patterns of the GAFOx nanoparticles can be indexed on the basis of an orthorhombic unit cell of space group, $Pc2_1n$, suggesting that all samples are pure phases without any impurity. The mean particles sizes of the GAFOx nanoparticles are around 28 nm. The fact that the value of lattice parameters *a*, *b*, and *c* of GAFOx nanoparticles decrease systematically with increasing Al-context (x) implies that the Al-ions do replace the Ga-ions. The magnetic characterization indicates that with increasing Al-content, up to 0.5, the ferrimagnetic transition temperature (T_C) increases from 310 to 350 K, as shown in the Fig.1. The magnetic hysteresis curves measured below T_C exhibit two-phase-like magnetic behavior consisting of soft and hard magnetic phases. The results could be explained by the site-disorder of the cations in GAFOx. In addition, the magnetization has been enhanced due to doping of Al^{3+} in GFO compared to that of the pristine sample. The cause of magnetic enhancement could be explained from the modification exchange interaction due to the substitution of smaller size cations of Al^{3+} in place of relatively larger size cations of Ga^{3+}. In GFO, Fe^{3+}-ions have a distorted octahedral local environment and the distortion is manifested as a tilting of the octahedron from the direction of the *c*-axis. Actually, this distortion arises due to the change in the bond length and bond angle introduced in the change in cation distribution of different cations among different crystallography sites. Owing to site-disorder, an anti-symmetric exchange interaction acts between Fe^{3+} pairs, and this would lead to a spin-canted magnetism with enhancement of magnetization in Al-doped GFO samples. The change in dielectric constant with the applied magnetic field is one of the important ways to study the ME coupling effect. In each GAFOx sample, the dielectric constant is strongly perturbed by the external magnetic field. It is to be noted that the value of MD increases in the doped samples for different applied magnetic fields. The values of MD for GAFOx samples are higher than that observed for bulk GFO. Furthermore, the simultaneous enhancement of magnetization and MD coupling effect in Al-doped samples are prominent candidates for the applications of RT multiferroic devices.

Abstract—This paper not only reveals the influence of coupled temperature and pressure on the magnetic properties of electrical steel sheets, but also analyzes the influence of the pressure direction perpendicular or parallel to the magnetic field lines on the measurement results. 1. Introduction Almost all motor designs need to be validated by using the finite element method (FEM), especially for motors operating in high temperature and pressure environments. However, if the analysis uses the magnetic properties of the electrical steel sheets measured under the normal environment (0.1MPa and 30K) [1, 2] or only a single environmental variable (temperature or pressure), there will be a significant difference between the results obtained by the finite element analysis software and the experimental results. The main reason for the difference is that the magnetic properties of electrical steel sheets are different under different environments. However, most of literatures only analyze the effect of temperature or stress on the magnetic properties. Therefore, in order to design a motor that can operate in high temperature and high pressure environment for a long time, it is necessary to know the magnetic characteristics of electrical steel sheets used. In this paper, the magnetic properties of electrical steel sheets under different temperatures and pressures are determined by ring specimen [2, 3] and laminated specimen [4]. The changes of magnetic properties with the changes of temperature and pressure were discussed in detail. By comparing the measurement results of the two specimens, the change of the magnetic properties under the Cartesian coordinate system when the pressure is perpendicular or parallel to the magnetic field lines is analyzed. There are only vertical cases in the ring specimen, while the lamination specimen contains the vertical and the parallel cases. 2. Measurement specimens Fig.1 shows two measurement specimens for measuring the magnetic properties of electrical steel sheets under high temperature and high pressure, and the specimens are cut from the same product lot number. The measured magnetic properties are different when compressive stresses are applied to the specimen in the rolling and transverse directions, respectively. However, when the stress is greater than -50 MPa, the difference in magnetic characteristics measured in these two directions will become smaller [4]. Therefore, in order to reduce the difference in the magnetic measurement due to the rolling direction and the transverse direction, when the ring specimen and the laminated specimen are stacked and glued, the rolling direction and the transverse direction specimen are alternately placed. 3. Measurement results and discussion The variation of the measurement results is consistent with the reported data measured under the influence of the finite axial stress. This result shows that the effect of pressure (equivalent to infinite axial stress) on magnetic properties under normal conditions is similar to the effect of finite axial stress. By comparing the measurement results of the two specimens, the effect of the relationship between the pressure direction and the magnetic field direction on the magnetic properties can be found, as shown in Fig.2. In the Cartesian coordinate system, the direction of the pressure perpendicular to the magnetic field has a greater effect on the magnetic properties than both the vertical and the parallel ones. This indicates that the direction of the pressure perpendicular magnetic field makes the magnetic properties of the electrical steel sheet deteriorate more than the parallel existence. However, when the direction of pressure is perpendicular to the direction of the magnetic field, the effect of different pressures on the magnetic properties is small, especially on the core loss. 4. Error analysis In addition to accidental factors, there are two main factors that lead to errors. The main factor is determining the cross-section ofcoil. Another factor is that whencoil is wound, a certain amount of mechanical stress may appear in the specimens, which may have an impact on the measurement results. 5. Conclusion The magnetic properties of the electrical steel sheets (DW460-50) were measured at different temperatures and pressures using a ring specimen and a laminated specimen. By comparing the measurement results of the ring specimen and the laminated specimen, the influence of the relationship between the pressure direction and the magnetic field line on the magnetic properties can be analyzed. In contrast to the lamination specimen, the ring specimen under high pressure has larger iron loss and smaller relative permeability. In the Cartesian coordinate system, the pressure exerted by the ring pattern is always perpendicular to the magnetic field lines, whereas in the laminated specimen, some of the pressure is parallel to the magnetic field lines. This shows that the magnetic properties of the electrical steel sheet under high pressure are indeed affected by the relationship between the pressure direction and the magnetic field lines. When the direction of pressure perpendicular to the magnetic field lines, the greater the impact of pressure, resulting in increased magnetic deterioration. However, different pressure values have less effect on magnetic properties.

EQ-06. Influence of In-plane Stress on 1D Magnetic Property of Silicon Steel.

J. Chen[1], D. Wang[1], Y. Jiang[1], X. Teng[1] and X. Zhang[1]
1. Naval University of Engineering, Wuhan, China

1 Introduction Silicon steel(FeSi) is the core material for conducting magnetic field in magnetic device such as electrical motors and transformers, which can be classified into grain-oriented(GO) and non-oriented steel(NGO). Due to shrink fitting or some incorrect installation, the influence of the compressive and tensile stresses on the magnetization exists more or less in electrical motors and transformers[1-2]. Recently, there are research articles about the measured stress dependent magnetic property[3-12], but physical mechanism of stress effect is seldom reported. This paper aims to quantify the stress effect on each of loss components of silicon steel, which is helpful for proposing a stress-dependent iron loss model based on loss separation theory. 2 Magnetic measurement In order to measure magnetic properties of FeSi steel sheet under in-plane tensile and compressive stress, a special single sheet tester was designed, shown in Fig. 1. The specimen used is the strip of 300mm(L)×30mm(W), whose middle region is chosen as the effective zone, where B coil is wound to inspect the induced EMF signal. Considering the magnetic potential drop is small enough in the compared with specimen, magnetic field strength of specimen is obtained based on Ampere's law. The mechanical part of the system allows both compressive and tensile stress up to 150 MPa. The key point of this design is to make sure that applied stress evenly distribute over the sheet specimen. Although collets may not apply ideal uniform force along width of specimen. Saint-Venant's principle points out that for a system of forces statically equivalent to zero force and zero couple, strains are of negligible magnitude at distances which are large compared with linear dimension of the part[13]. Fig. 2(a) shows the ideal case, that stress is evenly distributed along the length of specimen if both collets apply ideal uniform pull. Fig. 2(b) and (c) show two non-ideal cases of collets applying concentration pull, except the area close to the collets, stress distribution in other parts of specimen are always uniform, not influenced by end effect caused by collets. Based on facts above, designed test platform is effective and can be used to investigate stress effect on magnetic property of silicon steel. 3 AC Magnetic Measurement Result Fig. 3 shows the effect of stress on measured hysteresis loop at 50Hz from 0.1T to 1.7T, with the step of 0.1T. The tensile and compressive loading varies from -30 to 150MPa. It is obvious that elastic deformation affects the shape of the hysteresis loops and such magnetic properties index as coercivity, remanence, and permeability. Compared with hysteresis loop of unloaded specimen, shape of loop with compressive stress changed tremendously, even becoming S-shaped in first quadrant of B-H plane. It is obvious that at typical rated working point of 1.7T nearby, the in-plane stress influences GO steel more than NGO. While both the NGO and GO silicon steel is more influenced by compressive stress, which indicates that compressive stress is harmful and should be get rid of during the duty period of electromagnetic devices. From Fig. 3(a), the greater the compressive stress is applied on GO steel, the worse magnetization property it turns out to be, while tensile stress even advances the permeability, a 50MPa tensile stress can achieve a better permeability than 100MPa and 150MPa, which needs an in-depth study. From Fig. 3(b), unlike GO steel, tensile stress doesn't advance permeability of NGO steel, which indicates a different physical mechanism from GO steel. It is interesting that iron loss varies little when tensile stress increases from 50MPa to 150MPa, which indicates that tensile stress effect on GO steel exists a limit. 4 Stress-dependent iron loss separation According to loss separation principle, iron loss can be divided into static and dynamic loss. Static loss is known as hysteretic loss, which is related to energy consumed when domain wall moves and rotates. Dynamic loss is composed of classic eddy current loss and excess loss[14]. To find out root cause of iron loss's variation with in-plane stress, we have studied its effect on each of loss components, respectively. Ballistic method is adopted to measure the static hysteresis loop and loss with no eddy current involved. Fig. 5 shows the DC static hysteresis loss result versus magnetic induction B_m. The result of pure magnetic test also indicates compressive stress is harmful to magnetic property. Classic eddy current loss originates from electrical resistivity. To measure the DC resistivity of silicon steel sheet with in-plane stress applied, insulation system of experimental setup shown in Fig. 1 was upgraded. There is no more electrical contact and metallic parts except collets, winding and collets. Therefore, both collets at the end of specimen are also used as the electrodes to inject the DC current. Test was implemented by four wire method. DC conduction simulation shows that electrical equipotential line in the middle area of specimen is parallel to width direction. It is shown that stress influences the electrical resistivity significantly, which was seldom reported. With static hysteresis loss and resistivity of specimen, excess loss component is calculated by subtracting hysteresis and classic eddy current loss components from iron loss at various frequencies. So we can obtain the influence of stress on each loss components. Now, the data analysis is being done, due to the length of digest, the measured result and analysis will be given in full paper.

Recently, the magnetic-piezoelectric heterostructures show great potential for the next-generation of compact, lightweight, and energy-efficient RF/microwave devices [1-3]. The voltage applied to the piezoelectric layer produces a mechanical deformation that couples to the magnetic layer, and thus induces a change in the magnetic anisotropy and a shift in the resonance field for the ferromagnet. Large voltage-induced effective ferromagnetic resonance (FMR) field has been demonstrated in multiferroic composites such as YIG/PZT, FeGaB/PZN-PT, Fe_3O_4/PMN-PT [4-6]. Nevertheless, great efforts have been made to discover novel mechanisms and achieve tremendous magneotoelectric (ME) coupling effects. In this work, we established a bilayer $Mn_{0.8}Zn_{0.2}Fe_2O_4$ (MZFO)/PMN-PT multiferroic heterostructure (Fig. 1a). The external bias magnetic field (H) was applied along the in-plane and out-of-plane directions of the MZFO film, respectively. The FMR field (H_r) shift shows strong dependence with H field direction (Fig. 1b). We found a giant ferromagnetic resonance (FMR) field shift of 653 Oe took place at the critical angle of 30^o rather than the in-plane [100] direction, along which the maximum ME effect usually occurs. A giant ME tunability enhancement of ~1800 % was determined. We related this significant ME coupling strength improvement to the voltage control of spin dynamics, specifically, two-magnon scattering (TMS) mechanism. TMS is an extrinsic magnetic damping mechanism that scatter the k=0 magnons excited by FMR into degenerate states of magnons having wave vectors k≠0 [7-8], offering a framework for voltage control of spin dynamics and further increase the ME interactions. This demonstrating provides an alternative route for novel integrated multiferroic materials and energy-efficient electronic/spintronic devices devices.

I.Introduction Soft magnetic composites (SMCs) are magnetic materials composed of ferromagnetic powder particles surrounded by electrical insulations. These composite materials have several advantages compared with commercial laminated steel cores, which are traditionally widely used in electric machines [1-2]. At low frequency applications, the advantage of three-dimensional (3D) isotropic magnetic characteristics, and flexible machine design and assembly of SMCs is preferred for axial gap motors which need 3D magnetic design. At medium and high frequency regions, the advantage of low iron loss due to small particle size in SMCs is preferred for transformer and reactors for harmonics suppression etc. With potential wide applications of SMC materials expected in the future, this paper introduces a method to model the *B-H* characteristics of Fe-based SMC immersed in air, Fe_3O_4, and Ferrites until the pure iron particles are deep saturated. The effective permeability of magnetic composites is derived through nonlinear magnetic field analysis based on energy homogenization technique under the assumption that the structure of the magnetic composite is periodic and the particle is sphere. The obtained effective *B-H* curves are compared and analytical expressions for them are presented. II.Energy Equivalent Homogenization Method A.Analysis Models and Conditions Fig.1(a) shows the analyzed periodic 3D SMC material model, which includes pure iron particles surrounded by background materials: air,Fe_3O_4, or MnZn Ferrites. Here, it is assumed that the particles are distributed inside the model evenly and the cell holds structural isotropy. The calculated region consists 27 pure iron particles with a diameter of 50 micrometers and the volume fraction of the pure iron particles varies with the distance between two particles. The SMC material model is regarded as a homogeneous magnetic solid one with the effective permeability as shown in Fig. 1 (b). The original and the homogenized models have equivalent magnetic energy when they are imposed under the same uniform magnetic field. B.Magnetic Field Analysis 3D nonlinear magnetostatic field analysis using the magnetic vector potential *A* is carried out. The uniform magnetic field is imposed through the Dirichilet boundary conditions until the pure iron particles reaches saturation. The initial *B-H* curve for the pure iron particle is nonlinear .The relative permeability of Fe3O4 is set as 5 and that of Ferrite is 2000. C.Homogenization Method The effective permeability is defined on the basis of magnetic energy equivalence in the two models [3]. The magnetic energies in the original and homogeneous models are calculated as follows. $E_{origin}=\sum(B^{\wedge 2}_{ie}/u_{ie})$ (1) $E_{hom}=B^{\wedge 2}_{imp}/u_{eff}$ (2) where B_{ie} and m_{ie} represent the flux density and permeability in each element *ie* in the original model, *K* is the total element number in the original model, the magnetic field, B_{imp} is the imposed flux density. By equalize the energies in the original and homogeneous models, the effective permeability can be expressed as follows. $u_{eff}=B^{\wedge 2}_{imp}/(\sum(B^{\wedge 2}_{ie}/u_{ie}))$ (3) III. Results and Discussions The obtained effective *B-H* curves for the pure iron particles immersed in air and Fe3O4 versus different volume fraction of iron particles will be shown in full paper. The obtained effective permeabilities versus different volume fraction of iron particles for the pure iron particles immersed in air and Fe3O4 at 5000A/m is shown in Fig.2. The comparison with the famous analytical Ollendorff homogenization formula [4] as shown in (4) is also shown. It shows that discrepancy exists between the numerical results and the analytical equations. $u_{eff}=\eta(u_t-u_b)/(N(1-\eta)(u_t-u_b)+u_b)$ (4) where m_b represents the permeability in the background material, m_t represents the permeability of the particles, *h* is the volume fraction, and *N* is constant. Therefore, the analytical homogenization formula is modified according to the numerical results as follows. $u_{eff}=\eta(u_t-u_b)/(N(1-\eta)(u_t-u_b)+u_b)+u_b$ (5) The comparison between the original analytical and the modified formula is shown in Fig. 2. The discrepancy can be about 5% reduced by using the modified analytical equation. Furthermore, the modified formula is applied to the situation that the iron particles are at deep saturation state. Hence the effective permeabilities versus different volume fraction of iron particles for the pure iron particles immersed in air, Fe3O4, and Ferrite are obtained at 15000A/m, which will be shown in full paper. The discrepancy can be about 10%, 15%, and much reduced by using the modified analytical equation, respectively. IV.Conclusion With potential wide applications of SMC materials expected in the future, this paper introduced a method to model the effective *B-H* characteristics of Fe-based SMC immersed in air, Fe3O4, and Ferrites until the pure iron particles are deep saturated based on the homogenization technique. The obtained effective permeability are compared with an original analytical formula and an improved analytical formula is proposed according to the numerical results. And the results by using the improved formula shows better agreement with the numerical results.

I. INTRODUCTION Mn-Zn ferrite cores have been used in inductors and transformers in the power supply because of their high permeability and low loss at low frequency below a few hundred kHz. Recently, they are also expected to be driven at up to a few MHz for downsizing of the power supply. The loss per unit volume in Mn-Zn ferrite cores at high frequency depends on their core size because of the dimensional resonance that occurs at a frequency of a few MHz, which is induced by charge accumulation at high-resistive grain boundaries in low-resistive ceramics (the dielectric effect). In the usage of Mn-Zn ferrite cores at high frequency, therefore, accurate estimation of core loss requires consideration of the dimensional resonance effect. Some of the authors proposed an analytical method for core loss with consideration of the dielectric effect and confirmed effectiveness of the method by comparison with the experiment using commercial Mn-Zn ferrite toroidal cores [1]. However, the difference between the measured and calculated losses was about 20% at maximum. The reason could be that simple cylindrical approximation was used in the calculation although the cores have toroidal shape with rectangular cross sections. Simulation by a finite element method (FEM) will be more effective to accurately analyze loss in cores with complex shapes. In this paper, we prepared a series of Mn-Zn ferrite toroidal cores with different dimensions, and measured frequency dependence of the magnetic permeability and core loss. We then performed magnetic simulation for comparison by applying the FEM with a model considering the dielectric effect to the core models with real shapes. We show excellent agreement between our experimental results and model calculations: the observed systematic variations of the magnetic properties can be fully explained by the dimensional resonance effect. II. MEASUREMENT AND SIMULATION To observe the dimensional resonance effect without any influence of other factors such as inhomogeneity of material and residual stress in the manufacturing process, we prepared five samples of as-sintered Mn-Zn ferrite toroidal cores with different sizes but the same material, whose outer diameters are from 60 mm to 15 mm (LL, L, M, S, and SS). Complex permeability of the cores was measured at room temperature (RT) using the network analyzer, E5061B (Keysight Technologies Inc.), with the input power of –10 dBm, which corresponds to the excitation by the magnitude of magnetic flux density (Bm) of less than 1 mT. Core loss was also measured at RT with the excitation by Bm of 2.5 mT. For frequencies below 1 MHz, we used the B-H analyzer, SY-8219 (Iwatsu Electric Co. Ltd.). At over 1 MHz, we used our precise loss measurement system which utilizes electrical resonance with the capacitors connected in series to the core [2]. We analyzed the dimensional resonance effect by magnetic simulation based on the FEM with a model considering the dielectric effect, which was formulated by dealing with the capacitive performance at high-resistive grain boundaries in low-resistive Mn-Zn ferrite ceramics as the equivalent RC circuit [1, 3]. A linear relationship between the magnetic flux density and the magnetic field was assumed and the hysteresis loss was ignored. III. EXPERIMENTAL AND NUMERICAL RESULTS Figure 1 shows frequency dependence of measured and simulated complex permeability in the five Mn-Zn ferrite toroidal cores with different sizes. In the experiment, systematic variation of the permeability depending on the core size was observed. The simulation well reproduced the experiment. These results indicate that the experimental variation comes from the dimensional resonance effect in Mn-Zn ferrite cores and that all the samples were produced quite homogeneously. It should be noted that such size-dependence cannot be observed in high-resistive Ni-Zn ferrite cores with similar dimensions, which suggests that the dielectric effect at grain boundaries plays an important role in the dimensional resonance. Figure 2 exhibits frequency dependence of measured and simulated core loss in the five Mn-Zn ferrite toroidal cores with different sizes. The experimental results were again in good agreement with the simulation. In the previous work [1], the difference between the measurement and the analytic calculation was about 20% at maximum, and the slopes of the frequency dependence slightly diverged. In the simulation with the FEM, however, the difference was improved to be less than 10%, and the slopes showed good agreement as shown in Fig. 2. Such improvement would become larger when the core shapes are more complicated. Simulation with the FEM, therefore, would be quite important for accurate loss estimation at high frequency for cores with realistic core designs.

EQ-10. Gel-casting Hexagonal Ferrites for High Density and Low Loss Microwave Devices.

J. Adams[1], A.S. Sokolov[1] and V. Harris[1]
1. Electrical & Computer Engineering, Northeastern University, Medway, MA, United States

In this work, a high density hexagonal ferrite is processed and characterized using a unique gel-casting process and organic chemicals. The gel-casting processing method is a colloidal technique that provides a short forming time, while also having a high green body density and the ability to create complex shapes due to low shrinkage and cracking effects. The hexagonal ferrites used were M-type hexaferrites, chosen for their excellent applications in self biased RF, microwave, and mm-wave devices. It is well known that magnetic microwave devices rely on low ferromagnetic resonance (FMR) linewidths to achieve low loss and high performance of RF devices. Furthermore, the FMR of a ferrite is directly related to the density of the material. Therefore, in order to achieve a low loss polycrystalline magnetic material, achieving high density is of paramount importance. Typical maximum densities in polycrystalline hexaferrites is 90% of theoretical [5]. In this work, we approach 98% of theoretical density by use of gel-casting processing methods, and anticipate low FMR losses. In addition to the aforementioned benefits of lower FMR linewidths via higher densities, this process is very beneficial to self-biased hexaferrites. The use of self-biased hexaferrites at low enough FMR frequencies for device operation less than K band requires the modification of crystal structure with cation substitutions. This decreases the magnetocrystalline anisotropy field that is intrinsic to the hexaferrite structure and chemistry. While this is effective in reducing FMR, it also complicates the processing of textured compacts for the use as self-biased materials. These compacts are typically formed under the application of magnetic fields while simultaneously applying uniaxial mechanical pressure. However, this mechanical pressure imparts stress on the particles and often results in difficulties in achieving high remnant magnetization. Using the gel-casting method described herein, it is anticipated that this will improve both density and magnetic remanence. Gel-casting is a process by which a slurry of powders, water and water-soluble organic monomers are polymerized to form parts using inexpensive plastic molds. Following the green body formation, drying, burn out and sintering finish the process. This is a generic process that can be used with numerous types of ceramic powders, and has recently been successful with Alumina powders [3]. A similar process is slip casting, however gel-casting provides much more homogenous densities. Additionally, the very small percentage of organic components makes the removal during burnout far less dramatic. In this work, a water-soluble alternating co-polymer of isobutylene and maleic anhydride called ISOBAM was used. This is chemical is very beneficial because it uses one organic component that acts as a binder and dispersant at very low concentrations. Other works have shown the use of ISOBAM produces dense green bodies at high solid loading of up to 80% by volume, with low added organic content (i.e., <1 wt% of ceramic powder), and minimal shrinkage and cracking [3]. The gelling mechanism of ISOBAM is credited to surface interactions between ceramic particles and the long chains of polymer that wrap around the particles and interact with each other, creating an elastomer network of intramolecular interactions [3]. This paper is represents the first known use of ISOBAM for gel-casting of magnetic ferrites. The processing of samples for this digest is described as follows. High purity Barium M Type hexaferrite ($BaFe_{12}O_{19}$, Alfa Aesar) powders were obtained and the morphology of these powders were examined with a scanning electron microscope (SEM). An average particle size of 1 micrometer was observed. A solution of ISOBAM was made and then mixed with the hexaferrite material. The resulting solution was then dispensed into molds and dried at low temperatures for 24-48 hours. The final stage of processing consisted of sintering the samples. This processed was used to create cylinders with a radius of 4mm and a height of 5mm before drying. Twelve samples were made consisting of ISOBAM concentrations of 0.25%, 0.50%, 0.75% and 1.00% ISOBAM concentrations (with respect to the ferrite mass) and with 60%, 70% and 80% percent mass loading. Samples were analyzed with two independent methods to verify their densities. The first method was the use of an analytical balance and Pycnometer to determine the density. The second method used the analytical balance and a vibrating sample magnetometer (VSM) to determine the density through the known theoretical magnetization saturation values of pure Barium M type hexaferrites. The theoretical maximum value of M_s is 72 emu/g [4]. A plot showing various values of M_s, as a percentage of the theoretical maximum, for each sample is appended at the end of this digest. As can be seen, extremely high densities were attained near 98%. This data was corroborated, as mentioned previously, with pycnometer measurements and is within 1.15% on average. Also, the morphology of the highest density sample was observed with an SEM and is appended at the end of this digest.

EQ-11. Correlation of calcination temperature and flux doping on the microstructure and magnetic properties of low-temperature-fired NiCuZn ferrites.

H. Su[1], *Q. Luo*[1], Y. Jing[1], Y. Li[1], H. Zhang[1] and X. Tang[1]
1. University of Electronic Science and Technology of China, Chengdu, China

Multilayer chip inductors (MLCIs) play important roles in advanced electronic products, such as cellular phones, computers, video cameras etc. Currently, MLCIs are mainly prepared by low-temperature-fired NiCuZn ferrites because these ferrites have relatively low sintering temperature, high resistivity and good performance at high frequencies. The magnetic properties of NiCuZn ferrites are sensitive to their microstructures. Preparation conditions, such as calcination temperature and sintering curves, and doping schemes influence the microstructure of NiCuZn ferrites. For low-temperature-fired NiCuZn ferrites used in MLCIs, fluxes are the most important dopants because they can reduce the sintering temperature of NiCuZn ferrites to around 900 °C and obtain a dense microstructure and good magnetic properties. The effects of flux dopants on the microstructure of NiCuZn ferrites are correlated with ferrite preparation process, especially calcination and sintering temperature. However, studies of correlative influences of preparation process and flux dopants on the microstructure of low-temperature-fired NiCuZn ferrites have been seldom reported in literature. In this study, the correlative influences of calcination temperature and Bi_2O_3 doping content on the microstructure and magnetic properties of the low-temperature-fired NiCuZn ferrites were investigated. For ferrites with relatively low calcination temperatures, such as 750 °C and 850 °C, Bi_2O_3 doping easily triggered inhomogeneous grain growth. Controlling the flux amount to lower than the 'critical' value, which triggered abnormal grain growth, was preferred to obtain good magnetic properties. For ferrites with relatively high calcination temperatures, such as 950 °C and 1050 °C, flux doping was not prone to stimulating abnormal grain growth. Thus, the optimum doping content could be added when the highest sintered density was detected. With excessive Bi_2O_3 concentrations, low-temperature-calcined ferrites could produce homogeneous microstructures with a relatively large average grain size. By contrast, high-temperature-calcined ferrites could form homogeneous microstructures with a relatively small average size, which favoured a high Q-factor and was more favourable for high frequency applications.

Ferrites order ferrimagnetically through superexchange interaction mediated by an anion, which generally results in lower magnetization than ferromagnetic metals. An increase in the magnetization of ferrites is required for applications [1]. Recently we have reported a possibility to obtain higher magnetization in some of the ferrites in their nanocrystalline thin film form [1-3]. The bulk saturation magnetization of $MnFe_2O_4$ is ~ 7.0 kG (~ 4.6 μ_B) at 0 K which is the highest among binary ferrites [4]. This value can be increased further by Zn substitution [4]. The largest reported value of magnetization obtained in $Mn_{1-x}Zn_xFe_2O_4$ (MZF) is 10.8 kG (~ 7.1 μ_B) for x = 0.5 at 0 K [5]. Further increase of x in MZF system results in a decrease in the magnetic moment due to the weakening of superexchange interaction between A and B sites, which causes canting of magnetic moments on the B sites [3,5]. Here, we present a systematic study of pulse laser deposited (PLD) nanocrystalline MZF ($0.1 \le x \le 0.8$) films with an attempt to increase the magnetic moment higher than bulk. The single phase MZF PLD targets were prepared in our laboratory using the ceramic method in presence of Ar environment (based on Ellingham diagram). MZF thin films were deposited on an amorphous quartz substrate by PLD using Nd:YAG laser. Before starting the deposition, the PLD chamber was evacuated to a base pressure of 4.6×10^{-6} mbar. Thin films were deposited at T_S = 650 °C for 30 minutes in Ar environment at a pressure of 0.16 mbar. All the observed XRD peaks of the films could be indexed to spinel phase. The M-H loops were measured at 10 K and 300 K. The ferromagnetic resonance (FMR) spectra of the films were recorded at 300 K. The thickness of the films were measured using FEG-SEM and were observed to vary between 60 – 85 nm. The diamagnetic contribution of the substrate was subtracted before arriving at the final M-H loops. The spontaneous magnetization ($4\pi M_S$) of the films was estimated by linearly extrapolating the high field part (30 – 50 kOe) of M-H loops to the zero field, similar to our earlier work [1-3]. The average grain sizes of the films estimated from Scherrer's formula varies in the range ~ 30 – ~ 38 nm with no systematic variation as a function of x. Figures 1 (a) and (b) show $4\pi M_S$ values of the bulk and thin film of MZF measured at 300 K and 10 K respectively. As seen from these figures, the bulk $4\pi M_S$ values at 300 K do not show any significant variation between x = 0.1 to x = 0.4. However, for x > 0.4 the $4\pi M_S$ values decrease with increase in x and becomes paramagnetic for x = 0.8. The maximum value of $4\pi M_S$ obtained at 300 K was ~ 5.2 kG for x = 0.2. The bulk $4\pi M_S$ values at 10 K, on the other hand, initially increase from ~ 7.6 kG for x = 0.1 to ~ 10.9 kG for x = 0.5 and then show a monotonous decrease until ~ 1.8 kG for x = 0.8. The maximum magnetization observed at 10 K was 10.9 kG for x = 0.5. These $4\pi M_S$ values are in close agreement with standard reported values [5]. We see from figures 1 (a) and (b) that the value of $4\pi M_S$ for the thin film shows a very different behavior than bulk. At 300 K, we note a small drop in $4\pi M_S$ from 4.3 kG for x = 0.1 to 3.9 kG for x = 0.3. However, for larger values of x, the magnetization rises again and reaches a maximum value of ~ 6.1 kG for x = 0.7. This value is higher than bulk $4\pi M_S$ for the same value of x by 7.5 times. The thin film $4\pi M_S$ values become higher than bulk for $x \ge 0.4$. At 10 K, the $4\pi M_S$ values of the films show an overall increase from 5.5 kG for x = 0.1 to 9.2 kG for x = 0.7 and then drops to ~ 8.0 kG for x = 0.8. The $4\pi M_S$ values of the films become higher than bulk only for x > 0.6. The resonance field values of FMR spectra were used in Kittel's equation to estimate the $4\pi M_{eff}$ values. These values have also been shown in figure 1 (a) to compare with the $4\pi M_S$ values measured using VSM. We see that the $4\pi M_{eff}$ shows a similar trend as $4\pi M_S$ even though $4\pi M_{eff}$ values are generally higher. Such higher values of $4\pi M_{eff}$ in comparison to $4\pi M_S$ are often seen [6] and could be because of multiple reasons, one of which could be the presence of an anisotropy due to stresses [7]. The largest value of $4\pi M_S$ (~ 9.2 kG) observed by us for x = 0.7 is highest among all MZF thin films. Similar largest magnetization value was also reported for x = 0.7 in $Co_{1-x}Zn_xFe_2O_4$ ($0.1 \le x \le 0.7$) thin films and was 8.1 kG [3], while the bulk value there was 6.2 kG. The magnetic moment values in Bohr magnetons (μ_B) of bulk and thin films are listed in Table 1. The XRD densities of the films were used to convert $4\pi M_S$ of the films to μ_B as the actual density or mass was not known. Hence the actual magnetic moment values of the films given in the Table are underestimates. Thin film deposition techniques induce a different cation distribution in spinel ferrite thin film compared to its corresponding bulk distribution [8]. Higher than bulk magnetic moment in MZF thin films [refer to Table 1] can be understood on the basis of cation distribution in thin films. Due to quenching, the Zn^{2+} enters both on A and B-sites. A decrease in spin canting is resulted from strengthening of A-B exchange interaction when less number of Zn^{2+} occupying the A-sites. Also the presence of Zn^{2+} ions on B-sites would reduce B-B interaction making canting weaker [3]. This would result in an increase of net magnetic moment of the films compared to bulk even at higher Zn.

Both LiZn and NiCuZn ferrites are excellent microwave magnetic materials and have been extensively used in various high frequency and power micro/millimeter-wave devices [1]. With regard to LiZn ferrites, one have wide range of saturation magnetization M_s at room temperature, high Curie temperature T_c, low sensitivity of remanence B_r to stress, rectangular hysteresis loop and low fabrication cost [2]. Compared with LiZn ferrites, NiCuZn ferrites have lower ferromagnetic resonance (FMR) linewidth ΔH, however, one have relative lower T_c [3]. In order to meet the requirements of low insertion loss, high temperature stability, miniaturization and lightening of micro/millimeter-wave devices, it is an opportunity to explore an effective composite means to deal with the contradiction between the FMR linewidth ΔH and T_c for LiZn and NiCuZn ferrites. Here $Li_{0.35}Zn_{0.30}Fe_{2.21}O_{4-}\delta$ and $Ni_{0.52}Zn_{0.40}Cu_{0.10}Fe_{1.98}O_4$ ferrite have been fabricated by conventional ceramic process, respectively, and LiZn and NiCuZn powders were mixed together with 0.1wt% Bi_2O_3 and NiCuZn mass percent from 0wt% to 100wt% to prepare LiZn/NiCuZn ferrites with sintering temperature T_s from 800 to 1200°C. The ion diffusion and microwave electromagnetic characteristics of LiZn/NiCuZn ferrites have been investigated in detail. Fig. 1 shows Ni element atomic percent contents for the LiZn/NiCuZn ferrites with different NiCuZn ferrites contents from 20 to 80wt% for the sintering temperature from 800 to 1200°C. Considering a certain composition of LiZn/NiCuZn ferrite, dozens of grains in random region have been chosen to measure the Ni element atomic percent contents by means of EDS. The Ni element randomly distributes in different grains at the low sintering temperature, especially, when the sintering temperature is 800°C. The detected minimum and maximum of Ni element atomic percent contents keep on a rise with the increase of NiCuZn contents in LiZn/NiCuZn ferrites at T_s=800°C. However, the Ni element atomic percent contents show a convergence trend with the increase of sintering temperature and tends to be a stable state beyond T_s=1020°C, meanwhile, the stable state Ni element atomic percent contents at T_s=1200°C increases from 4.3 to 14.3 corresponding to the increase of NiCuZn ferrites contents from 20 to 80wt% in LiZn/NiCuZn ferrites. When the sintering temperature is 800°C, due to the melting point 825°C of Bi_2O_3, the Ni ion diffusion mechanism would be solid phase transfer, which causes its contents be randomly distributed. But the liquid layer of Bi_2O_3 would promote the solid state reaction when the sintering temperature beyond 825°C, and the Ni ion diffusion would be easier so that Ni element contents exhibit a convergence trend, which reflects the LiZn/NiCuZn ferrites be homogeneous mass. FMR linewidth (ΔH) spectra has been measured and fitted by Lorentz model for LiZn/NiCuZn ferrites with sintering temperature of 1200°C in Fig. 2, and the Lorentz fitting curve coincides well with the experimental data, which is consistent with previous relevant illumination [4]. ΔH monotonously decreases with the increase of NiCuZn contents. ΔH of polycrystalline ferrite consists of single crystal or intrinsic linewidth ΔH_i, the crystalline anisotropy and porosity induced line broadening contributions ΔH_a and ΔH_p, respectively. Because of the large crystalline anisotropy and porosity linewidth contributions, the small ΔH_i part (on the order of few Oe from single crystal [5]) could be neglected. Thus, ΔH is affected mainly by ΔH_a and ΔH_p.

I. INTRODUCTION Magnetic stimuli-responsive magnetorheological (MR) fluids composed of magnetic particles dispersed in non-magnetic carrier fluids have been extensively investigated as smart and intelligent magnetic materials due to their reversible and rapid changes when an external magnetic field is applied [1] along with their industrial applications such as damper, shock absorber and polishing devices [3]. They are distinctive with their dramatic change in rheological properties such as yield stress and dynamic moduli [2]. Among the many magnetic particles available, carbonyl iron microspheres have been widely used as magnetizable particles for MR fluids due to their high magnetic permeability, soft magnetic property and common availability [4]. As for a new MR material, we introduce iron–gallium (Fe-Ga) alloy particles, in which the Fe-Ga alloy (Fe_{100-x} Ga_x where $5 < x < 35$) is commonly known as Galfenol, a rare-earth free magneto-strictive alloy [5] with a high Curie temperature and corrosion resistance. The raw materials used to produce Fe-Ga alloys are relatively inexpensive, thus making Galfenol have great promise as an engineering material for myriad sensing, actuating, and energy harvesting devices [6]. In this study, we prepared Fe-Ga alloy particle-based MR fluid to investigate its MR characteristics using a rotational rheometer with a magnetic field supply device. II. EXPERIMENT Soft magnetic Fe-Ga alloy particles were fabricated using the Fe-Ga alloy materials (Eterma Products Inc.) consisted of melting elemental Ga with pure iron. They were chill-casted into an ingot form through an induction melting technique, and the ingot was then enclosed in a stainless steel can and sealed to prevent an oxidation. The Galfenol flakes were prepared through a conventional rolling and texture annealing process using Fe-Ga alloy ingot. The MR fluid was then prepared by dispersing Fe-Ga alloy flake-typed particles in silicone oil (50 cSt, Shin-Etsu, Japan) with a weight fraction of 30%. Morphology of the Fe-Ga particles was confirmed using scanning electron microscopy (SEM), while their crystal structure and magnetic property were confirmed by X-ray diffraction (XRD) and vibration sample magnetometer (VSM), respectively. The MR properties of the Fe-Ga alloy based MR fluid were measured via the rotational rheometer (MCR 300, Anton Paar, Germany) equipped with a parallel-plate geometry (PP20, gap distance of 1 mm) and a magnetic field supply device (MRD 180). The steady shear test was applied at shear rates ranging from 0.1 to 200 s^{-1} under a range of magnetic fields, while viscoelastic properties of the Galfenol based MR fluid was also investigated by strain amplitude sweep and angular frequency sweep tests. III. RESULT AND DISCUSSION As shown in Fig. 1, SEM image of the Galfenol particles exhibit approximately 50 μm of particle size with the thickness of 1 μm. From the SEM image, we can confirm that the Galfenol particles show a flake structure. In addition, the Galfenol particles were almost soft-magnetic with their saturation magnetization value of 174 emu/g, measured from VSM data. Figure 2 represents shear stress curve as a function of shear rate for Galfenol based MR fluid under four different external magnetic field strengths ranging from 0 to 343 kA/m. Without an external magnetic field, the MR fluid behaves as like a Newtonian fluid. However, when the magnetic field was applied, the Galfenol based MR fluid exhibited typical Bingham fluid-like behavior because the particles form chain-like structures via magnetic dipole-dipole interaction between the adjacent particles. Furthermore, the plateau shear stress region on a broad shear rate range could be explained by reconstitution of the destructed chain-like structure. The extent of the shear stress increased depending on the magnetic field strength at a whole shear rate range. Based on these rheological data, an attempt was made to fit the flow curves using the Bingham model Eq. which is one of the most widely used models for traditional MR suspension systems, as follows: $\tau = \tau_y + \eta_0$ where τ_y and τ are the dynamic yield stress and shear stress, respectively, and η_0 is the shear viscosity at high shear rate. The solid lines in Fig. 2 for Galfenol based MR suspension were obtained from the above mentioned equation and demonstrate a deviation from the experimental data. Furthermore, to obtain τ_y of the MR fluid from the flow curves, we extrapolated the corresponding shear stress in Fig. 2 to a zero-shear rate. The dynamic yield stress also increased with increasing magnetic field strength and the τ_y was dependent on the magnetic field strength (H) as follows: $\tau_y \alpha H^{\alpha}$. Based on VSM results of Galfenol particles, the slope (α) of Galfenol based MR fluid was proportional to $H^{1.5}$ at low magnetic field strengths [7]. However, as the magnetic field strength increases, the Galfenol particles become easily saturated and the slope of Galfenol based MR fluid decreases to 1. From this study, Galfenol particles showed their typical MR characteristics for the first time.

ER-01. Study of characteristics on stability of the yoke equipped magnetic rotor in the HTS Magnetic Bearing.

T. Arai[1], T. Minami[1], S. Hiraoka[1] and S. Ohashi[1]
1. Electrical and Electronic Engineering, Kansai University, Suita, Japan

Pinning effect of the high temperature superconductor (HTS) is introduced to realize magnetic levitation without gap control [1], [2]. Applications for the contact less magnetic bearing system [2] have been developed. For example, there is application to a flywheel electric power storage device. The rotor is supported by pinning effect of the HTS with contact less and control less. The conventional rotor has two magnetic poles [3] [4]. The flux use of the rotor is inefficient. The system consists of the stator and the rotor in this paper. The stator generates the rotating magnetic field. The induced current is generated in the rotor by this rotating magnetic field. The rotor is rotated by the induced current and the rotating magnetic field using the principle of the induction motor. It consists of the iron equipped magnet and the aluminum. In the iron equipped magnet, the yoke covers the permanent magnet in order to increase the linkage flux on the HTS. The aluminum is installed around the iron equipped magnet in order to generate rotational torque. But, the rotating magnetic field affects the magnetic field in the iron equipped magnet. The flux inside the iron equipped magnet is disturbed. Therefore, the iron is installed as a shield and it is defined as the magnetic shield. It is used to guide the rotating magnetic field to the outside without getting inside the iron equipped magnet. Thus, the air gap and the magnetic shield are attached between the iron equipped magnet and the aluminum. As a result, the influence of the rotating magnetic field in the iron equipped magnet becomes small. Fig.1 shows the structure of the iron equipped magnetic rotor. The yoke is installed around the permanent magnet to increase the linkage flux on the HTS. The aluminum is installed as the secondary of the induction motor. The induced current is generated in the aluminum by the rotating magnetic field. The air gap and the magnetic shield are attached between the iron equipped magnet and the aluminum to suppress the magnetic disturbance by the stator. The levitation gap between the upper surface of the HTS and the lower surface of the rotor is 10 mm. The air gap between the stator and the aluminum is 2 mm. The width of the air gap is defined as W_{Air}, and the width of the magnetic shield is defined as W_{shield}. The turn of the stator coil is 300 turns, and it is distributed winding of 6 poles. The Three Dimensional Finite Element Method (3D FEM) analysis is carried out to calculate the flux density and the torque. The flux density is calculated at the boundary between the air gap and the yoke. The torque is calculated in the shield part and the aluminum part. The width of the air gap and the width of the shield are changed in this analysis. However, the total width of the air gap and the shield is 10 mm. The analysis is performed using the 3D FEM software JMAG Designer. The analysis conditions are coil current 4 A, frequency 60 Hz and sliding 0.01 in the stator. Figs.2 shows the analysis result of the flux density distribution at the boundary between the air gap and the yoke, and the analysis result of the torque. From Figs.2 (a), the flux of the iron equipped magnet is disturbed by the rotating magnetic field in the non-shield type. Then, the models with the shield are considered. (W_{Air}, W_{shield}) = (5, 5) is defined as the large shield type. (W_{Air}, W_{shield}) = (7, 3) is defined as the small shield type. The influence decreases by enlarging the width of the air gap. This is because the magnetic resistance between the shield and the iron equipped magnet is increased by enlarging the width of the air gap. From Figs.2 (b), average torque T is calculated at steady state. The torque is 0.0381 Nm in the large shield type, 0.0371 Nm in the small shield type. There is little difference. Thus, we designed the iron equipped magnetic rotor under the condition of the small shield type. The characteristics of the iron equipped magnetic rotor are studied. The linkage flux on the HTS is calculated by the 3D FEM analysis. The levitation force and the restoring force are improved because the linkage flux on the HTS increases. Thus, the pinning force is improved in the iron equipped magnetic rotor. The iron equipped magnetic rotor is suppressed the horizontal vibration at the resonance state because the restoring force is improved. Thus, the proposed model uses flux from the permanent magnet effectively.

ER-02. A Proposal of Noncontact Baton-pass System for a Thin Steel Plate Based on Magnetic Levitation Technique.

Y. Sudo[1], Y. Arita[1], M. Yamada[1] and T. Nakagawa[1]
1. Electrical and Electronic Engineering, Tokyo City University, Setagaya, Japan

1. Introduction Thin steel plates widely used for many industrial products have mainly been conveyed on rollers or by suckers in workspaces. However, for such contact types of conveyance method, there is a problem that quality deterioration by scratches or pressed marks occurs on steel plate-surfaces. In order to resolve this problem, adoption of magnetic levitation techniques can be effective in a conveyance system for steel plates. For this reason, other institutions are studying such a system intensively ([1], [2] and [3]). Our laboratory has already succeeded in stable levitation and noncontact conveyance for thin steel plates ([4]). As the next stage, we aim at the realization of noncontact baton-pass system, in which electromagnets hand a levitating steel plate to the adjoined electromagnets without any contacts. If such a motion is realized, it will be utilized as "branching mechanism" in a conveyance lane for steel plates. Moreover, if the motions of baton-pass are repeated, the levitating steel plates can continue to proceed along the conveyance lane. In this paper, we will propose an interesting baton-pass mechanism for a thin steel plate. In addition, we will show the successful experimental results when the thin steel plate is handed to the adjoined electromagnets without any contacts. 2. Structure and Control Method of Magnetic Levitation System Our magnetic levitation system for steel plates consists of six electromagnets, six gap sensors, four sideslip sensors, and LabVIEW-PXI (DSP with A/D and D/A converters). Basically, the steel plate can levitate by four electromagnets, four gap sensors, two sideslip sensors, and LabVIEW-PXI as proposed in our original paper ([5]). In this study, we deal with the apparatus structure shown in Fig. 1(a), in order to verify experimentally that the thin steel plate can be handed to the adjoined electromagnets without any contacts. As for the levitation control in our series of studies, we have designed the controller for each independent motion mode of the steel plate, based on "Optimal control theory". On the other hand, as for the guidance control in our series of studies, we have adopted an idea of tilting the steel plate. This idea is very interesting, because we don't need any actuators for guidance control. That is, a levitating steel plate is tilted so as to obtain the guidance-force, as shown in Fig. 1(b). (As for the detail, refer to [5]) 3. Proposal of Noncontact Baton-Pass System and Experimental Verification Figure 2(a) shows a flow in the baton-pass process of the levitating steel plate that moves to the adjacent electromagnets without any contacts. First, as the step1, the steel plate is levitated stably. Second, as the step2, it is tilted by regulating the attractive force of the front and rear electromagnets and is proceeded to the adjacent electromagnets. As the step3, the levitating steel plate is grasped by the adjacent electromagnets without any contacts. As the step4, the levitating steel plate is tilted inversely to stop itself. Finally, as the step5, the steel plate keeps stable levitation. Figure 2(b) shows the photos captured from the movie taken when the thin steel plate is handed to the adjoined electromagnets, corresponded to each step in Fig.2(a). As a result, we succeeded in realization of noncontact baton-pass system, in which electromagnets hand a levitating steel plate to the adjoined electromagnets without any contacts.

ER-03. A study on Optimal Operating Point of Linear Induction Motor considering Normal Force and Efficiency in MAGLEV Vehicle.

J. Lim[2], J. Jeong[1] and D. Park[2]
1. Electrical Engineering, Chung Nam National University, Daejeon, The Republic of Korea; 2. Magnetic Levitation and Linear Drive, Korea Institute of Machinery & Materials (KIMM), Daejeon, The Republic of Korea

Introduction This paper deals with the analysis of the optimal operating point of linear induction motor(LIM) which is used in magnetic levitation trains. LINIMO of Japan and ECOBEE of Korea have been developed as the urban maglev of 110km / h class, and have successfully operated commercial operation. China is developing three routes independently and some have begun commercial operation. All of the developed low speed maglev trains use LIM as propulsion system. The secondary of LIM is advantageous in that the production cost of the line is low and the maintenance cost is significantly lower than other systems. In the rotating induction machine, the dq-axis-based vector control is widely used. The LIM as the magnetic levitation propulsion system, however, the applied voltage and the frequency are the main control variables for scalar control. In detail, a constant slip frequency control has been used to stabilize the levitation of the Maglev. The constant slip frequency has a constant normal force on the levitation system regardless of the speed at the maximum thrust control [1]. However, in actual train operation, various thrust are required to operate at various speeds. The normal force of the LIM is also proportional to the current command of the demanded thrust. While the train is under operation, the maximum vertical force of the LIM will only occur at the maximum thrust point. Although the constant slip frequency control is advantageous in terms of normal force, it operates in a region with low operation efficiency due to the characteristics of the LIM. Therefore, variable slip control has been applied as an effective method to improve the operation efficiency. Propulsion system spends the largest portion of the power consumption of maglev trains, and improvement of the propulsion efficiency has been continuously required in order to achieve the higher operating efficiency of the entire system. In addition, the propulsion efficiency of an actual vehicle may fluctuate by 5 to 10 depending on the operating conditions. In order to increase the propulsion efficiency of the LIM, it is important to operate in a low slip frequency region. As noted earlier, lowering the slip causes a higher attraction force. Therefore, interference with the levitation system should be considered for low sleep frequency domain operation. Main Body The thrust due to speed and slip is shown in Fig. 1. In the constant thrust region, the applied voltage and frequency rise with the speed based on the fixed slip frequency. In the constant power region, the driving frequency increases with the speed to create thrust. In the figure, three additional lines are drawn, which denote constant slip frequency operation (red line), maximum thrust operation (blue line), and maximum efficiency operation (green line). In the case of the constant slip frequency control, as the speed increases, the slip at the operating point decreases, and thus it can operate in a relatively high efficiency region at high speed operation. At low speeds, the slip of the operating point is large due to the fixed slip frequency, so it operates in low thrust and efficiency regions. Therefore, when the vehicle is operated in the low slip region within the maximum normal force of the LIM, a higher driving efficiency can be achieved. The thrust, efficiency and the attraction force of the LIM according to the operation slip are shown in Fig. 2. For a semi-high speed maglev vehicle, the LIM is designed to meet the maximum thrust of 4 kN at a rated speed of 90 km/h and a slip frequency of 12.5Hz. However, due to the nature of the LIM as a means of transportation, a thrust command of 4 kN is not always required at a speed of 90 km/h. The driving force of the LIM is defined as an acceleration pattern determined according to the train 's driving pattern. When the propulsion command is 50% of the thrust, the voltage and current are reduced to 50%, and the normal force of the LIM is also reduced. Applying a low slip frequency to maintain a constant normal force, the LIM can be operated with the slip frequency down to 10.5 Hz. It can be defined as a constant normal force control. When driving at a slip frequency of 10.5 Hz for a command of 50% at a speed of 90 km/h, the efficiency is 63%, which is 5% higher than the efficiency of 58% when the motor is driven at a slip frequency of 12.5 Hz. Conclusion In this paper, by analyzing the characteristics of LIM used in magnetic levitation trains, the thrust and normal force for velocity and slip were analyzed, and a constant normal force control method was proposed to suggest a high efficiency driving scenario for the same normal force. In the final paper, we will present a comparison of driving scenarios and efficiency for the proposed driving method.

ER-04. Improvement of damping factor on the lateral guideway displacement by using weight-reduced damper coil on superconducting magnetically levitation bogie.

R. Nakakita[1], E. Shin[1], T. Takeuchi[1] and S. Ohashi[1]
1. Electrical and Electronic Engineering, Kansai University, Suita, Japan

Superconducting magnetically levitated transportation system has been developed in Japan since 1962 [1-2]. Results of numerical simulations show that the damping factor of the EDS system is small. Therefore, the damper coils are installed in front of the SC coils to increase damping factor. The damper coils are used to increase damping of the EDS system against oscillation of the bogie, but the energy loss is larger because of the weight of the damper coil [3-6]. Therefore, by changing the shape of the conventional coil, its weight and the energy loss is reduced. The number of operation types of the damper coil is two. One is the passive mode, and the other is the semi-active mode. In the passive mode, the damper coils are used just as the short circuit coils. The effect of the conventional damper coils is larger than that of the weight-reduced damper coils in this mode, and damping factor becomes larger than without the conventional damper coils. However, this system may generate unnecessary damper coil current because of the discrepancy of the phase of the damping current and the oscillation velocity generated by the self-inductance of the damper coils. The effect of the conventional damper coil becomes large in this mode. In the semi-active mode, the IGBT which also has a part to protect the circuits from large current is installed, and damper coils are switched according to the oscillation velocity of the bogie and the magnetic force generated by the damper coils. When the switch is ON, the damper coils are short circuited, and OFF, open circuited and resistances are inserted to the circuits. The effect of the weight-reduced damper coil becomes large in this mode. In Japan, ground condition is not good, so the guideway displacement may occur by earthquakes and it is important to estimate effects of the guideway. When the bogie passes the lateral displacement, rolling angle occurs at the same time, and just after this, the levitation force changes and it induces vertical displacement, pitching angle and yawing angle. In this study, simulations when the conventional damper coils and the weight-reduced damper coils pass the lateral displacement $y = 0.01$ m are shown. Fig.1 shows the shape and position of the weight-reduced damper coil. The levitation force is generated by the SC coils attached to the bogie. The eight-figure null-flux connection is used for the levitation coils on the ground. When the bogie passes the center of the eight-figure coils, the levitation force is generated to the bogie. The current induced in the levitation coils is calculated. EDS system has an air-coil system and modeled as electric circuits. The mutual inductance between the SC coils and levitation coils is calculated from the electric circuit equations and in order to solve the electric circuit equations, the current of the levitation coils is calculated. Also, the motion of the bogie is calculated from the motion equations. By repeating these procedures, the transient motion of the bogie is given. Runge-Kutta method is used to solve these equations [7]. Running simulations of the conventional damper coils and the weight-reduced damper coils in the semi-active mode are studied. The bogie moves to the running direction at the constant velocity $v = 120$ m/sec. The bogie passes the lateral displacement $y = 0.01$ m at the time $t = 0.6$ sec. Fig.2(a) shows the lateral displacement and Fig.2(b) the rolling angle. In the lateral displacement, the maximum oscillation of the weight-reduced coils is smaller than that of the conventional damper coils. Thus, 1.804% improvement is seen. Also, the convergence time of the weight-reduced damper coils is shorter than that of the conventional damper coils. Thus, 59.02% improvement is seen. In both the maximum oscillation and the convergence time, improvements are seen. In the rolling angle, the maximum oscillation of the weight-reduced coils is smaller than that of the conventional damper coils. Thus, 5.333% improvement is seen. Also, the convergence time of the weight-reduced damper coils is shorter than that of the conventional damper coils. Thus, 57.40% improvement is seen. In both the maximum oscillation and the convergence time, improvements are seen. In conclusion, improvements in the lateral displacement and rolling angle are seen when the weight-reduced damper coils pass the lateral guideway displacement in the semi-active mode compared with the conventional damper coils. Especially in the convergence time, drastic improvement is seen.

INTRODUCTION: Flywheel energy storage system (FESS) is a kind of physical energy storage device for electromechanical energy conversion. In order to simplify the system structure and improve the critical speed, magnetic levitation electric machines that combine magnetic bearing and electric machine are applied in FESS [1]. Bearingless switched reluctance machine (BSRM) fully preserves the excellent characteristics of switched reluctance motor, and improves the high speed performance and operation efficiency by active control of its own radial force. Introducing the BSRM into FESS, the system volume and loss could be greatly reduced, suspension performance could be improved, and critical speed and power density could be increased. BSRM is one of the ideal choices for flywheel suspension support and energy conversion [2]. There are serious electromagnetic coupling between torque winding and suspension winding of the traditional 12/8 poles type BSRM, which lead to the difficulty of controlling [3]. In this paper, a novel BSRM with axial split phase inner stator permanent magnet (PM) structure is proposed to cancel the electromagnetic coupling between torque winding and suspension winding. Meanwhile the power density of the BSRM is improved due to the PM bias magnetic field for suspension. TOPOLOGY: Fig. 1 shows the structure of the BSRM with axial split phase inner stator PM structure, where outer rotor is combined with the flywheel directly to improve the axial utilization ratio, reduce the volume of the whole system, and increase the specific capacity and specific power of the flywheel energy storage system. The proposed BSRM could been seen as combination of two single-phase 12/12 poles type BSRM along axial direction, and the angle difference of their rotors is q_r. As shown in Fig. 1(a), There are two kinds of stator poles with different tooth width in the stator, namely suspension pole (wide tooth) and torque pole (narrow tooth), respectively. They are used to assemble suspension winding and torque winding, respectively. There are magnetic isolation sleeves between suspension poles and torque poles. Then the physical decoupling of the magnetic circuits of the torque pole (Y_{ma}) and the suspension pole (Y_{sa}) is realized, as shown in Fig. 1(b). There is PM between two stators to provide the bias magnetic field for suspension pole. Then a larger suspension force could be produced by smaller current input to suspension winding, and the power density of the BSRM could be improved. As the existence of magnetic isolation sleeve, the PM flux (Y_{PM}) will not cross through the torque winding as shown in Fig. 1(b). Then PM flux will do not impact on the torque control, and the main circuit and control method are the same as the traditional two phase switched reluctance machine. FINITE ELEMENT ANALYSIS: In order to verify the effectiveness of the proposed BSRM, its electromagnetic field is analyzed by the finite element method (FEM), and the results are shown in Fig. 2. Fig. 2(a) shows the distribution of magnetic field in the proposed BSRM without currents input to the torque winding and suspension winding. It can be seen that the PM flux only crosses through the suspension windings and rotor, and there is not PM flux cross through the torque winding. Fig. 2(b) shows the distribution of magnetic field in the proposed BSRM where currents input to the torque winding and suspension winding. It can be seen that the magnetic flux generated by torque winding and suspension winding cross the torque poles and suspension poles respectively, and the physical decoupling are realized. If the current is inputted to two suspension windings in series on y-axis, the magnetic fields of two airgaps on y-axis are strengthen and weaken according to the direction of current, respectively, and the suspension force will be generated. Fig. 2(c) and Fig. 2(d) show the decoupling characteristics of suspension winding and torque winding. When 2A current is input to the torque windings, if the current input to suspension windings changes among 0A and 4A, the variation of torque is small, as shown in Fig. 2(c). When 1.5A current is input to the suspension windings, if the current input to torque windings changes among 0A and 4A, the variation of suspension force is small, as shown in Fig. 2(d). So the coupling of the torque wingding and suspension winding is weak, and the torque and suspension force could be controlled separately. CONCLUSIONS: In this paper, a novel BSRM with axial split phase inner stator PM structure is proposed to realize the physical decoupling of the torque winding and suspension winding, and improve the power density of the BSRM. The topology and operation principles of the proposed BSRM are introduced. Moreover, the electromagnetic characteristics, such as torque, suspension force and decoupling are analyzed by FEM to verify the performance superiority.

ER-06. Analysis of a Multi-Phase Bearingless PMSM With Double-Winding Based on MMF.

Y. Qin[1] and H. Zhu[1]
1. Jiangsu University, Zhenjiang, China

I. INTRODUCTION Bearingless motors have wide application prospects in high-purity and high-speed areas for the virtues of no wear and lubrication [1]. And, multi-phase motors have higher torque density, lower torque ripple and superior fault-tolerant operation when compared with three-phase motors [2]. So, the multi-phase bearingless motors combining the advantages of bearingless and multi-phase motors have better performances and higher reliability. Compared with the integer-slot concentrated-winding (ISCW) topology, the multi-phase fractional-slot concentrated-winding (FSCW) bearingless permanent magnet synchronous motor (BPMSM) has higher torque density and smaller torque ripple [3]. However, the air gap magnetomotive force (MMF) harmonic distribution in the FSCW BPMSM is quite complex, which will interact with each other to affect the suspension force, so, they must be emphasized and quantified. Hence, a five-phase 10-slot/8-pole (10/8) FSCW BPMSM is proposed in this paper. The principle of the suspension force is elaborated based on the armature and rotor MMF harmonic distribution. And the new general mathematical model of armature MMF is first established in detail based on the winding function method which verified by the finite element analysis (FEA). In addition, the mathematical model of the suspension force is derived based on the Maxwell tensor method. For comparison, a 10-slot/2-pole integer-slot concentrated-winding (ISCW) BPMSM with the same size of outer stator is designed, and the torque and suspension force of the two motors are computed, compared and analyzed. Finally, the dynamic experiments on a prototype are developed to validate the analyses. II. THE MMF OF ARMATURE AND ROTOR There are two groups of armature winding on the stator slot, one is for torque driving (pole pair P_M is 4) and another is for self-suspension (pole pair P_B is 3), as shown in fig.1 (a). The armature MMF is a function of the spatial windings distribution and the phase current, so it generated by suspension force current can be given by $f_s=\sum\sum\sum N_v I_s \cos v[\alpha-\theta(j-1)]*\sin m[\omega t-\theta P_B(j-1)]=5F_{mv}\sin(v\alpha\pm m\omega t)$, $v\pm mP_B=10k$ (k=0,1,2, …) (1) where $\theta = 2\pi/5$, $F_{mv} = N_v I_{sm}$, v and m are the space and current harmonic order. The armature MMF produced by the mth suspension force and torque current has $10k \pm mP_B$ and $10k \pm mP_M$ (k is an integer which makes v as positive integer) harmonic components, respectively. Such as 3rd, 7th, 13th... and 4th, 6th, 14th... generated by suspension force and torque fundamental current, respectively. The rotor MMF will mainly contain the fundamental (4th) components when the surface-mounted permanent magnets (SMPMs) on the rotor are optimized into sine-shape. III. PRINCIPLE OF SUSPENSION FORCE Fig.1 (b) shows that the air gap MMFs can be basically equivalent into 2 types: one is the synthesis $MMF_{r,t,4}$ generated by the 4th rotor and armature MMF, and another is the 3rd armature $MMF_{s,3}$ generated by the suspension force current. The balance of $MMF_{r,t,4}$ is broken by the $MMF_{s,3}$, which produces a constant suspension force $F_{3,4}$. Besides, the amplitude of 6th armature $MMF_{t,4}$ is only 1.5% of the $MMF_{r,t,4}$, so the suspension force $F_{6,7}$, $F_{13,14}$ and etc. can be negligible in this paper. The radial suspension force is the resultant force of controllable suspension force F_c and unilateral magnetic force F_u. In the case of rotor eccentricity, and according to the Maxwell stress tensor method, the x- and y-axis components of the resultant radial suspension force F_x and F_y can be expressed as $F_x=F_c+F_u=k_m(i_f i_{sd}+i_M i_{sq})+ k_e x$, $k_m=5\mu_0 lrN_1N_2k_mk_b/(2\pi\delta_0^2P_BP_M)$, $k_e=25\mu_0 lrN_1^2k_m^2i_{Mf}^2/(2\pi\delta_0^3P_M^2)$ (2) where N_{mf} and N_s are the turn numbers of equivalent torque windings and suspension force windings, respectively; k_{mw} and k_{bw} are the fundamental winding distribution coefficient of torque and suspension force windings, respectively; l and r represent the stator inner diameter and motor length, respectively. It can be seen from (2) that the controllable suspension force is linear with the suspension force current in unsaturated state. And, the unilateral magnetic force is linear with the eccentric displacement in a small range. So the rotor can be effectively pulled back to the center by controlling the suspension force current. IV. SIMULATION AND EXPERIMENTAL For comparison, a 10/2 ISCW BPMSM with the same size of outer stator is designed, the comparison results are shown in Fig. 2 at the same armature current. When the motor speed is 3000 rpm, the average torque and torque ripple of the five-phase 10/8 FSCW BPMSM are 4 times and 34% of the 10/2 ISCW BPMSM, respectively. And the average controllable suspension force and its ripple of the former are 101.5% and 88.7% of the latter which is in accordance with the mathematical mode. Note that the five-phase 10/8 FSCW BPMSM is easy to realize the stability control because of its suspension force ripple is smaller than the 10/2 ISCW BPMSM. At last, a prototype of the five-phase 10/8 FSCW BPMSM is designed and experiment to verify the feasibility of the proposed motor. V. CONCLUSION The five-phase BPMSM has higher torque density and lower torque ripple when compared to the traditional three-phase BPMSM. Besides, the performance of FSCW topology is superior to ISCW topology. And with the capability of the fault-tolerant performance, the proposed motor will have a wide prospect in the future.

ER-07. Design and Control of Radial Homopolar Hybrid Magnetic Bearing.

A. Roshanzamir[1] and B. Kwon[1]

1. Electronic Systems Engineering, Hanyang University, Ansan-si, The Republic of Korea

1. Introduction Now a day the magnetic bearing system used in vacuum technology, machine tools, turbomachinery, artificial heart system etc. The use of magnetic bearing is rising day by day because of some advantages compared to mechanical bearing such as control capability, contactless, long life and has no lubrication [1,2]. In spite of the fact that the magnetic bearing has much superiority, it can make some weaknesses such as hysteresis loss, needing bias current and back up bearing to protect the rotor [3]. Magnetic bearings are categorized into three main structures such as Passive Magnetic Bearing(PMB), Active Magnetic Bearing(AMB) and the last but not the least is Hybrid Magnetic bearing(HMB). [4]. PMBs levitate rotor by using permanent magnets which mostly use as the backup bearing or axial bearing. Radial Magnetic bearings are classified by Heteropolar and Homopolar configurations. The Heteropolar Magnetic bearings have more applications because of easy produced and low cost, but if we need more efficiency Homopolar configuration must be used. The hysteresis loss, eddy current loss, rotational loss, and field variation can be reduced by using homopolar configuration bearings. HMBs use a permanent magnet to generate bias flux and electromagnet to control the flux to reduce copper loss and price of power amplifier [3,5]. In control point of view magnetic bearing is difficult to control because the system is nonlinear, time variant, multi input-multi output, and strongly unstable that's why we must use the robust controller. [6,7]. This paper proposed a new Radial Homopolar Hybrid Magnetic Bering(RHHMB). In conventional HMB used a permanent magnet to provide bias flux but they need backup bearing to protect the rotor. The proposed RHHMB uses the permanent magnet to generate bias flux and make system safe. Therefore, by using this topology the system does not need the radial backup bearing that causes decrease the size and the weight of the system. Some losses such as hysteresis loss can be reduced because of the Homopolar forming as well, it makes the system more stable and robustness especially in high-speed applications. In the homopolar model, the polarity of the magnetic field is the same as rotor rotating to reduce the hysteresis loss. In this paper, we will consider in radial suspension system by finding the mathematical formulation and design Sliding Mode Controller(SMC) for rotor position control. 2. Topology and working principle The new Radial Homopolar Hybrid Magnetic Bearing(RHHMB) is shown in figure 1. Top view of the RHHMB that shown in Figure1_a, illustrates that the system has four pairs of electromagnets and four pairs of permanent magnets which can produce magnetic force separately. Four pairs of permanent magnet used as radial backup bearing and bias flux generator. On the other hand, four pairs of the electromagnet can make control flux to levitate the rotor if the system has the disturbance. Sketch view in figure1_b can be shown the homopolar configuration and magnetic flux of the poles. If the system has disturbance in direction the air gap in the same axis will be decreased and magnetic force will be increased on the opposite side air gap and magnetic force will be increased and decreased respectively, on that time control flux will be provided by electromagnets to counteract the variation of magnetic force and keep the rotor in the central position. Each pair of permanent magnets make attractive force independently, regarding angle between each pair in the normal condition without disturbance all forces counteract each other therefore rotor place in the central position, the total force calculates $F_{x,y}=(F_1+F_2)-(F_3+F_4)$ where $F_{1\sim4}$ are first, second, third, and fourth pair of permanent magnet respectively. So, it can be used as radial backup bearing and can generate bias flux for radial axis as well. Both permanent magnet and electromagnet always generate the magnetic field in the same polarity as rotor rotating which can reduce hysteresis loss. 3. Mathematical Modelling & Control Design The mathematical formulation of the system is found by using the equivalent circuit of the system. Assume that the rotor moves in x-direction so: $F_x=(\mu_o A_{go})/2\ [N^2\ ((i_p^2/(L_{go}-x)^2 - (i_p)^2/(L_{go}+x)^2) + (\sqrt{2}\ (f_m^2)/(L_{go}-\sqrt{2}/2\ x)^2 + (\sqrt{2}\ (f_m)^2)/(L_{go}+\sqrt{2}/2\ x)^2]$ (1) Where F_x is the magnetic force in the x-direction, F_m is the magnetomotive force, x is displacement, μ_o, A_{go}, i_p, L_{go}, and N are vacuum permeability, cross-section area, control current, air gap and number of turn respectively. By using Taylor series for linearization: $F_{tot}=K_r\ X+K_i\ i_p$ (2) Since that the magnetic bearing is nonlinear system and inherently unstable we should design a robust nonlinear control system. In this paper, Sliding Mode Controller(SMC) has used the controller for the RHHMB system which is four degrees of freedom. We suppose that the system in vertical condition and has two RHHMB as upper and lower bearings. Rotor displacement by using SMC for the system is shown in figure 2.

ER-08. Study on propulsion force characteristics by improving distance between the coils and excitation method in permanent magnet-HTS hybrid magnetically levitated conveyance system.

T. Inui[1], Y. Takaki[1], H. Sasaki[1] and S. Ohashi[1]
1. Electrical and Electronic Engineering, Kansai University, Suita, Japan

Conventional conveyance systems using wheels and belt conveyors occur friction and wear at the contact portions. And vibration, noise and dust occur. In order to solve these problems, a noncontact conveyance system has been developed. In this research, a permanent magnet repulsion levitation system and superconducting magnetic levitation system are adopted. The permanent magnet repulsion levitation system cause a large levitating force at the loading part. Superconducting magnetic levitation system cause a stable levitation at the carrier body. There is no influence of large load weight on the levitation of the carrier because the loading part and the carrier body are connected by the linear way. The carrier moves above the magnetic rail. The coils are installed on magnetic rail, and the magnetic field gradient is generated by the exciting coils. The carrier is propelled by the magnetic field gradient. By increasing the flux of the coil behind the HTS in the propulsion direction and reducing the flux of the HTS in the propulsion direction, magnetic field gradient is generated and the carrier propels. The coil pitch is optimized and propulsion force is examined by adding the exciting coils [1] ~ [4]. Fig.1 shows the experimental device. The change of the magnetic field gradient is analyzed when changing the coil pitch by 5mm in the range of 25~50mm with the magnetic analysis software JMAG-Designer. Also, the propulsion force is measured. Experimental condition is as follows; current of the coil I=2.0A and levitation gap g=23mm. The propulsion force is measured at interval of 5mm in the range of -25~25mm. The center of the two coils is defined as x=0. The propulsion force is measured by the load cell installed in front of the carrier. From the analytical result, when the coil pitch is changed, the position of peak value of the flux density due to the magnetization and demagnetization on the magnetic rail changes, but the crest value of the magnetic field gradient is not changed. In the range of coil pitch 40~50mm, the excitation coils are separated. The flat section is formed between the positive peak value and the negative one in the magnetic gradient field. Thus, in the z-axis direction, the surface flux density of the HTS is the strongest at the center. Fig.2 (a) shows the average value and the maximum value of the propulsion force at each the coil pitch. At the coil pitch 50mm, both the average propulsion force and the maximum propulsion force are largest. As a result, the optimum value of the coil pitch under the HTS is 50mm. Center of the HTS keeps the largest flux from HTS. The coils are arranged on the magnetic rail at the coil pitch 50mm, as the diameter of the coil used in this research is 22mm, only the odd number coil in Fig.1 (b) will be installed. Thus, the excitation switching interval becomes large. Thus, as shown in Fig.1 (b), coils are installed at intervals of 25mm. At first, No.1 coil and No.3 coil in Fig.1 (b) are excited. Next, their excitation is stopped, and No.2 coil and No.4 coil are excited. Then their excitation is stopped, and No.3 coil and No.5 coil are excited. In this way, the coils to be excited are switched, and coil pitch 50mm is realized. Next, the case of exciting the coil between the two excited coils is considered. No.1 coil shown in Fig.1 (b) is magnetized, No.2 and No.3 coils are demagnetized. The flux density in the y-axis direction at that time is analyzed with the magnetic analysis software JMAG-Designer. In the range of x=-20~20, the flux density in the y-axis direction in three excitation coil case is smaller than that in two excitation coil case. As the magnetic rail is composed of Halbach array, the y-axis direction flux density is strong on the magnetic rail. Therefore, the change of the flux due to the excitation of the coil tends to occur in the y-axis direction. The propulsion force is compared when exciting two coils at intervals of 50mm with the propulsion force when three coils are excited at intervals of 25mm. No.1 coil in Fig.1 (b) is magnetized, No.2 and No.3 coils are demagnetized. The load weight 0, 19.6, 39.2, and 58.8N is placed on the carrier. Fig.2 (b) shows the maximum propulsion force for each load weight. Larger propulsion force is given when No.1, No.2 and No.3 coil in Fig.1 (b) are excited at all load weight. This is because the range of the magnetic field gradient is increased by adding a coil to be excited. In the case of three coils excitation, as the change of flux density in the y-axis direction is large, it is necessary to consider the magnetic gradient field in the y-axis direction. In the case of two coils excitation, it is suitable to install the coils at intervals of 50mm so as to catch the center of the HTS. In addition, in the case of three coils excitation the propulsion force increases by generating a gradient in the flux density in the y-axis direction.

Abstract—In this paper, one novel heteropolar radial hybrid magnetic bearing (HRHMB) with double-layer stator is proposed for flywheel energy storage system (FESS). Firstly, its topology and working principle are introduced in details. Then, some main dimension parameters are optimized to improve its suspension performance based on the equivalent magnetic circuit (EMC) and three-dimension finite element analysis (3-D FEA). Finally, the comparison of main performance indexes between the proposed HRHMB and conventional one under the same constraints is made, such as displacement stiffness, current stiffness and iron loss. It indicates that the novel HRHMB has smaller displacement stiffness, larger current stiffness and lower rotor iron loss, which is more suitable for high-speed FESS. *Index Terms*—Heteropolar radial hybrid magnetic bearing (HRHMB), double-layer stator, flywheel energy storage system (FESS), equivalent magnetic circuit (EMC), three-dimension finite element analysis (3-D FEA). I.Introduction Traditional heteropolar radial hybrid magnetic bearing (HRHMB) with eight poles has been widely applied in high-speed applications, such as flywheel energy storage system (FESS), because of its simple structure, low power loss, high critical speed, *etc*. [1]. However, this topology suffers large displacement stiffness, magnetic coupling, and non-negligible rotor iron loss, which are harmful to its stable suspension and cooling [2]. With the development of magnetic bearing technology, many studies in the new structures of HRHMB have been conducted to improve its performances. Recently, one HRHMB with only four active magnetic poles, which has less alternating frequency of magnetic field and low power loss, has been studied in [3]. However, the introducing of second air gap in X-axis would increase the needed control current and thus reduce its current stiffness. To overcome these drawbacks, one novel HRHMB with double-layer stator is proposed in this paper, whose pole number is reduced from eight to four without introducing the second air gap. Such improvement could reduce the displacement stiffness, rotor iron loss, and magnetic coupling, while the control flux and current are unaffected. Thus, the novel HRHMB is especially suitable for high-speed and low-loss situations, such as the FESS. II.Configuration and Working Principle The configuration of the proposed HRHMB is shown in Fig. 1. From this figure, it can be seen that the stator consists of two parts, namely, X (upper) and Y (lower) stators. Each layer of the stator includes two poles, which is distributed in one dimension. Meanwhile, each pole is wounded by a coil, which is used to produce the control flux. Four permanent magnets (PMs) are located between X and Y stator teeth, and X and Y stators are separated by PMs and PM ring. The bias-flux consists of two parts: one part is closed through PMs, X and Y stator teeth, air gap and rotor, while another part is closed through PM ring, X and Y stator, air gap and rotor. And the control-flux is closed through X/Y stator, air gap and rotor respectively. For limited space, more details will be given in the full paper. III.Electromagnetic Optimization In this section, some refinement specifications for the proposed HRHMB are given. Moreover, the HRHMB are optimized to improve its suspension performance based on EMC and 3-D FEA. More details will be given in the full text. IV.Performance Comparison A.Displacement Stiffness and Current Stiffness The force-displacement and force-current curves for both machines are shown in Fig. 2(a) and Fig. 2(b). From this figure, the stiffness is obtained by calculating the slope of curve. Compared with the conventional HRHMB, the displacement stiffness for novel HRHMB can be reduced from 1.36 to 0.87 N/μm and the current stiffness for novel HRHMB can be increased from 179.2 to 218.5 N/A with the equal coil turns. B.Iron Losses Reducing iron losses is vital to FESS, especially while it is in standby state frequently. As shown in Fig. 2(c) and Fig. 2(d), the rotor iron losses distribution under no load for the two HRHMBs are analyzed at rated speed 20,000 rpm. It can be seen that the rotor iron loss is nearly distributed around the edge of the magnetic pole where magnetic field occurs fluctuation. Besides, the rotor iron losses for Fig. 2(c) and Fig. 2(d) are calculated to be 22 and 5.9 W, respectively. Compared with conventional HRHMB, the rotor iron losses of the novel HRHMB are reduced to 26.8%. V.Conclusion In this paper, one novel HRHMB with double-layer stator has been proposed. In comparison with conventional eight-pole HRHMB, the novel HRHMB with double-layer stator exhibits several merits, as summarized below: 1) In the novel HRHMB, the displacement stiffness (k_d=0.87 N/μm) can be reduced to 64% from that of the conventional HRHMB. In addition, its current stiffness (k_i=218.5 N/A) can be enhanced by 21.9% due to the large area of the magnetic pole. 2) The alternating frequency of bias magnetic flux of the novel HRHMB is decreased from 8 to 4 times, which would greatly reduce the rotor iron loss.

Abstract: This paper presents a floating magnet rotor with a toothed shape in diamagnetic levitation system. The floating rotor is levitated between two pyrolytic graphite sheets to allow for friction-free rotation. The rotor has a special shape with three notches which are evenly distributed on circle direction. The revolution of the rotor is demonstrated by applying a pulsing airflow with a mechatronics cylinder, showing pulse actuation with the minimum speed of 8 r/min. The promising results suggest potential applications of the mechanism toward frictionless sensors and actuators INTRODUCTION: In 1939, the diamagnetic levitation was firstly realized by Braunbek[1] with the levitation of small pieces of graphite and bismuth in a non-uniform strong electromagnetic field. At present, the diamagnetism of the pyrolytic graphite [2] is the strongest of all materials. In a diamagnetic levitation system, the levitated object does not contact with any bodies. In other words, the levitated object is free-friction when the object moves, which is the most valuable point of the diamagnetic levitation system. Diamagnetic levitation system can be used by for sensors [3], actuators[4] and energy harvester[5]. Clara[6] presented an advanced device based on a diamagnetically stabilized levitated permanent magnet for viscosity and density measurements. Gao and Zhang[7] proposed a novel bistable vibration energy harvester using the diamagnetic levitation mechanism. In this paper, a diamagnetic levitation system with a specially shaped rotor was studied. STRUCTURE OF THE DIAMAGNETIC LEVITATION SYSTEM: The diamagnetic levitation system consists of a shell, a lifting magnet (type N35), two pyrolytic graphite (PG) sheets and a floating magnet rotor (type N35) with three teeth, as shown in Fig. 1(a). The rotor has a special shape with three notches which are evenly distributed on circle direction, as shown in Fig. 1(b). The rotor is freely levitated between the two pyrolytic graphite sheets. The gap spacing produced by the levitation serves essentially as an air bearing of the rotor. Because the lifting magnet is cylindrical, the magnetic field distribution is horizontally symmetrical. In this magnetic field, the rotor will be reached to the center position automatically. Two flow-guiding holes are set on the wall of the shell, one is the air inlet, and the other one is the air outlet. The height of the two holes is equal to the levitation height of the rotor. When the airflow enters the cavity through the air inlet, the rotor will be driven by the airflow and rotate around the centerline of the lifting magnet. EXPERIMENT: To explore the rotational behavior of the levitation rotor, a simple experiment was implemented. In the experiment, a 10 ml syringe was used as an air pump, and the syringe piston was fixed on the tip end of the shaft of a mechatronics cylinder (SCN5, Dyadic systems co., Ltd) which consists of a rotary-linear motion transfer mechanism, a stepper motor, an encoder, and a servo controller. By controlling the mechatronics cylinder, the shaft can do the reciprocating linear motion. So pulse airflow will be produced by the syringe. A hose with an inner diameter of 1.5mm was attached to the syringe. One end of the hose positioned close to the rotor. The stroke of the reciprocating linear motion of the shaft was set to 60mm. With the reciprocating linear motion of the syringe piston, the rotor will be driven by airflow. The speed of the rotor was measured with a laser speed sensor (ERS-1, Expert Technology Co., Ltd). The relationship between the velocity of the syringe piston (v) and the rotating speed of the rotor (ω) is shown in Fig. 2. When v is smaller than 50mm/s, the rotor cannot be driven; when v is approximately 50mm/s, the rotor simply waggled between the two graphite sheets without producing rotational motions; When v is larger than 50mm/s, the rotor is driven to rotate. If the airflow is continuous, the rotor can be driven by a smaller flowrate. When v is approximately 450mm/s, the increment of the speeds of the floating rotor gradually reduced. Since the maximum velocity of the mechatronics cylinder is 450 mm/s, only 9 groups of data tested were obtained. CONCLUSIONS: The basic actuating mechanism of a magnet rotor diamagnetically levitated was explored in this paper. The feasibility of the floating magnet rotor was verified, and the rotation characteristic of the floating rotor was studied by experiment. The minimum speed of the rotor was 8 r/min when the velocity of the mechatronics cylinder was 50mm/s, which is the minimum velocity that can drive the rotor to rotate. In the future, some more accurate experiments with continuous airflow and a high precision flowmeter will be carried out to further understand the characteristics of the floating magnet rotor. The floating rotor in diamagnetic levitation system can be used as sensors and actuators. This work is supported by the National Natural Science Foundation of China under grant no.51475436 and the Henan Province Key Project on Science and Technologies under grant no.152102210042.

ER-11. Design and analysis of a centripetal force type-magnetic bearing for a flywheel battery system.

W. Zhang[1], L. Cheng[1] and H. Yang[1]
1. Jiangsu University, Zhenjiang, China

Introduction Flywheel battery, as a new energy storage device in recent years, it has the characteristics of high current charge-discharge capability, very short charging-discharging time, good environment adaptation, high energy conversion efficiency and long cycle life[1-2]. Flywheel battery technology is relatively mature after years of development, including the applications in electric vehicle systems. For a vehicular magnetically flywheel battery, the gyroscopic effect can be caused by the different driving conditions and the road conditions of the vehicle. Therefore, the flywheel battery has very strict requirements for bearings. The most popular magnetic bearings today are the magnetic bearings with cylinder structures, which have many industrial applications [3-4]. However, an inevitable unbalanced magnetic pull parallel (The pull can be considered as a disturbance force) to the axis of the rotor will be produced when the rotor is deflected. The disturbance force and the resultant disturbance torque to the rotor will accelerate the gyroscopic effect and it is very bad for the stability control of the flywheel battery. In this paper, a novel centripetal force type magnetic bearing (CFT-MB) for a flywheel battery system is proposed. Whether the rotor is shifted or deflected, the magnetic force will point to the centre of the rotor because of the centripetal force, which can substantially reduce the interference force and torque. New Topology As shown in Figure 1, the CFT-MB is a radial magnetic bearing(2 DOF CFT-MB) and it is made up of two mirror symmetrical stators with three poles, six radial control coils, a rotor, some aluminum rings or blocks for flux-insulation (an outer aluminum ring, a inner aluminum ring, three central aluminum blocks), and three permanent magnets. The overall topology of the CFT-MB is a section body of structure of spherical. There are three spherical envelopes in a bearing. They are shell envelope, poles envelope and rotor envelope. Six stator poles are spherical structure and their spherical points are coincided, which constitutes a spherical envelope. The spherical rotor is located in the in the centre of the spherical envelope formed by the stator magnetic poles. The center of the rotor is coincident with the centre of the spherical enveloping surface formed by the stator poles, which forms the spherical gas gap between them. Stators and rotor are made of stacked silicon steel sheets. There are three pieces of non-complete axial-magnetized permanent magnets distributed on the circumference within 120 degrees due to the spherical envelopes. Each piece of permanent magnet is sandwiched between two mirror symmetrical poles. The three central aluminum blocks are also distributed on the circumference within 120 degrees, which is a complementary way of placement with permanent magnet to make a full ring. The material of permanent magnet is Neodymium-iron-boron (Nd-Fe-B). Results In order to verify the proposed flywheel, the finite element method is used to analyze the electromagnetic characteristics of the proposed magnetic bearing. As shown in Fig.2, when the rotor reaches its displacement of 0.05mm in x direction and rotation of 0.5 degrees around the x axis, the interference torque of the cylindrical magnetic bearing-rotor is -3.5047mN.m, the interference torque of spherical magnetic bearing-rotor is –1.59830mN.m. The interference torque produced by cylindrical magnetic bearing-rotor is as much as 2.2 times of that of spherical magnetic bearing-rotor for the complex motion. The magnetic pull of the cylindrical magnetic bearing-rotor is as much as 3.5 times of that of spherical magnetic bearing-rotor for the complex motion. The tests results have shown that the final stationary values of magnetic pull and even torque of the CFT-MB are far more advanced than that of the cylindrical magnetic bearing-rotor, which show the superior performance of the CFT-MB.

ER-12. Proposal of New Superconducting Magnetic Bearing Using High Tc Superconducting Bulk and Coil.

M. Komori[1], K. Yamanaka[1], K. Asami[1] and N. Sakai[1]
1. Kyushu Institute of Technology, Kitakyushu, Japan

1. INTRODUCTION Recently, magnetic levitation techniques have been developed for various fields such as energy storage flywheels[1] and magnetically levitated vehicles[2]. The magnetic levitation techniques are very useful because of friction free, energy-loss free, etc. Thus, there are many reports about levitation techniques using high critical temperature (*T*c) superconducting magnetic bearings (SMBs) [3]-[5]. SMBs are composed of superconducting (SC) bulk and permanent magnet (PM). These SMBs are based on pinning forces between SC bulk and PM. In this paper, new SMBs composed of SC bulk, SC coil and PM are proposed. *2. SC BEARING AND EXPERIMENTAL METHOD* *2.1 SC bearings* In this paper, we propose two types SC bearings Type-I and Type-II. Both SC bearings are composed of SC bulk, SC coil and PM. The levitation is performed using pinning force between SC bulk and PM. The schematic illustration of the SC bearing Type-I is shown in Fig.1-1. A neodymium (NdFeB) PM with a diameter of 27 mm and a thickness of 3.4 mm is used. The SC bulk ($Dy_1Ba_2Cu_3O_X$, J_c=3 $\times 10^8$ A/m^2 at 77 K and 1.0 T) is 44 mm in diameter and 7.5 mm in thickness. The yttrium type SC coil (I_c=150A) is 35mm in inner diameter, 38mm in outer diameter and 5mm in thickness with four turns. *2.2 Experiment method* After the PM is put on a mechanical support, the SC bulk and the SC coil are field-cooled using liquid nitrogen. Then, the PM is levitated by pinning force after the mechanical support is removed. In order to study the levitation characteristics by pinning force, impulse responses for the levitated PM are performed in the vertical direction as shown in Fig.1-2. Impulse forces are applied to the PM using a small hammer (D1.8mm xL33.5mm, 0.73g) made of brass. Then, damped free vibrations of levitated PM are measured using a laser displacement sensor. Supposing that the SC bearing is represented by a mechanical model with a spring and a damper, stiffness *k* and damping coefficient *c* are calculated using impulse responses. *3. EXPERIMENTAL RESULTS AND DISCUSSIONS* In the experiments, the SC bearing with SC coil is compared with the SC bearing without SC coil. The distance between SC bulk and PM is changed in the range of 7mm, 8mm, 9mm. At each distance, impulse responses for the SC bearing without SC coil are performed, and the results are shown in Fig.1-4. The displacement amplitude for each distance of 7mm, 8mm, 9mm decreases gradually as the time increases. Especially, It is found that the displacement amplitude at a distance 7mm decays to zero within 2.0s. Impulse responses for the SC bearing with SC coil are shown in Fig.1-5. The displacement amplitude for each distance of 7mm, 8mm, 9mm decreases rapidly. Especially, the amplitude at a distance 7mm decays to zero within 0.3s. The damping for the SC bearing with SC coil in Fig.1-5 is larger than that in Fig.1-4. Stiffness and damping coefficient are calculated using the damped free vibration curves in Figs.1-4 and 1-5. Fig.2-1 shows the relationships between (a) stiffness and distance and between (b) damping coefficient and distance for three cases. In the figures, white circle, black circle and triangle show SC bearing without coil, SC bearing with coil and coil effect, respectively. The coil effect means the difference between SC bearing without coil and SC bearing with coil. Fig.2-1(a) shows that the stiffness with coil and that without coil decrease as distance increases. The coil effect on damping coefficient is not so large. Fig.2-1(b) shows that the damping coefficient with coil and that without coil is almost constant as the distance increases. Thus the coil effect on damping coefficient is not so large. As a result, the SC bearing Type-I is not effective on the damping coefficient. As shown in Fig.2-2 the SC bearing Type-II is proposed to compare with the SC bearing Type-I. The SC bearing Type-II is composed of a SC bulk with 24 mm in diameter and 10 mm in thickness, a SC coil and a PM. The SC coil and the PM are the same as the SC bearing Type-I. Impulse responses for the SC bearing Type-II are performed in the range of 7 mm, 8 mm and 9 mm. The experimental method is the same as that for the SC bearing Type-I. The experimental results for the SC bearing Type-II show the relationships between (a) stiffness and distance and between (b) damping coefficient and distance as shown in Fig.2-3. In the figures, white circle, black circle and triangle show SC bearing without coil, SC bearing with coil and coil effect, respectively. Fig.2-3(a) shows that the stiffness with coil and that without coil decreases as distance increases. The coil effect (triangle) on stiffness is rather large compared with Fig.2-1(a). Fig.2-3(b) shows that the damping coefficients with coil and that without coil decrease as the distance increases. The damping coefficient with coil is very larger than that without coil. As a result, the SC bearing Type-II is more effective on the damping coefficient than the SC bearing Type-I. *4. CONCLUSION* In order to compare the SC bearings Type-I and Type-II, impulse responses are performed. Then, damped free vibration curves for impulse responses are observed. The SC coil is effective for the SC bearings Type-II. The damping coefficient for the SC bearing Type-II is larger than the Type-I. From the experimental results, both stiffness and damping coefficient for the SC bearing Type-II are improved compared with the Type-I.

ER-13. Design and Analysis of a Magnetic Levitation Voice Coil Actuator for Multi-Degree-of-Freedom High-Precision Positioning System.

Y. Zhou[1], B. Kou[1], H. Zhang[1], F. Xing[1] and X. Yang[1]

1. School of Electrical Engineering and Automation, Harbin Institute of Technology, Harbin, China

I. INTRODUCTION Multi-degree-of-freedom high-precision positioning system (MHPS) is one of the key technologies in many advanced industrial applications [1-2]. In general, the MHPS can be realized by three solutions: stacking linear actuators, planar actuators [3-4], and combining coarse positioning module (CPM) and fine positioning module (FPM) [5-11]. Benefiting from the two-module structure, the third solution becomes a widely adopted scheme, which can simultaneously satisfy the requirements of long stroke and high accuracy. Among various FPMs, the magnetic levitation fine positioning module (MLFPM) is considered to be the state of the art because of its feature of no mechanical contact. In the MLFPM, a stage that integrates multiple actuators and sensors is often adopted, in which the actuator is an electromagnet [7-8], or a voice coil actuator (VCA) [9-11]. As a key component, the performance of actuators strongly determines the MLFPM's positioning ability. Compared with single-degree-of-freedom applications, the MLFPM has special technical requirements for the actuators because of its multi-degree-of-freedom motion. When an actuator works in multi-degree-of-freedom, not only its output force in the driven direction will be influenced by the movements in the other directions, but also it will produce parasitic force and torque in the other directions, which will reduce the MLFPM's performance and increase the control system's complexity [12]. Therefore, the actuators used in MLFPMs should be specially designed to be able to output a force which is independent from position, and it is named as force uniformity here. In this paper, we put forward a novel magnetic levitation voice coil actuator using rhombus magnet array (RMA-MLVCA). With the specially designed magnet array, the proposed RMA-MLVCA has the advantage of excellent force uniformity, which makes it suitable for multi-degree-of-freedom applications. II. BASIC STRUCTURE AND OPERATING PRINCIPLE The proposed RMA-MLVCA consists of two components, i.e., stator, and mover, as shown in Fig. 1(a). The stator consists of two rectangular stator coils and a stator frame. The mover consists of a rhombus magnet array and a mover frame. The rhombus magnet array consists of four cubic mover magnets which are arranged on the four edges of a rhombus, and the magnetization of mover magnets are shown as arrows in Fig. 1(b). The RMA-MLVCA works based on the Lorenz force law. When the mover moves around the initial position, the horizontal component of the magnetic field generated by the magnet array interacts with the current in the stator coils, by which the force and torque will be produced. The difference between the RMA-MLVCA and conventional VCAs is that the magnetic field in the RMA-MLVCA is a cluster of hyperbolas. This is the most important reason why the RMA-MLVCA can achieve excellent force uniformity, and it is discussed in Section III. In addition, the MLFPM's load stage will be levitated and positioned using at least six RMA-MLVCAs, as shown in Fig. 1(c). To determine the force and torque of the RMA-MLVCA, the magnetic flux density distribution is required. Considering the six-degree-of-freedom motion, a global coordinate system and four local coordinate systems are defined first. Then, the magnetic field generated by one mover magnet is derived in the corresponding local coordinate system with an equivalent current model, as shown in Fig. 1(d) and converted to the expression in the global coordinate system. Finally, the force and torque can be calculated with Lorenz's force law. III. FINITE ELEMENT ANALYSIS Considering the six-degree-of-freedom motion, a three-dimensional finite element model (3-D FEM) is employed for accurate consideration of the complex magnetic field distribution and asymmetry caused by motion. The six-degree-of-freedom force and torque characteristics are analyzed, as shown in Fig. 2. Then, in order to find a useful optimized method for future design process, the influence of fundamental parameters are also analyzed. IV. EXPERIMENTAL VERIFICATION To validate the performance of the RMA-MLVCA, experiments are conducted on a prototype. The test platform for measuring force characteristics of the RMA-MLVCA is composed of a three-degree-of-freedom position adjuster, a force sensor, a high-precision multimeter and a support, as shown in Fig. 1 (e). Then, the characteristics of the RMA-MLVCA are compared with conventional VCAs. V. CONCLUSION In this paper, a novel RMA-MLVCA has been investigated. The equations of magnetic flux density, electromagnetic force and torque are deduced based on an equivalent current model. Then, its six-degree-of-freedom force and torque characteristics, as well as the influence of structural parameters on force density and uniformity are analyzed by 3-D FEA. To verify the analysis, a prototype has been built and tested. The results show that the RMA-MLVCA possesses the advantage of excellent force uniformity, and is suitable for multi-degree-of-freedom applications.

ER-14. Radial Suspension Forces Modeling for Bearingless Flus-Switching Permant Magnet Motor.

C. Zhao[1] and H. Zhu[1]
1. Jiangsu University, Zhenjiang, China

I. INTRODUCTION Bearingless permanent magnet (PM) motors have advantages of high efficiency, high power density, and no wear, no lubricant and maintenance-free because a magnetic bearing function is magnetically integrated into a conventional motor, the bearingless PM motor is a competitive candidate for high power density [1]. However, the conventional bearingless PM motors usually suffer from the problems of mechanical integrity and thermal instability due to their PMs located in the rotor, which lead to a discount of the maximum electric loading performance. In order to realize stable control of suspending of the BFSPM motor, it is essential to establish a precise mathematical model of radial suspension force [2]. By using the Lorentz force, the analytical radial suspension force and torque equations for parallel magnetized magnets have been derived. As show in Fig. 1, by feeding a suitable current into suspension force windings, the balance and symmetry of rotating magnetic field produced by the torque windings in the motor airgap can be disturbed. In other words, the magnetic fields in some partial areas of the airgap are enhanced and those in the corresponding symmetrical areas can be weakened due to the contribution of suspension current. Thus, the radial resultant force, namely suspension force can be produced in the direction with the enhanced magnetic field. Based on the operation principle of the BFSPM motor in [3], the relative mathematical models have been constructed, including the permeance of airgap, the magnetic motive force (MMF) of torque windings, the MMF of suspension force windings and the MMF of PMs. Then, based on the theory of Maxwell stress tensor, the mathematical models of radial suspension force are derived. And the validity of the mathematical model is proved by finite element analysis (FEA) predictions. It can be concluded that the mathematical model of radial suspension force can reflect the radial suspension force correctly as shown in Fig. 2. The specific derivational process of mathematical model will be shown in the full paper. II. MOTOR STRUCTURE AND OPERATION PRINCIPLE The configuration of the proposed motor is very similar with that of the traditional FSPM motor which adopts a three-phase 12/10-pole (12-stator-teeth and 10-rotor-poles) configuration. The key difference is that there are two sets of windings wound around the stator teeth, namely torque windings and suspension force windings. ϕ_f is generated by the PMs sandwiched in the stator. The suspension magnetic flux ϕ_s generates when *Y-axis* suspension force winding current is excited. When forward current I_1~I_6 flows through relevant suspension force windings, the direction of flux ϕ_s is shown in Fig. 1. The flux density in the top air gap is increased due to the direction of ϕ_f is the same as ϕ_s. Oppositely, the flux density in the bottom air gap is decreased since direction ofϕ_f is opposite to that of ϕ_s. So the flux density in bottom airgap would be reduced while the flux in top airgap enhanced, the radial suspension force generated as shown in Fig. 2. Naturally, this superimposed magnetic field results in the radial suspension force F_y acting on the rotor toward the positive direction in the *Y-axis*. A radial suspension force toward the negative direction in the *Y-axis* can be produced with a negative current. III. MATHEMATICAL MODEL For the proposed BFSPM motor, radial suspension force is generated by the flux density in the air-gap as well as torque, so the air-gap flux density should be calculated. The permeances can be given as: $\Lambda_{srk=}\ \Lambda_0+\Lambda_1\cos(N_r\theta_{0sr}+(5\text{-}2k)N_r\pi/N_s)$, (k=1,2,3,4) (1) where θ_{0sr} is the relative position between the rotor and stator. The maximum flux linkage is obtained when a rotor tooth is aligned with the *d-axis,* i.e., $\theta_{0sr} = \pi/2Nr$. N_r is the rotor tooth number. The air-gap flux density MMF should be composed of three components: the MMF of torque windings $F_{T,}$ the MMF of PMs F_{mag} and the MMF of suspension force windings F_s, The air-gap flux density can be written as: $B_{srk}=(F_T+F_{mag}+F_s)\Lambda_{srk}$, (k=1,2,3,4) (2) The radial suspension force of the BFSPM motor acting on the rotor can be calculated by using the theory of Maxwell stress tensor: $dF_{srk}(\theta)= B_{srk}(\theta,t)^2dS/2\mu_0=B_{srk}(\theta,t)^2lr/2\mu_0d\theta$ (3) where *r* is the outer radius of the rotor, *l* is the stack length of the motor. V. CONCLUSION The calculation results are verified by FEA, and a series of comparisons between the FEA computed and calculated values are conducted, and the results indicate that the calculated values closely agree with FEA results.

INTRODUCTION: In recent decades, bearingless switched reluctance motors (BSRMs) have been proposed [1]. However, few researchers focused on the optimal design of the BSRMs [2-4]. In this paper, the multi-objective optimal design of BSRMs is investigated [5-6]. At first, an analytical design model is derived from the mathematical model of the BSRMs. An initial design is calculated by the analytical design model. Then, the objective functions, constraints, and decision variables are also determined. Corresponding sensitivity analysis of the decision variables such as stator yoke,rotor yoke ,stator pole arc and rotor diameter is implemented. Then, a novel multi-objective atifical bee colony particle swarm optimizer (ABC-PSO) is presented. The proposed ABC-PSO is applied for the optimal design of BSRMs to increase the radial force and efficiency. The electromagnetic performance is compared with the initial design and verified by the FEM. Verification results show that the optimal design of BSRMs based on the analytical design model and the proposed MOGPSO is feasible and effective. PROPOSED MULTI-OBJECTIVE Atifical Bee Colony Particle Swarm Optimizer: The PSO has been proposed and developed in recent decade. The Pareto dominance is used to determine the dominated or non-dominated solutions in all particles, and all non-dominated particles are filtered and stored in a repository during iteration. In order to avoid the particles falling into local optimums, a moderate mutation operator was utilized at the beginning of the search. However, with the iteration process, fewer particles are affected by the mutation. This phenomenon may lead to particles trapping into local optimums in the later period of iteration and cannot reach more accurate Pareto front. Hence, the conventional PSO may be not suitable for the multi-objective optimization of the BSRM in this paper. An improvement of ABC-PSO is investigated, and the ABC-PSO is proposed. The ABC-PSO combines atifical bee colony mechanism with the particle swarm optimizer, which can obtain the global Pareto front and avoid converging to the local optimal solutions. OPTIMIZATION OF BSRM: After the validation of the proposed ABC-PSO, it is applied to optimize the BSRM. The optimization variables include stator yoke,rotor yoke ,stator pole arc and rotor diameter, which to enhance efficiency and increase radial force. It is regarded motor's fixed shape as constrained condition. The fig.1 (a) shows the design variables of novel BSRM. Fig1 (b) shows relations between radial force and stator pole arc at different stator yokes. Fig1 (c) shows relations between radial force and stator yokes at different rotor yokes. Fig1 (d) shows relations between radial force and rotor yokes at different rotor diameter. As shown in fig.1, it is complicit to optimize motor. RESULTS: we should provide multiple objectives in line with above requirements: we expect efficiency and levitated force to be larger, but BSRM's fixed shape to be changeless. Fig.2 (a) shows the BSRM's efficiency optimization results with different single variable. Fig2 (b) shows efficiency optimization results with different variables. Fig2 (c) shows multi-objective optimization results with different variables. Fig2 (d) shows the magnetic flux density by 3-D finite element analysis, it can be seen that the proposed ABC-PSO is particularly suitable for solving disconnected, non-uniformly distributed optimization problem.

ES-01. Comparison of the Magnetic Field and Torque Characteristics for Axial Magnetic Gears with Various Permanent Magnet arrays.

X. Liu[1], Y. Zhou[1], D. Wan[1] and Z. Chen[2]

1. College of Electrical and Information Engineering, Hunan University, Changsha, China; 2. Department of Energy Technology, Aalborg University, Aalborg, Denmark

INTRODUCTION Magnetic gears (MGs) could offer some distinct advantages over mechanical gears, such as no lubrication, no maintenance, low acoustic noise, high reliability, long lifetime and inherent overload protection [1-2]. They are particularly attractive for those applications desiring a high speed reduction ratio, such as electric vehicles [3] and wind turbines [4]. Most of the previous work on magnetic gears has focused on the radial field topology because axial magnetic gears (AMGs) are difficult in construction. However, AMGs show superiority in applications requiring hermetic isolation and high torque density. In according to the various arrays of permanent magnets (PMs), the AMG could be classified as the conventional axial field magnetic gear (AFMG), the axial flux focusing magnetic gear (AFFMG) [5], and the axial magnetic gear with Halbach permanent magnet arrays (HAMG) [6]. In this paper, the magnetic field and torque characteristics of the above three AMGs are compared basing on 3D FEM simulation. In addition, the advantages and disadvantages of the three AMGs will be discussed based on 3D finite element analysis. TOPOLOGIES OF THREE AMGs The topologies of three AMGs are shown in Fig. 1. All the three AMGs are composed of three parts, namely, the high-speed rotor, the low-speed rotor and the modulation ring sandwiched between the two rotors. The difference of the three topologies lies in the magnetization modes of PMs. The PMs of the AFMG are magnetized along the axial direction. The AFFMG consists of PMs magnetized along the azimuthal direction. The HAMG has different orientations of PM pieces. For the HAMG, the numbers of PMs per pole on the high-speed rotor and the low-speed rotor are equal to 3 and 2, respectively. For the three topologies, the numbers of pole pairs on two rotors are respectively 4 and 13 and the number of the modulator pieces is 17. In order to carry out a fair comparison, the same radius of 70 mm and axial length of 45.5 mm are applied for all the three topologies. Magnetic HARMONICS ANALYSIS In order to clarify the torque transmission abilities of the three AMGs, the axial spatial harmonic components of the magnetic field of the three AMGs are firstly studied. Fig. 2(a), Fig. 2(b) and Fig. 2(c) show the axial spatial harmonic components in the air gap adjacent to high-speed rotors of three AMGs. According to the PM pole pairs on the high speed and low speed rotors, the harmonic components with 4, 13, 21, 30, 38 and 47 pole pairs are effective harmonics which may contribute to torque transmission. These effective harmonics match well with the major harmonics in the harmonic spectrum shown in Fig. 2(a), Fig. 2(b) and Fig. 2(c). The harmonic components shown in Fig. 2(c) with 12, 20, 29 and 36 pole pairs are decreased which may cause torque ripples and iron losses compared with Fig. 2(a) and Fig. 2(b). The axial spatial harmonic components in the air gap adjacent to low-speed rotors of three topologies are shown in Fig. 2(d), Fig. 2(e) and Fig. 2(f). The harmonic components with 4, 13, 21, 30, 38 and 47 pole pairs are effective harmonics contributing to torque transmission in the air gap adjacent to low-speed rotors. These effective harmonics match with the major harmonics in the harmonic spectrum shown in Fig. 2(d), Fig. 2(e) and Fig. 2(f). The 13th harmonic components shown in Fig. 2(e) and Fig. 2(f) are significantly improved compared with Fig. 2(d). Compared with Fig. 2(d) and Fig. 2(e), the harmonic components shown in Fig. 2(f) that are the source of torque ripples and arouse iron losses in the ferromagnetic modulator pole-pieces are suppressed. TORQUE TRANSMISSION The maximum static torques of the AFMG, AFFMG and HAMG are 47.5 Nm, 55.2 Nm and 55.5 Nm, respectively. Compared the AFMG, the maximum static torque of the other two topologies has a growth of 17%. However, the PM consumption of the AFFMG is only 87.5% of that of the other two topologies, which implies a higher torque/cost ratio for the AFFMG. CONCLUSION The 3D FEM simulation results show that the HAMG could offer lower torque ripple and higher effective magnetic harmonics than the AFMG and the AFFMG. Both the HAMG and the AFFMG could offer 17% higher output torque than the AFMG. The AFFMG may achieve highest permanent magnet utilization. The specific comparison on the magnetic field and torque characteristics of the three AMGs and the 3D FEM simulation results will be presented in detail in the full paper.

ES-02. Investigation of the Torsion and Vibration Characteristics of a Dual-Flux-Modulator Coaxial Magnetic Gear.

X. Liu[1], Y. Zhao[1], Z. Chen[2], D. Luo[1] and S. Huang[1]

1. College of Electrical and Information Engineering, Hunan University, Changsha, China; 2. Department of Energy Technology, Aalborg University, Aalborg, Denmark

I.Introduction Coaxial magnetic gear (CMG) is a promising power transmission device, which could realize non-contact torque and speed transmission by the interaction of the modulated magnetic fields in the air-gaps [1]. The CMG takes the advantages of low friction loss, minimum acoustic noise and no maintenance. The dual-flux-modulator coaxial magnetic gear (DFM-CMG) presented in [2] shows a higher torque capability, comparing to other CMGs. However, the DFM-CMG works like a torsion spring and the torsional stiffness of the conventional CMG is lower than that of the mechanical gearboxes [3]. Although the steady-state performance of the DFM-CMG has been studied by using the analytical model method and finite-element method (FEM) [2], the torsion properties and vibration characteristics of the CMG has not yet been studied in depth [4]. Moreover, the DFM-CMG has the drawbacks of vibration caused by electromagnetic force (EMF) generated by the interaction between the pole-pieces of the auxiliary flux modulator and the two rotors compared with conventional CMGs, which will affect the overall vibration performance significantly. Motivated by this, the presented research mainly focuses on the torsion properties and vibration characteristics of the DFM-CMG. In this paper, firstly, electromagnetic finite-element (FE) model and analytical model of the DFM-CMG are developed to analyze the torsion properties. Then, the torsion properties of a DFM-CMG prototype are tested to validate the simulation results. Finally, a multi-physics simulation model is established to calculate the radial displacement caused by the EMF and the vibration characteristics of the DFM-CMG. II.Modeling and torsional performance of the DFM-CMG Fig. 1(a) shows the topology of the DFM-CMG. The DFM-CMG employs surface-mounted permanent magnets (PMs) on the inner rotor but adopts spoke-type PMs on the outer rotor. A stationary auxiliary flux modulator is introduced in the outermost layer of the DFM-CMG [2]. The studied DFM-CMG in this paper has 4 pole-pairs for the inner rotor (p_{in}) and 26 pole-pairs for the outer rotor (p_{out}), which has a theoretical gear ratio of 6.5. The magnetic torque exerted on the inner are calculated by Maxwell 3-D static magnetic solver. The calculated static pull-out torque on the inner rotor is 30Nm. Afterwards, an analytical torsional model of the DFM-CMG is established. In the torsion properties model, the outer rotor was locked to standstill, while the inner rotor was connected to sudden application of a load torque. Fig. 1(b) shows a photograph of the test rig for the torsion properties measurement, where the relative angular position was measured by an encoder. The initial torque is fixed to 10.7Nm and the total moment of inertia J with inner rotor, rod and load is 0.405kgm^2. The torsion properties of the inner rotor could be estimated by calculating the developed model. Fig. 2(a) and (b) present simulation and experimental load angle of the inner rotor under a sudden load of 5Nm at t=0s. As could be seen, the end load angle θ obtained from simulation and experiment reaches a value of 6.95° and 6.92°, respectively. This discrepancy is due to the resolution of the encoder and the compromises made on the structure design. Moreover, the simulated oscillation period T=0.38s agrees well with the experimental results of T=0.37s as shown in Fig. 2(a) and (b). In the torsion properties analysis, two of the most important parameters are the torsional stiffness K and coefficient of damping B. The K and B of the inner rotor in experiment are K=116Nm/rad and B=2.36Nms/rad that are very close to the simulation results K=120Nm/rad and B=2.4Nms/rad, respectively. III.EMF and vibration characteristics of the DFM-CMG In the DFM-CMG, the inner rotor and main flux modulator are very similar to those of conventional CMG. However, the spoke-type pole-shoes and the auxiliary flux modulator are relatively unique. Firstly, the multi-physics models for EMF, structural displacement and vibration are developed by using the software ANSYS Workbench. Then, the flux densities in the three air gaps are obtained by Maxwell 2-D transient magnetic solver. The Maxwell stress tensor method is used to calculate the EMF [5]. Fig. 2(c) and (d) present the transient distribution EMF acting on each pole-piece of auxiliary flux modulator and their time harmonic spectra at no load and rated load, respectively, when the speeds of inner rotor and outer are 650rpm and -100rpm. The average radial forces for each pole-shoe of the auxiliary flux modulator are 316N and 201N at no load and rated load conditions. The first largest frequency of the EMF is $2\mu p_{in} f_{in}$=86.67Hz (f_{in} is the frequency of the inter rotor and μ=1, 2,...). Finally, the distribution of the EMF obtained from the electromagnetic model is loaded to the surface of the auxiliary flux modulator and spoke-type pole-shoes in the 3-D structural FE model of the DFM-CMG. Modal superposition method is adopted to calculate the vibration by using the software ANSYS Workbench. The detailed analyses on the structural vibration characteristics of the spoke-type pole-shoes and the auxiliary flux modulator under different operation conditions, will be presented in the full paper.

ES-03. Torque Parameter Characteristics of Non-contact Magnetic Coupling considering Rotor Volumetric Modeling.

J. Park[1,2], K. Lee[1], S. Lee[1] and S. Jung[2]
1. Korea Institute of Industrial Technology, Gwangju, The Republic of Korea; 2. School of Electronics and Electrical Engineering, Sungkyunkwan University, Gwangju, The Republic of Korea

Magnetic couplings that transmit torque without mechanical contact are widely used in underwater electrical machines. It is advantageous to increase the reliability of the underwater structure and to reduce the maintenance cost by utilizing the air gap between the inner rotor and outer rotor. However, most commercial magnetic couplings are larger in size than their capacities. Magnetic coupling is a major component that affects the size of underwater electrical system, and research on miniaturization and weight reduction is needed. The structure of the magnetic coupling is classified into a radial flux type and an axial flux type. In the case of an underwater electric propellant, the radial magnetic flux type is more advantageous because the magnetic coupling and the propeller are integrated. In addition, the radial magnetic flux type ensures sufficient air gap and torque for waterproof structure inside the underwater electrical system. Magnetic couplings of radial flux type have been studied to derive torque characteristics with analytical magnetic field calculations [1-2]. In this study, we derive the torque by calculating the relationship between the inner rotor and the outer rotor as parameters by using the electromagnetic transfer relation method. Through the derived equation, the torque per rotor volume of the magnetic coupling is calculated and the rotor volume design is presented according to the relation of rotation speed, torque and output power. The volume design results using the torque parameters were confirmed to be similar to those of the finite element analysis results. Finally, the magnetic couplings of 2[kW] output power were fabricated to reflect the volume design results and the validity of rotor volume modeling was verified through testing. Fig. 1(a) shows the structure of a magnetic coupling used in an underwater electric propulsion system. It has a structure of 8 poles in radial flux type, the inner rotor is connected to the gear and the outer rotor is integrated with the propeller. The magnetization and the magnetic vector potential are calculated as the boundary condition of the material region by applying the electromagnetic transfer relation and the magnetic flux density of the air gap region is derived. The torque of the rotor was calculated using the Maxwell stress tensor and the volume design modeling parameter were derived. The main components of the parameters are rotor diameter, lamination, air gap and material properties of permanent magnet. Rotor volume modeling is performed by torque per rotor volume considering rotation speed and output power. Fig. 2(a) shows the rotor volume modeling curve using the torque per rotor volume. Volume curves of the air gap [3mm, 5mm. 7mm] and torque [10Nm, 15Nm, 20Nm] were presented by volumetric modeling according to the rotational speed and output power characteristic of the magnetic coupling. Smaller air gaps and smaller torques confirm that the size is smaller and the volume of the magnetic coupling is optimized using design parameters and volume curves. Next, magnetic coupling was designed through volume modeling and output power characteristics were compared through finite element analysis. Fig. 2(b) shows a photograph of the evaluation system of the magnetic coupling. The magnetic coupling was fabricated to reflect the rotor volume modeling results and the dynamo evaluation system was constructed. The servo motor is connected to the inner rotor of the magnetic coupling and rated at rated speed. The outer rotor was connected to the hysteresis brake to evaluate the load characteristics. It is confirmed that the design results and test results of volume modeling are similar. At the end of this study, we modeled the volume of magnetic coupling by deriving the torque per rotor volume through an analytical method. The volume of the magnetic coupling can be optimized using parameters such as rotor diameter, stack length, air gap, rotating speed, output torque. Furthermore, the size of the underwater electrical system can be further reduced in size and weight by optimizing volume modeling of the magnetic coupling.

ES-05. Modeling and Transmission Characteristics Analysis of Dual-Mechanical-Port Magnet-Geared Machine Using Control Block Diagrams.

C. Chen[1] and *M. Tsai*[1]
1. Mechanical Engineering Department, National Cheng Kung University, Tainan, Taiwan

I. Introduction The dual-mechanical-port magnet-geared machine (DMPMGM) has gained great research interest due to the development of the electronically controlled continuously variable transmission (E-CVT) in hybrid electric vehicles. The analysis for transmission characteristics, including torque and speed relationships between input and output ports, plays a crucial fundamental role in extending control applications. This study aims to propose a simple and intuitive approach to analyze the DMPMGM from the view of control engineering [1]. Both the kinematic and dynamic characteristics are represented with the block diagram descriptions. The concepts of feedforward and feedback loops are employed to illustrate the transmission interactions between DMPMGM rotors. The modeling method in this study conveniently integrates into an E-CVT control system. The feasibility of the proposed approach is verified by the corresponding simulation results with the finite element analysis-based method. II. Model Description and Simulation The non-contacting transmission of a DMPMGM is realized by the magnetic flux modulations. The induced polarized poles are generated at inner and outer air-gaps to transmit mechanical power. This study proposes a new concept, by which a DMPMGM would have a full structural correspondence with its mechanical planetary gear as shown in Fig. 1. The inner/outer PM rotors and the modulator correspond to the sun gear, ring gear, and the carrier, respectively. It should be noted that the virtual PM rotors are considered as the magnetic planet gears. The block diagram description of the DMPMGM is then obtained as shown in Fig. 2(a). The pole-pair numbers of the inner and outer PM rotors are n and p, respectively. The pole-piece number of the modulating ring rotor is q. J and B denote the moment of inertia and damping coefficient. The subscripts of OPM, IPM, Ind, and Mod separately indicate the outer, inner, and virtual PM rotors, and the modulator. ω and T are the angular velocity and torque imposed on the rotor. θ_{DO} and θ_{DI} are defined as the angular displacement differences between the virtual and real PM rotors. Moreover, T_{CI} and T_{CO} are the peak values of magnetic coupling torques in the inner and outer air-gaps, respectively. In the proposed block diagram description in Fig. 2(a), the transmission interactions of the DMPMGM can be easily illustrated for the multi-port or single input/single output transmission modes. The kinematic characteristics of DMPMGM can also be obtained from the description in Fig. 2. Consider that the inner and outer PM rotors are utilized as the main driving and regulating inputs. The modulator is the output port. The kinematic torque and speed relationships are given as shown in Fig. 2(b) without any power loss for the kinematic analysis. In this transmission mode, the regulating input ω_{OPM} has a positive effect of speeding up the output ω_{Mod}. Moreover, a negative feedback loop exists in this transmission mode such that the outer PM rotor brings the other transmission path to compensate for the speed difference between ω_{IPM} and ω_{Mod} via its own rotary speed ω_{OPM}. Distinct from the speed transmission, the torque between the PM rotors and the DMPMGM modulator are transmitted via the feedforward loop, which gives the additional acceleration path and strengthens the torque response. Based on the simulation results in Fig. 2(c), the E-CVT application is realized by the DMPMGM such that the required speed and torque assistance can be generated for different operation conditions. Furthermore, the multi-port transmission mode of DMPMGM is simulated by the proposed approach as shown in Fig. 2(d), where T_{IPM}=10Nm and T_{OPM}=5Nm are applied as the main driving and regulating torques, respectively. Note that the dynamic responses of the three rotors based on the proposed approach are all close to the simulation results from the FEM in ANSYS Maxwell. The verification of the proposed block diagram description shows the accuracy of the kinematic and dynamic analysis of the DMPMGM, which is much more intuitive and simpler than the FEA-based method. III. Conclusion This study has proposed a block diagram description for the DMPMGM in the view of control engineering. The concepts of feedforward and feedback control loops are employed to illustrate the speed and torque transmission between the input and output ports. The kinematic and dynamic relationships of the DMPMGM based on the proposed block diagram technique are consistent with the FEA-based method [2]. A new transmission description of magnetic planet gear is also proposed in this study to characterize the internal power interaction between DMPMGM rotors. This approach places the DMPMGM in full structural correspondence with the mechanical planetary gear. Moreover, this study provides the analysis convenience for more advanced control applications, by which the control system can be designed directly based on the block diagram description of DMPMGM.

Edu., Chungnam National University, Daejeon, The Republic of Korea

Low-speed high-torque machines are being increasingly used in various applications such as electric vehicles, wind-power generation, electric vessels, industrial robots, and home appliances, because they can offer direct-drive operation, which avoids the inconveniences of mechanical gearboxes [1]. The magnetic geared permanent magnet (MGPM) machine, which works similar to an electrical machine coupled with a coaxial magnetic gear, can be used as a substitute for direct drive systems and mechanical gears [2]. The MGPM machine is gaining interest owing to its significant features, such as reduced acoustic noise, maintenance-free operation, improved reliability, precise peak torque transmission capability, and inherent overload protection. In addition, an MGPM machine can further reduce the overall size and weight, compared to the simple combination of gear and electric motor. Despite these advantages, it is difficult to gain insight into the influence of the design parameters on the electromagnetic performance of MGPM machine. Analytical methods are useful for the first evaluation of machine performances and for design optimization, because continuous derivatives, which are obtained from the analytical solutions, are required during most optimization methods. Detailed knowledge about the magnetic field distribution in an air gap is vital for the design and optimization of permanent magnet (PM) machines, especially MGPM machines. Although numerical tools such as the finite element (FE) method offer precise field prediction, they can provide neither a closed-form solution nor physical insight. In recent years, much progress has been made in the analytical modeling of PM machines. The corresponding analysis is generally based on magnetic circuit methods in which only the fundamental component is considered, while the harmonic components are ignored [3]. Alternatively, a few viable analytical methods have been proposed for magnetic gears and other PM machines [4], [5]. Fourier analysis is used to obtain the solutions of Laplace and Poisson equations that represent the field behavior in each analysis region. The validity of the proposed analytical approach was verified by comparing the calculated results with those obtained from the FE results. In this paper, an analytical modeling based on Fourier analysis is proposed to compute the electromagnetic performance of MGPM machines. Fig. 1 (a) shows the configuration of the MGPM machines. As seen in Fig. 1 (b), the entire domain of the field problem is divided into six subdomains: Region I and II (air-gap subdomain); Region III (PM subdomain); Regions b (b = 1, 2,…, N_s) (N_s air subdomains); Regions i (i = 1, 2,…, Q) (Q stator slots-opening subdomains); and Regions j (j = 1, 2,…, Q) (Q stator slots subdomains). The subdomains I, II, and III have annular shapes and the subdomains b, i, and j have non-periodic shapes. By using the separation of variables technique, we obtained the analytical solutions to Poisson's equations in the PM and slot subdomains (magnetization or current density regions), and Laplace's equation in the slot-opening, air, and air-gap subdomains. The governing equation in all subdomains can be solved, and the field distribution can be obtained by applying the boundary conditions on the interfaces between the subdomains [6]. Based on these solutions, the electromagnetic performance can also be determined analytically. The magnetic field and the electromagnetic performance obtained using the analytical method were compared with those obtained using the FE analysis, and the comparison validates the analytical methods presented in this paper, as shown in Fig. 2. Using the analytical solution, a design method, which includes outstanding operating characteristics (wide operating range and low torque ripple), is proposed in this paper, according to the selected pole-slot combination and the gear ratio. Specific illustrations of the analyses and the experimental results will be presented later on in the full paper. ACKNOWLEDGMENTS This work was supported by the Basic Research Laboratory (BRL) of the National Research Foundation (NRF-2017R1A4A1015744) funded by the Korean government.

ES-07. Design of Doubly Fed Magnetic Geared Motor Considering Inherent Characteristics.

H. Shin[1] and J. Chang[1]
1. Electrical engineering, University of Dong-A, Busan, The Republic of Korea

As shown in Fig. 1(a), the doubly fed magnetic geared motor (DFMGM) has the 3-phase AC winding in both the inner and outer windings, and the modulating pieces, which modulate the winding flux, are used as the output rotor [1]-[2]. The speed of the output rotor is determined by the frequencies of the inner and outer windings, and the ratio of output rotor speed to the frequency of each winding is defined by the numbers of pole of winding and the modulating piece. At this operating principle, the variation of the frequencies in the inner and outer windings has no effect on the average torque of the output rotor, and it only changes the speed of the output rotor. Thus, the speed of the output rotor can be adjusted by both of the frequencies of inner and outer windings without the torque variation, and hence, the DFMGM has the wide constant torque region compared to the magnetic geared motor with single AC winding [4]-[8]. In addition, the DFMGM has much wider field-weakening region because it can directly adjust the field flux by handling the amplitude of the winding current, and due to the high torque by the magnetic gearing effect, the DFMGM can be applied in the traction system including the electric vehicles. Unlike the general synchronous motor, the DFMGM has the operating principle by the magnetic gearing effect and the excitation structure by two windings, and the frequencies in the inner and outer windings are individually controlled. Hence, some important characteristics should be considered when the DFMGM is designed. Firstly, the flux modulation characteristics in the inner and outer windings should be separately analyzed. The modulated magnetic fields by the inner and outer windings are different in the amplitude of the working harmonic and the order of the space harmonics. Due to these difference, the back-EMFs of the inner and outer windings have different characteristic each other. Fig. 1(b) shows the time harmonic spectra of the no-load back-EMF with 360Hz in each winding, when the excitation winding and the output rotor operate at 0Hz and the 1,662rpm, respectively. The fundamental component of no-load back-EMF in the outer winding is 40% smaller than that of inner winding, and the total harmonic distortions (THDs) of 2.4% and 4.5% are produced in the inner and outer windings, respectively. Secondly, the characteristic variation according to the frequency condition in the inner and outer windings should be considered. Fig. 1(c) shows the time harmonic spectra of the no-load back-EMF with 360Hz in each winding, when the excitation winding and the output rotor operate at 180Hz and the 2,492rpm, respectively. Compared with the case of the excitation frequency with 0Hz in Fig. 1(b), the fundamental component of the no-load back-EMF in the inner winding is decreased by 4.5%, and in the outer winding, it is increased by 3.8%. But, the THDs are 19.4% and 24.5% in the inner and outer windings, respectively, and these are considerably higher than those of the case of the excitation frequency with 0Hz. It means that the characteristics are varied by the conditions of the frequency of the excitation winding and the speed of the output rotor. Finally, the characteristics according to the winding MMF should be investigated. Fig. 2(a) and Fig. 2(b) show the variations of the amplitude of the no-load back-EMF and the output torque according to the winding MMF, respectively. The no-load back EMF of inner winding are increased as the MMF of the outer winding is getting bigger, while the increment of the no-load back EMF of the outer winding is gradual when the MMF of inner winding is increased. Furthermore, as shown in Fig. 2(b), the torque distribution by the variation of the inner and outer winding MMFs is not symmetric because the torque variations according to the winding MMF are different in each winding. Based on these characteristics, in this paper, the design process of the DFMGM, considering the flux modulation characteristics and the performance variation according to the frequency condition and the winding MMF in the inner and outer windings, is presented. First of all, based on the torque characteristics according to the winding MMF, the MMFs in the inner and outer windings, which are to produce the target torque, are determined. Secondly, the characteristics of the no-load back-EMF in each winding are analyzed, and the maximum frequencies of each winding in the constant torque region are selected. And then, the no-load back-EMF at the maximum frequency and whether the DFMGM can be operated at the maximum speed or not, are checked. Based on these performances, each winding is assigned as the armature and field windings. Finally, the total losses and the efficiencies at the main operating points are examined, and the whole process is repeated if the efficiencies at the main operating points are lower than the target efficiencies. By the systematic approach considering the inherent characteristics, the novel design process of the DFMGM is presented, and the possibility to apply the DFMGM to the traction system is proven.

I Introduction Magnetic geared Machine (MGM) have gained importance in recent years for low speed large torque (LSLT) applications, such as wind power generation, traction drives and industrial robot arms [1]. Chau and Atallah have introduced MGM, which is combination of the magnetic gear (MG) and the permanent magnet (PM) type motor. The idea regarding MGM was further developed into two different topologies, which are outer armature stator (OAS) and inner armature stator (IAS), respectively [2], [3]. As the pole-pair combination has direct effects on the machine performance of MGM, it has been studied in many literatures for OAS-MGM and IAS MGM [4]-[7]. The sandwiched armature stator MGM (SAS-MGM), which is one of the recently proposed MGM topologies, utilizes not only the magnetic gearing effect from inner rotor torque, but also the vernier effect generated by stator compared to other types of MGM, as shown in Fig. 1. [8]-[10] However, the pole-pair combination of SAS-MGM is anticipated to follow that of the conventional MG, OAS-MGM, and IAS-MGM, indicating that additional research is required to derive proper pole-pair combinations to maximize the torque density of the SAS-MGM. In this paper, we analyzed the torque characteristics of SAS-MGM according to the various combinations of the outer rotor and armature pole pairs, to derive which pole-pair combination is more suitable for SAS-MGM. Then, we have proposed the SAS-MGM design of high torque density with proper pole-pair combination. II. OPERATING PRINCIPLE The magnetic gearing effect and the Vernier effect are theoretically identical. However, there are some differences in terms of source of the magnetic flux, which are modulated by the pole pieces. The main flux source of the magnetic gearing effect is generated from an internal rotor that rotates at high speed, and that of the Vernier effect comes from the stator armature winding. The number of pole-pair in the space harmonic flux density distribution produced by high and low speed rotor PM, is given by $p_{m,k} = \left| mp + kN_m \right|$, $m=1,3,5,\ldots$ $k=0,\pm1,\pm2,\pm3,\ldots$ (1) Where p is the number of pole-pairs on PM rotor and the N_m is the number of modulation ring. The speed of the flux density space harmonics is $\omega_{m,k}=mp/(mp+kN_m)\,\omega_r$ *(2)* Where ω_r is the speed of the PM rotor. Due to the effect of modulation ring, the rotating speed of the space harmonics of the flux density is not equal to that of the high speed PM rotor. Consequently, the number of modulator ring, as well as the high and low speed rotor pole-pair number should follow (3), in order to employ the magnetic gearing effect and the Vernier Effect. $N_m= p_{HS}+ p_{LS}$ (3) Where p_{HS} and p_{LS} are the number of high and low speed PM rotor pole pair, respectively. The operating principle of the SAS-MGM can be described by separating the machine into two PM motors and a magnetic gear. The first PM motor is of the high speed rotor and armature winding current, as the second PM motor is a Vernier motor, which is of the modulated armature winding and the low speed outer rotor. The high and low speed rotor, and the modulator forms magnetic gear that provides additional torque to the low speed rotor using the magnetic gearing effect. Under high current density conditions, core of the high speed rotor is magnetically saturated, limiting the magnetic gearing effect, which generates additional torque by means of the Vernier effect. [10] Due to the distinct configuration of the SAS-MGM, the effective air gap length is shorter than that of the OAS-MGM and IAS-MGM, which emphasizes use of the Vernier effect. III COMBINATION OF ROTOR AND STATOR POLE PAIRS Considering the manufacturing constraints, the gear ratio is selected between 3.2 and 12.5 with combination of P_{HS}=2,3,4,5 and 27, 24, 21 as given in Table I, as p_{LS} is calculated by means of (3). The torque characteristics of the pole pair combinations are analyzed, which is amplified by the gear ratio of the machine that significantly increases its torque density. In other perspective, the requisite input torque for its operation is determined by the gear ratio of the machine. The slope of the torque curve according to the gear ratio has inflection point, while the torque of Vernier effect has different inflection point. The combination of these two inflection points will result in optimal combination of SAS-MGM, which is designed based on the parameters of Table II. In the manuscript, the torque characteristics variation due to combinations of rotor pole pair ratio will be described and the torque-curve of optimal design model will be addressed.

ES-09. Efficiency Improvement of Magnetic-Geared Motor by Open-Slot and Interior Permanent Magnet Structure.

K. Nakamura[1], T. Kadomatsu[1] and Y. Hane[1]
1. Graduate School of Engineering, Tohoku University, Sendai, Japan

Magnetic gears can transmit torque without any mechanical contacts. Hence, they have low vibration, no wear and fatigue, which offer maintenance-free operation. Various kinds of magnetic gears have been introduced in previous papers and patents. Among them, a flux-modulated type magnetic gear, which consists of an inner and outer rotor with surface–mounted permanent magnets, and ferromagnetic stationary parts which are called pole–pieces, is attracting interest since the torque density is higher than the other magnetic gears [1]. Furthermore, torque generation principles of a magnetic gear and a conventional permanent magnet (PM) motor are the same, hence both can be magnetically combined (not mechanically), which offers reduction of size, weight, the number of parts, and the cost. Several papers report torque increase of the magnetic-geared motors [2], [3], however the reports on efficiency improvement are few [4]. This paper describes the efficiency improvement of the magnetic-geared motor. First, a proposed magnetic-geared motor with open-slot stator and interior permanent magnet (IPM) rotor is compared to a conventional one in terms of efficiency. Next, it is demonstrated that a prototype magnetic-geared motor has high efficiency as designed. Fig. 1(a) shows configuration of a conventional magnetic-geared motor. The inside part of the magnetic-geared motor is an outer-rotor type PM motor, while the outside one is a flux-modulated type magnetic gear. As shown in the figure, the outer-rotor of the PM motor and the inner rotor of the magnetic gear are shared each other. Fig. 1(b) shows a proposed magnetic-geared motor. Basic configurations of both motors are the same, but the shared-rotor of the proposed motor has IPM structure, thereby eddy current loss of the magnets can be reduced. In addition, the number of parts and cost are expected to be reduced. Furthermore, the stator has the open-slot structure, which increases winding space factor. Although the open-slot structure causes large cogging and ripple of torque in general, the proposed motor employs 9-slot and 8-pole combination and the pole number of inner rotor and pole-pieces of the magnetic gear are chosen 8 and 27 so that the least common multiple of both number becomes large. Fig. 1(c) indicates the comparison of efficiency calculated by three-dimensional finite element method (3D-FEM). The figure reveals that the efficiency of the proposed magnetic-geared motor is higher than that of the conventional one, and reaches 90%. Based on the above results, a trial magnetic-geared motor was prototyped. Fig. 2(a) shows an experimental setup of the prototype magnetic-geared motor. Fig. 2(b) indicates the current density versus torque characteristics. It is understood that the proposed magnetic-geared motor has the good characteristics as designed. Fig. 2(c) represents the efficiency of the prototype machine. The measured maximum efficiency is about 85%, which is smaller than that of the calculated one because mechanical loss cannot be taken into account in 3D-FEM. A part of this work was supported by JSPS KAKENHI Grant-in-Aid for Scientific Research (b), Grant Number 16H04310.

1. Korea National University of Transportation, Uiwang-si, The Republic of Korea; 2. Hanyang University, Seoul, The Republic of Korea

1. Intoduction Conventional driving system of hybrid electric vehicle (HEV) or electric vehicle(EV) are composed of traction motor, mechanical or magnetic reduction gear, and wheels, so that the structure of the driving system is complicated and there is a limit in reducing the size and weight of each component. In addition, the conventional driving system has problems of increase in maintenance cost due to transmission oil leakage and tooth wear of the ruction gear, and low efficiency due to additional power loss by the mechanical gear. Therefore, it is necessary to develop a new technology that can increase the output power density and maintainability of the conventional system in a driving system for HEV or EV. Currently, research on magnetic gears to replace mechanical reduction gears is being carried out variously all over the world [1]-[3]. Japan conducted a comparative analysis of the fuel consumption in LEXUS IS300h hybrid electric vehicle with a mechanical reduction gear and a traction motor, and with a magnetic split and traction motor. The use of magnetic gears has reduced fuel consumption by up to 3.6%, which has proven the superiority of magnetic geared system over mechanical reduction system [4], [5]. Fig. 1 demonstrates the structure of an MG-PMSM system as opposed to a conventional driving system. In this paper, the design technique of the MG-PMSM is first studied for the application of the MG-PMSM structurally integrated with magnetic gear and PMSM to the electric vehicle driving system. In addition, a small-scale MG-PMSM model is designed and characteristic analysis were conducted using an electromagnetic FEM tool. *2. Design and analysis* Unlike conventional traction motors, the MG-PMSM presented in this study features a dual-rotor structure in which the outer and inner rotors rotate at different speeds. Generally, the inner rotor has a high-speed, low-torque characteristic, while its outer counterpart functions in low-speed, high-torque conditions [6]-[8]. Therefore, when the MG-PMSM is applied in a driving system for electric vehicles, the wheels should be directly linked to the outer rotor, with its low-speed and high-torque qualities. This study presents an additional process that allows for the simultaneous design of pole-pieces consisting of a low-speed outer rotor, which is based on the PMSM design process for inner rotors that apply the loading distribution method commonly used in traction motors for electric vehicles. In this paper, a basic design was performed to establish MG-PMSM models for electric vehicles. The pole number of the permanent magnet of the inner rotor of the MG-PMSM was set to 4. The gear ratio in a typical gear reducer for electric vehicles ranges from 3 to 8 [1]. In this study, the gear ratio was restricted to 5:1 or less in consideration of the production viability of the MG-PMSM miniatures, where the rated torque and rotational speed of the low-speed rotor was set to 12 Nm and 800 rpm, respectively. Table I shows the design criteria for the 1kW-class MG-PMSM. In compliance with the established criteria, models 30-7(Model A), 42-9 (Model B) and 54-11 (Model C) were designed, where the pairs of numbers, 30-7, 42-9 and 54-11, indicate the slot number followed by the number of pole-pieces of the stator. A final version of the designed models was established for the 1kW-class MG-PMSM based on the geometric data of the determined stator and rotors, as summarized in Table II. Fig. 2 shows the cross section of the basic 1kW-class MG-PMSM models designed in this study. This study analyzes the electromagnetic characteristics of three MG-PMSM Models, which were designed using the 2D-FEA (Finite Element Analysis) tool. The Back-EMF and the magnetic flux density of the MG-PMSM at the inner and outer air gaps were analyzed in the no-load and full-load conditions. In addition, the cogging and rated torque analysis of the MG-PMSM models were analyzed in the no-load and full-load conditions. Table III summarizes the characteristics of the electromagnetic parameters of the 1kW-class MG-PMSM models. *3. Conclusions* In this study, the design technique of the MG-PMSM for electric vehicles was examined in the application of the MG-PMSM being structurally integrated with a magnetic gear to the electric vehicle driving system. In designing the MG-PMSM models, this study presents an additional process that allows for the simultaneous design of pole-pieces consisting of the low-speed outer rotor, which is based on the PMSM design process for inner-rotors that apply the loading distribution method, commonly used in traction motors for electric vehicles. A comparative analysis of the three 1kW-class MG-PMSM models, in terms of electromagnetic properties, was performed to assess their general performance. 3 models showed performance levels that met the design requirements, while Model B had better torque performance than Model A and C. Yet, the magnetic flux density of both models was distributed asymmetrically at the air gaps and the core of the stator, and less than 90 percent of the torque was delivered to the inner rotor. Our follow-up study will develop an improved model in which an even number of pole-pieces is included in the outer rotor so that the magnetic flux density is distributed symmetrically at the air gaps and the core of the 1kW-class MG-PMSM, as well as optimizing pole-piece designs to improve the efficiency of torque delivery.

TABLE I : Design criteria for 1kW-Class MG-PMSM

Specification	Value
Gear Ratio	Under 1:5
Rated Speed of Outer Rotor	800 RPM
Rated Torque of Outer Rotor	12 Nm
Output Power of Outer Rotor	1 kW
DC Link Voltage	Under 150 V
Phase / PM Poles	3 / 4
Current Density	4.5 A_{rms}/mm^2
Operation Temp.	150 ℃
Core / Magnet Material	S08 / $SmCo_5$

TABLE II : Design results of 1kW-Class MG-PMSM

Dimension	Value		
	30S-7P-4P	42S-9P-4P	54S-11P-4P
Rated Speed / Torque of Inner Rotor	2000 rpm / 3.5 Nm	2800 rpm / 3.43 Nm	3600 RPM / 2.67 Nm
DC-Link Voltage / Voltage Limit (SVPWM)	120 V_{dc} / 69 V_{peak}	120 V_{dc} / 69 V_{peak}	100 V_{dc} / 57.7 V_{peak}
Phase Rated Current	6.5 A_{peak}	6.5 A_{peak}	5.0 A_{peak}
Slots of stator / Pole Pieces	30 / 7	42 / 9	54 / 11
Outer Dia. of Stator	190 mm	183.8 mm	170 mm
Outer / Inner Dia. of Inner Rotor	60 mm / 30 mm	58 mm / 31.9 mm	65 mm / 32.5 mm
Stack Length / Thickness of PM	100 mm / 3 mm	100 mm / 3 mm	120 mm / 3 mm
Inner / Outer Airgap	0.5 / 0.5 mm	0.5 / 0.5 mm	0.5 / 0.5 mm
Thickness / Angle of Pole-piece	4.5 mm / 25.7 °	7 mm / 20.3 °	5 mm /16.4 °

TABLE III : Electromagnetic characteristic analysis results of the 1kW-Class MG-PMSM models

Dimension	Value		
	30S-7P-4P	42S-9P-4P	54S-11P-4P
Back EMF (No-load/Full-load)	27.7 V_{peak} / 68.1 V_{peak}	29.2 V_{peak} / 61.3 V_{peak}	28.3 V_{peak} / 54.9 V_{peak}
Average Airgap B_r per pole (No-load)	Inner 0.67 / Outer 0.38 T	Inner 0.67 / Outer 0.39 T	Inner 0.64 / Outer 0.43 T
Average Airgap B_r per pole (Full-load)	Inner 0.64 / Outer 0.43 T	Inner 0.65 / Outer 0.37 T	Inner 0.63 / Outer 0.42 T
Cogging Torque of Inner/Outer Rotor	2.6 / 2.6 Nm_{ptop}	0.95 / 1.07 Nm_{ptop}	2.70 / 2.82 Nm_{ptop}
Rated Torque of Inner/Outer Rotor	3.8 / 12.6 Nm	3.20 / 12.6 Nm	2.32 / 12.3 Nm

ES-11. Comparative Study and Analysis of Two Different Types of Coaxial Magnetic Gears Considering Magnetic Losses and Magnet Volume.

J. Lee[1], T. Bang[1], K. Shin[1], S. Cho[1] and J. Choi[1]
1. Dept. of Electrical Engineering, Chungnam National Universtiy, Daejeon, The Republic of Korea

A gear is a mechanical device that transfers rotational force or power through the engagement of its teeth on the primary and secondary sides. Currently, gears are used in many industries, including automotive systems, conveyors, consumer electronics, and rotating machineries [1]. Mechanical gears that are normally used are mainly made of metal materials. Gears have mechanical friction due to physical contact and have many problems, such as noise, vibration, and dust. Another disadvantage is that the life of a system is shortened because its gear is worn or damaged when the system is overloaded. To overcome these problems, maintenance work with lubricants is necessary [2]. In recent years, magnetic gears using permanent magnets have being studied as alternatives to mechanical gears. The structure of the magnetic gear has a permanent magnet attached to the inner and outer rotors, and transmits the rotational force or power in a noncontact manner (without physical contact) using the force of attraction of the permanent magnet. Further, noncontact driving can compensate for the disadvantages of mechanical gears, such as noise and vibration, and does not require maintenance. Moreover, it has the advantage that it can be used semi-permanently because the gear is not worn or damaged by slip when overloaded [3]. However, due to China's export restrictions on rare earth recently, the prices of rare earth elements are unstable and have problems with price fluctuations. Due to these problems, various structures that are useful in minimizing the use of permanent magnets have been studied recently. In this paper, the characteristics of surface-mounted coaxial magnetic gear (SMCMG) and consequent pole coaxial magnetic gear (CPCMG) were analyzed. The SMCMG model has a structure in which permanent magnets are attached to the inner and outer sides, and a fixed iron core is located between them [4]. Figure 1 shows the structure and prototype of a magnetic gear. The CPCMG structure is similar to that of SMCMG; however, it has a structure using inner and outer permanent magnets with only N poles [5]. The gear ratio of a magnetic gear can be calculated by the number of poles of the inner and outer permanent magnets. For CPCMG, the pole pitch of the inner and outer permanent magnets was changed, and the optimum pole pitch with the maximum torque was selected. Further, CPCMG uses only N pole for permanent magnets, resulting in a lower pull-out torque characteristic than that of SMCMG. Therefore, the stack length of the CPCMG is increased by about 1.5 times and the torque is designed to be the same as that of the SMCMG. Thus, when the two types meet the same 7.75 gear ratio and torque characteristics, the total amount and weight of the used permanent magnets and the loss characteristics of each gear were analyzed. When the same torque is satisfied, the characteristics analysis result of SMCMG shows 0.947 kg of permanent magnet used and 0.941 kg used for CPCMG. The total weight of the magnetic gear was 3.794 kg for SMCMG and 5.82 kg for CPCMG. For CPCMG, as the axial length increases, the permanent magnet usage decreases as compared to that for SMCMG; however, its total weight increases. The torque characteristic analysis result shows that the torque total harmonic distortion (THD) was not significantly different for both CPCMG and SMCMG. However, the torque ripple characteristics are larger in CPCMG than in SMCMG. As per the loss analysis, the SMCMG uses more permanent magnets than the CPCMG, resulting in more eddy current losses being generated than the CPCMG. However, the CPCMG uses more steel core. Therefore, the core loss is lower in SMCMG than in CPCMG. In this paper, a comparative study and analysis of two different types of coaxial magnetic gears were performed. As per the analysis, the stack length of the CPCMG must increase in order to satisfy the condition of having the same torque characteristic as that of the SMCMG. In the ripple characteristics, SMCMG is advantageous; however, in terms of efficiency, CPCMG is more effective. Therefore, we have completed the analysis to select the most suitable and efficient coaxial magnetic gear for the use conditions. More detailed analysis results will be explained in the final paper. 1. The University of Sheffield, Sheffield, United Kingdom

I. Introduction Magnetic gears (MGs) have recently been proposed to replace conventional mechanical gears in various electromechanical systems. MGs have competitive torque transmission capability compared with their mechanical counterpart [1]. Moreover, by integrating an MG into a conventional PM machine, a magnetically geared machine has emerged, greatly broadening the machine topology. It always has the merits of high torque density and reduced overall size in comparison with conventional PM machine axially combined with MGs [2]. In general, the same as conventional machines, magnetically geared machines can be considered by their flux orientations, i.e. radial and axial flux machines. Axial flux permanent magnet (AFPM) machines have unique advantages over radial flux PM (RFPM) machines, such as high torque density, low rotor losses, and high efficiency. Among various AFPM machines, the yokeless and segmented armature (YASA) machine has shown to exhibit superior performance. The machine has a unique design in which the stator is formed by separated segments with windings, and moreover, two identical surface mounted PM rotors are axially located on both stator sides [3]. Based on YASA machine, a new axial flux magnetically geared machine for power split applications has been presented in [4]. The presented machine essentially has the same stator structure as the conventional YASA machine. However, by employing different rotor pole pairs in the YASA machine, a new axial flux magnetically geared machine can be created. In this study, the axial flux magnetically geared machine and the conventional YASA machine with the same volume will be comparatively studied. Individual optimizations have been carried out to maximize the average torque of two machines. Moreover, the machine performance at no load and on load will be compared. II. Machine structure and principle of operation In the full paper, the compared machine dimensions and parameters, as well as the principle of operation, will be fully described. The axial flux magnetically geared machine structure is shown in Fig. 1(a). The machine consists of 12 stationary ferromagnetic iron pieces equipped with concentrated windings and located between two surface mounted PM rotors with different poles and rotate at different speeds. By assuming high-speed rotor (HSR) of 10 poles and low-speed rotor (LSR) of 14 poles, the torque can be transferred between both rotors due to the MG effect. On the other hand, YASA machine shown in Fig. 1(b) also has 12 stator pole numbers sandwiched between two identical 14 poles surface mounted PM rotors which are physically connected to each other. The torque of the axial flux magnetically geared machine consists of two parts: the MG torque which is a function of the relative angle between HSR and LSR and electromagnetic torque produced by the interaction between winding armature reaction flux harmonics and PMs flux harmonics of each rotor. The machine MG torque is calculated at maximum relative angle between HSR and LSR. It has been stated that maximum torque can be transferred between HSR and LSR when the angle between both rotors is 90 elec. Deg. [5]. Moreover, by considering that the LSR torque is the output which is connected to the drive shaft and the HSR is connected to the external prime-mover, the total torque of the LSR is increased by the armature reaction torque produced by the applied current. III. Performance comparison of axial flux magnetically geared with conventional YASA machine In the full paper, with the aid of 3D-finite element analysis (FEA), the axial flux magnetically geared machine and YASA machine will be analysed and compared with the same machine outer diameter, axial length and copper loss. A comparison between the MG torque performance (no-load) and the torque at rated current (on-load) of the axial flux magnetically geared machine with YASA machine torque is illustrated in Fig.2. It is obvious that magnetically geared machine has higher output torque exerted by LSR due to the MG effect of about 5.2 Nm. Moreover, the torque can be increased by armature reaction to reach just below 7 Nm. Both are higher than YASA machine torque of 3.2 Nm. It clearly shows that higher torque density can be obtained by the magnetically geared machines compared with the conventional PM machines. IV. Conclusion In this study, the proposed axial flux magnetically geared machine and the conventional YASA machine have been designed with the aid of 3D-FEA. Their machine no-load and on-load performances have been analysed and compared. Simulation results show that a significantly higher torque density can be obtained compared with YASA machine. Moreover, more performance aspects at no-load and full load will be given in details and compared in the full papers, together with the measured results.

ES-13. Design of Marine Current Power Generation System Based on a Magnetic Gear.

N. Feng[2,1], H. Yu[1], X. Liu[1] and R. Guo[1]
1. School of Electrical Engineering, Southeast University, Nanjing, China;
2. School of information and electrical engineering, Ludong University, Yantai, China

1. introduction This paper presents the design and analysis of a marine current power generation system (MCPGS) for capturing energy from marine current. In this paper, a magnetic gear will be presented for an MCPGS application. The marine current turbine (MCT) blade speed is amplified by a magnetic gear (MG) and then converted into electrical energy for supplying the loads by a permanent magnet synchronous generator (PMSG). The main features of the MCPGS based on the MG will be described. The technological solution could lead to a feasible marine-current-power future scenario. 2. MCPGS 2.1 Design of MG The MG consists of the outer armature (stator) and the inner armature (high-speed rotor) carrying PM arrays with different numbers of poles and the intermediate low-speed rotor having a set of annular ferromagnetic pole pieces. The torque and speed transformation between the two rotors can be transmitted by the modulation effect of magnetic field of the ferromagnetic pole pieces, so as to generate the appropriate space harmonic with the same pole-pairs as the other permanent magnet armature. The MG is designed with 3 pole pairs PMs in the inner armature and 22 pole pairs PMs in the outer armature. Between inner armature and outer armature locates 25 ferromagnetic pole-pieces, which modulate space harmonic flux distribution. The magnetic field distribution under no-load is depicted in Fig.1 (a). The radial flux densities in the inner and outer air gap are shown in Fig1. (b) and Fig1. (c), respectively. It is worth mentioning that the 3th and 22th space harmonic components are the most dominant ones. It can be seen that the ferromagnetic segments modulate the appropriate harmonic components having the same number of pole-pairs as the PMs of the other armature. If the outer armature is kept stationary, the inner armature and ferromagnetic ring have the same rotation direction. The gear ratio between inner armature and the ferromagnetic ring is followed: $G_r=n_s/p_{1=25/3=8.33.}$ 2.2 Fundamental CONFIGURATION of MCPGS The MCPGS unit consists of four-blade MCT, a MG, a three-phase PMSG, and a power converter that is used for converting generated energy to be stored in the battery. The MG with a single-input shaft and a single-output shaft is specially designed and manufactured to couple the output rotor shaft of the designed MCT to the input rotor shaft of the employed PMSG. The gear ratio of 8.33 is designed for the MG in order to increase the low rotational speed of the MCT (around 26 rpm) to the required rotational speed of the PMSG (around 220 rpm). The output terminals of the PMSG are connected to a load through power converters with appropriate control. 3.Design of Test Bench For the performance tests of MG, the MG is to couple the output shaft of the three-phase drive motor on low-speed side to the input shaft of the load PMSG on high-speed side, as shown in Fig.2(a). In this scheme, the drive motor on the low-speed side is geared up by a MG and then converted into voltage by a PMSG.The performance of MG is analyzed in the test bench. Because of processing precision of parts, mechanical assembling accuracy and measurement error, compared to simulation results of static torque, there was a fall of 20 percent in the test results. When the ferromagnetic rings and the inner armature rotate at rated speed (26 rpm and 220 rpm) respectively, the steady torque characteristics are obtained. The inner armature test torque is T_1 = 10 Nm, and the outer armature test torque is T_2 =71 Nm. With the parameters of MG, the peak torque of the ferromagnetic ring is 81 Nm, giving an active region torque density of 79 Nm/L. 4. MCPGS Test The experimental conditions are as follows: a water depth of 0.6-0.7 meters and the current speed of 0.4-0.5m/s. The blade diameter of the MCT is 0.6 m. Due to the limitations of experimental conditions, four MCTs are cascaded so as to obtain the bigger drive torque. The marine current generation device is presented in Fig. 2(b). The rated voltage and rated speed of the PMSG are 12V and 220 rpm, respectively. The no-load EMF of the MCPGS is 9.8V at the current speed of 0.4 m/s in test tank. For the load of 10 ohm, the peak voltages of the MCPGS at different current speed are presented. Typically, when the speed of ferromagnetic ring and the inner armature is 22.7rmp and 190rmp respectively, the peak voltage is 7.09V.The output voltage of the MCPGS shows a linear relationship for rotational speed of MG. 5.Conclusion This paper presents a MCPGS consists of a PMSG driven by a MCT with an accelerated diffuser through a MG. We shall describe the main features of the MCPGS based on the MG.The proposed MCPGS equipped with an accelerated diffuser can capture the kinetic energy of marine currents efficiently and improve the system efficiency. The high-performance MG is designed for a low speed ocean generation application and adopted to improve the system reliability. The technological solution could lead to a feasible scheme for MCPGS in the future.

ES-14. Analysis of Doubly Fed Magnetic Geared Motor with Maximum Efficiency Operation by Individual Frequency Control.

H. Shin[1] and J. Chang[1]
1. Electrical engineering, University of Dong-A, Busan, The Republic of Korea

As shown in Fig. 1 (a), unlike the general synchronous machine, the magnetic geared motor has the modulating pieces which modulate the winding flux and the permanent magnets (PMs) flux, respectively. The winding flux of the magnetic geared motor is changed into the magnetic field with the high number of poles by the magnetic gearing effect, and they are synchronized with the PM flux [1]. Thus, the speed of the output rotor is reduced by the ratio of the pole number between the winding and the PMs, and the output torque is increased by the same ration. Due to these characteristics, many researches of the magnetic geared motor have been focused on the low-speed, high-torque applications, and the efforts to replace with the magnetic geared motor to the power transmission of the electric vehicle (EV), which consists of the synchronous machine and the mechanical gear box, have been continued [2]-[4]. But, the narrow field-weakening region by the PM excitation and the problems for unstable supply and price by the usage of rare-earth magnet are regarded as the shortcomings in the traction applications including the EVs. Meanwhile, as shown in Fig. 1(b), recently, the doubly fed magnetic geared motor (DFMGM), which is done the 3-phase windings in both the inner and outer stators, is proposed [5]-[6]. The speed of the modulating pieces output rotor is adjusted by the individual frequency control in the inner and outer windings. Fig. 1(c) shows the example for the speed-torque curve of the DFMGM with the division of operating region by the individual frequency control. While the frequency of the outer winding is fixed at 0 Hz corresponding to the DC operation, the frequency of the inner winding is increased until the base speed I, $\omega_{base\ I}$. And then, the frequency of the outer winding is increased until the base speed II, $\omega_{base\ II}$, without variation of the frequency of the inner winding. Thus, the frequency range and inverter power of each winding can be reduced because the operating region of the DFMGM is divided into two sub-regions according to the selection of the frequency range of the inner and outer windings. Moreover, the field-weakening region of the DFMGM can be considerably extended thanks to the field flux which can be adjusted by the winding current. With these characteristics of DFMGM, it is very important to determine the frequency ranges of the inner and outer windings and roles of each winding as a part of field and armature by considering the iron loss and the efficiency. Fig. 2 shows the iron loss map and the efficiency map for the difference in the two cases which have different frequency range each other. In the case I, the inner and outer windings have the maximum frequencies of 180Hz and 360Hz, respectively. In contrast, in the case II, the maximum frequencies of the inner and outer windings are 360Hz and 180Hz, respectively. The current of the inner winding is adjusted when the current of the outer winding is fixed, and as mentioned above, the frequency of the inner winding is increased until the maximum value, and then the frequency of the outer winding reaches the maximum value. As shown in Fig. 2(a), in the high-torque region, the case II, which the frequency range of the inner winding is wider than that of the outer winding, has the bigger iron loss than that of the case I. However, in the low-torque region, the case I, which the frequency range of the outer winding is wider than that of the inner winding, has the larger iron loss than that of the case II. It means that, in the constant torque region, the frequency ranges of the inner and outer winding, which has the advantage in the iron loss, are different according to the amplitude of the current of the armature winding. Besides, as shown in Fig. 2 (b), there is 4% or more efficiency difference between the case I and II in the low-torque region. Based on these characteristics, the DFMGM can operate at each point with the maximum efficiency by the individual frequency control in the inner and outer windings when the operating point is changed according to the driving conditions in EVs. Furthermore, the overall efficiency in the traction system can be increased by the frequency combination map of inner and outer windings with the maximum efficiency for the whole operating region. To do the task of the efficiency maximization for the whole operating region by the individual frequency control and the frequency mapping, firstly, the iron losses at the inner core, outer core, and the modulating pieces are presented according to the frequency variations in the inner and outer windings. In addition to this, the effect of the space harmonic components of the air-gap flux density on each ferromagnetic material is separately investigated. Secondly, the iron loss maps and the efficiency maps according to the frequency map are drawn, and the causes of the difference between the maps are analyzed. Finally, the maximum efficiency map for the whole operating region is obtained.

ES-15. Performance Evaluation of Magnetic Lead Screws Equipped with Segmented Arc Magnets Instead of Helical Ones.

F. Gao[1], Q. Wang[1] and J. Zou[1]
1. Department of Electrical Engineering, Harbin Institute of Technology, Harbin, China

I. Introduction Recently, there has been growing interest in the magnetic lead screw (MLS). Integrated with the permanent magnet (PM) rotational machine, the MLS has brought an electromagnetic linear actuator with high thrust force density into reality [1]. Generally, there are three types of MLS, i.e., PM-type, reluctance type and inductor type, among which the PM lead screws exhibit much higher force densities than the other two and are becoming the focus of research interest. In the PM lead screw, the helical PMs are key components. Since it's quite hard to manufacture the ideal helical PM poles, the PM was obtained by cutting the arc magnet with the same arc angle in [2] and [3]. The number of required PMs were decreased significantly and the characteristic of thrust force and torque had a better approximation with the ideal one. However, it still has a larger error with the ideal helical PM. Furthermore, it's noticed that almost all investigations had regarded the thrust force and torque as the assessment indicator of the approximation technology, and the gear ratio wasn't taken into account. As will be highlighted in the paper that the gear ratio is the fundamental indicator for a motion transmission. This paper proposes a novel PM reshaping method. Segmented arc magnets are adopted to replace the ideal helical PMs. For the MLS equipped with the resultant PMs, the performance is evaluated and analyzed compared with the ideal one, and the effect of magnetization on the performance is investigated. Finally, additional consideration on the fabrication of MLS is presented as well. II. Principle of approximation for helical PMs A MLS is shown in Fig. 1 (a), where helical PMs with radial magnetization are mounted on the inner surface of nut and outer surface of screw, respectively. Limited to the current processing technic of sintered NdFeB PMs, helical PMs are difficult to be obtained. One popular approach to approximate the helical PM segment is to cut the arc magnet with the same arc angle. An ideal helical PM segment and the approximated one by cutting method are shown in Fig. 1 (b). It's observed that the side surfaces of helical PM are identical rectangles, whereas the corresponding are skewed into different parallelograms, which causes mismatches on the side surfaces during assembling. Fig. 1 (c) and (d) depicts the geometry of the cut PM segment with different arc angle scope, δ is the angle of reference plane versus the side surface. A bigger error will occur when the arc angle are greater than $\pi/2$. To avoid this situation, some limits are made. With the geometry of PM segments, the cutting angle is derived. There're four combinations of nut and screw to be selected, and the best combination is verified by three-dimensional (3-D) finite element method (FEM). III. Performance Optimization The PM segment is optimized from the aspects of reference angle, arc angle and magnetization. The reference angle affects the resultant shape of PM segment, whereas the thrust force and torque of MLS by different reference angles are almost overlapped totally. Therefore, the gear ratio is investigated as shown in Fig. 2 (a), and the steady gear ratio is preferred. Fig. 2 (b) shows the difference of axial component with the helical PM. Obviously, a smaller arc angle leads to a closer shape to the helical PM and a better performance of MLS. However, it needs a balance between the number of PM segments and the performance of MLS. Fig. 2 (c) shows the torque of MLS with the PM segment magnetized radially and in parallel. Evidently, there are lower thrust force and torque when magnetized in parallel. Furthermore, the PM segments with parallel magnetization result in a distorted torque curve, which may cause instability problems during the transmission. IV. Additional consideration As stated in this paper, the helical PM poles are assembled by approximated PM segments. There will exist magnetic force to prevent the PM segments of same polarity from getting close, which make it hard to assemble the MLS. To make the fabrication of the MLS simpler, dovetail bulge and groove are set up on the side surface of the PM segment as shown in Fig. 2 (d). In this way, the PM segments will snuggle closer to each other compulsively. More detailed analysis and results will be presented in the full paper.

ET-01. Unravelling the effects associated with ferromagnetic dynamics in non-magnet/ferromagnet metallic multilayers.

O. Gladii[1], L. Frangou[1], *G. Forestier*[1], S. Auffret[1], U. Ebels[1], S. Gambarelli[2] and V. Baltz[1]

In physical systems, out-of-equilibrium vibration dynamics is governed by numerous parameters, like local anisotropy and coupling. In practice, dynamics is most often driven by resonance. Resonance experiments are therefore powerful to characterize physical systems to an extent which depends on how well it is possible to disentangle the effects associated with dynamics. In non-magnet/ferromagnet metallic multilayers for example, the physical properties related to the ferromagnet (e.g. saturation magnetization, anisotropy, damping), to the non-magnetic metal (e.g. spin penetration length, relaxation mechanisms, eddy currents) and to the interface (e.g. spin filtering, roughness) can be recorded through measurements of ferromagnetic resonance spectra (e.g. absorption vs. magnetic field for a fixed frequency) and determination of their position, linewidth, and symmetry [1]. In this work we investigated experimentally the ferromagnetic resonance response of a 8-nm-thick NiFe film sandwiched between two conductive Cu layers, the whole stack being sputter-deposited on thermally-oxidized silicon substrates (Si/SiO_2). We compared the changes induced by varying the thicknesses of either the buffer- or the capping-layer of Cu [Fig. 1(a)], in an attempt to disentangle and characterize the different effects associated with ferromagnetic dynamics. The spectra measurements were carried out by using a coplanar waveguide setup [Fig. 1(a)]. Through measurements of the spectra linewidths we observed a non-monotonous dependence of Gilbert damping with Cu buffer-layer thickness. We attribute such a behavior to the possible non-monotonous changes in Cu/NiFe interface properties. It is actually known that Cu wets poorly on SiO_2 compared to NiFe on SiO_2 and NiFe on Cu. In addition, roughness creates spatially inhomogeneous stray fields that results in strong incoherent dephasing of the spin current injected from the NiFe to the Cu, and thus leads to damping enhancement [2]. In this regards, varying the capping layer thickness has virtually no influence on damping. We observed that the spectra position is also influenced by the buffer-layer thickness. It gradually reduces as a likely consequence of gradual NiFe surface-anisotropy enhancement for thicker buffer-layer [3]. Most interestingly, we detected that a spectrum asymmetry gradually build up when the Cu layer thickness increases [Fig. 1(b)]. The amplitude of this effect is independent on the buffer or capping nature of the Cu layer, in contrast to its sign. Such a behavior reveals the non-negligible impact of eddy currents circulating in the conductive Cu layers. A scenario involving eddy currents generated directly by the microwave excitation cannot readily explain the sign change observed here between capping and buffer layer [4]. We rather consider that the oscillation of the NiFe magnetization generates a time varying out-of-plane magnetic flux that creates eddy currents in the plane of the surrounding Cu layers. In return, the eddy currents generate a feedback rf magnetic field that contributes to the dephasing of the NiFe magnetization dynamics. This dephasing translates into an absorption-dispersion admixture ($\chi=(\chi+i\chi)e^{i}\Phi$) and gives rise to the asymmetry of the NiFe resonance lineshape. In this scenario, the feedback rf magnetic fields of the top and bottom Cu layers are then naturally in antiphase to one another. ET-02. Temperature dependence of spin-torque driven ferromagnetic resonance in MgO-based magnetic tunnel junction with a perpendicularly free layer.

X. Wang[1], J. Feng[1], P. Guo[1], H. Wei[1], B. Fang[2], Z. Zeng[2] and *X. Han*[1]

Recently, magnetic tunnel junctions (MTJs) with a perpendicular magnetic anisotropy in combination of high tunnel magnetoresistance and high thermal stability were demonstrated to be a promising candidate for spin-torque (ST) magnetic random access memory, or ST nano-scaled oscillators. In such systems, the perpendicular anisotropy plays an important role in determining the magnetization dynamics. Here, We report the temperature dependence of the ST driven ferromagnetic resonance in MgO-based MTJ nanopillars with a perpendicularly free layer and an in-plane reference layer. From the evolution of the resonance frequency with magnetic field, we clearly identify the free-layer resonance mode and reference-layer mode. For the reference layer, we demonstrate a monotonic increase in resonance frequency and the effective damping with decreasing temperature, which suggests the saturated magnetization of the reference layer is dominant. However, for the free layer, the frequency and damping exhibit almost no change with temperature, indicating that the perpendicular magnetic anisotropy plays an important role in magnetization dynamics of the free layer[1]. The related parameters, such as the effective $\mu_0 M_s$ of in-plane reference layer, (H_k-4$\pi\mu_0 M_s$) cosϕ of the perpendicular free layer, and the damping factor of both free and reference layers, have been obtained in the temperature range from 300 K to 100 K. The values of $\mu_0 M_s$ and (H_k-4$\pi\mu_0 M_s$) cosϕ at 300 K are 1.66 Tesla and 180 Oe, while the effective damping factors of both free and reference layers at 300 K are 0.0057 and 0.01, respectively. The effective damping factor of the reference layer shows normal temperature dependence, while that of the free layer remains almost unchangeable with temperature due to the suppressed Hk and $\mu_0 M_s$ when the free layer remains in-plane. From our work, one may find MgO MTJ stack with a perpendicular free layer and an in-plane reference layer is good candidate for studying the microwave oscillation at high frequency using the ST-FMR effect.

ET-03. Role of intersublattice coupling in current-induced spin torque in Rashba antiferromagnet.

C. Ho[1] and M.B. Jalil[1]
1. Department of Electrical and Computer Engineering, National University of Singapore, Singapore

We investigate the spin-orbit torque in Rashba antiferromagnet (AFM). The model AFM composes of two square sublattices with magnetizations m_1 and m_2 (Fig. 1) [1,2]. The intersublattice electron dynamics is described by the hopping energy *t,* and Rashba coupling α_{Ri} is sublattice-dependent. In linear response theory, the spin-torque acting on m_i is derived as $T^i=\Delta J_{dd}$ $(m_i \times m_{j\neq i}) + m_i \times H_i$, where the first term represents the modified AFM exchange coupling between m_1 and m_2 with additional strength ΔJ_{dd}, the second term is the current induced torque with $H_i \propto \alpha_{Ri}(z\times j_e)$. Firstly, we show that ΔJ_{dd} is induced by the intersubllatice electron dynamics. As shown in Fig. 2a, when the hopping is small, ΔJ_{dd} increases with *t* and reaches its maximum ΔJ_{max}=$2J_{sd}/3\sqrt{3}$ at $t=\sqrt{2}\ J_{sd}$ (red circle), where J_{sd} is the *sd* coupling. However, when $t\geq\sqrt{2}J_{sd}$, the modulation becomes diminishing. To explain this trend, we can consider the exchange time scale which is $\tau_{sd}\sim 1/J_{sd}$, and the inter-sublattice hopping time scale $\tau_{hop}\sim 1/t$. When $t<J_{sd}$,i.e., $\tau_{sd}<\tau_{hop}$, adiabatic condition can be applied, which allows the angular momentum carried by the electron can be adiabatically transferred between m_1 to m_2, and ΔJ_{dd} is scaled with the hopping rate, i.e., $\Delta J_{dd}\sim t$. However, when $t>J_{sd}$, which means $\tau_{sd}>\tau_{hop}$, the angular momentum transfer would be less effective due to the relaxation, similar to strong spin-flip effect, thus resulting in the diminishing trend as shown. Second, the torque fields acting on m_1 and m_2 are staggered for α_{R1}=-α_{R2} as shown in Fig. 2b. Moreover, the magnitude of the torque fields are reduced as a result of the intersublattice electron dynamics. Indeed, opposite Rashba fields induced opposite spin polarizations in each sublattices, and that can cancel each others through the intersublattice dynamics, thus reduces the torque fields.

ET-04. Quasi-oscillating transition between magnetic states in Pt/Co/Ir/Co/Pt/GaAs spin valves.

G. L'vova[1,2], R. Morgunov[1,2], T. Fache[3] and S. Mangin[3]
1. 1 Institute of Problems of Chemical Physics, Chernogolovka, Russian Federation; 2. Tambov State Technical University, Tambov, Russian Federation; 3. Institut Jean Lamour, Nancy, France

The multilayered heterostructures attract great attention due to the Giant Magneto Resistance (GMR) applications in spintronics, since they can be used as biomedical sensors. An understanding of the origin of magnetic relaxation in large sized structures will allow an acceleration of the sensor switching to develop optimal conditions of the sensor exploration. Analysis of magnetic relaxation in the multilayered Pt/Co/Ir/Co/Pt/GaAs system is subject of our work. The time dependence of the magnetic moment M(t) was recorded by SQUID magnetometer in the magnetic fields corresponding to the transition fields between four stable states (Fig. 1). Fig.1. Sketch of Pt/Co/Ir/Co/Pt/GaAs. The states M_2, M_3 and M_4 correspond to the parallel and antiparallel mutual orientations of the magnetization vectors of the free and hard Co layers. Fig. 2. Time dependence of the quasi-oscillating relaxation of the magnetic moment M(t) recorded in the sample at T=100 K for sample Pt(3.2nm)/Co(0.7nm)/Ir(1.4nm)/Co(1nm)/Pt(3.2nm). The dependences were recorded in the fields corresponding to the $M_2 \rightarrow M_4$ transition fields. MOKE images of the surface magnetization accompanying similar transition at 300 K are shown in the insertions. In the Pt/Co/Ir/Co/Pt/GaAs heterostructure, an inverse magnetic relaxation (opposite to the external magnetic field direction) is observed. This process starts from M_2 initial metastable state, passes through M_4 transient metastable state and finalizes in M_3 stable state (Fig. 2). The stability of these magnetic states can be understood as a competition between the anisotropy energy, the interlayer exchange coupling and the Zeeman energies providing the sequence of the spin valve switching in external magnetic field [1]. Transition MOKE pictures illustrate spreading of the M_4 state corresponding to magnetic moments of the both magnetic layers aligned along the external field. The fact that dipolar field of state M_2 favors M_4 state instead of M_3: at 10 minutes (Fig.2), there is no more state M_2. State M_3 is energetically favored due to antiferromagnetic exchange between ferromagnetic layers. Final equilibrium state of the system is M_3 that is reached by tilting of the magnetic moment of the free Co layer. This $M_4 \rightarrow M_3$ transition leads to the final system state corresponding to the dark MOKE image (see insert in Fig.2). Thus, we have found an unusual quasi-oscillating mode of the transition between stable magnetic states of the bilayer system with perpendicular anisotropy. The work was supported by Ministry of Education and Science of the Russian Federation (grant 3.1992.2017/4.6)

ET-05. Exchange coupling induced giant damping enhancement in $Y_3Fe_5O_{12}$/ $Co_2FeAl_{0.5}Si_{0.5}$ bilayers.

M. Li[1], L. Jin[1], Y. Rao[1], H. Zhang[1], C. Hong[1], Z. Zhong[1] and Q. Yang[1]
1. University of Electronic Science and Technology of China, Chengdu, China

The spin pumping effect induced Gilbert damping enhancement in $Y_3Fe_5O_{12}$(YIG)/heavy mental bilayers has been intensively investigated. $Co_2FeAl_{0.5}Si_{0.5}$ (CFAS) is a promising ferromagnetic material in spintronics devices due to its high spin polarization and low Gilbert damping. We studied the microwave dynamic magnetizations in YIG/CFAS bilayers by combining vector network analyzer ferromagnetic resonance (VNA-FMR) and revealed a giant damping enhancement about five times compared that of YIG/Pt bilayers. This phenomenon was attributed to both the exchange coupling effect and spin pumping effect. By inserting a 10nm Cu spacer, the direct exchange coupling can be excluded. A spin mixing conductance of $7.75\times10^{18}m^{-2}$ generated by spin pumping was obtained. The study provides an effective approach to tailor the damping in magnetic thin films.

I. INTRODUCTION Recently, more and more interests focus on the stripe domain structure of magnetic films due to their tunable microwave properties, which are useful for microwave signal processing devices, including inductor, resonator, phase shifters, and filter. The magnetic films with stripe domain overcome the restraint in devices of uniaxial anisotropy films, such as in-plane orientation dependence on magnetic device applications. What's the more, the stripe domain films show different resonance modes when the direction of stripes is parallel or perpendicular to the microwave magnetic field, namely acoustic mode and optic mode [1-3]. In this work, we fabricated the permalloy film with stripe domain with in-plane anisotropy induced by oblique sputtering with oblique incidence angles were set at 31^o, 34^o, 36^o, 40^o and 42^o, respectively. Then we find the samples reveal unlike microwave responses at acoustic mode when the direction of stripe domain along the easy magnetization axis (EA) [0-configuration] or hard magnetization axis (HA) [1-configuration] of samples. It's interesting to note that the resonance frequencies keep constant firstly, and then flips to a higher value suddenly when it reaches to a turn-on applied field at 1-configuration. Maybe it can be used for special microwave devices. II. RESULTS AND DISSCUSION The zero-field magnetic permeability spectra and MFM images of film with oblique sputtering angle of 31^o were shown in Fig. 1. We can find the permeability spectra show different resonance modes. In the case of 0-configuration, the domain width is about 315 nm, which is smaller than that of 388 nm of the 1-configuration measured by MFM images. When the direction of in-plane anisotropy field and stripe domain is inconsistent, the magnetic moments deflect to the in-plane anisotropy field with a small angle. So the magnetic domain is wider. Fig.2 shows magnetic permeability spectra of imaginary part under sweeping field from 0 to 180 Oe at (a) 0-configuration and (b) 1-configuration of film with oblique sputtering angle of 31^o. In the case of 1-configuration, the resonance frequency increases with applied magnetic field, which is agreement with Kittle's equation. However, the resonance frequencies keep a constant, and suddenly jump to another value when the magnetic field reaches to a threshold value (Turn-on field). Turn-on field (H_{on}) as a function with different oblique sputtering angles was shown in Fig. 2(c). It is found that the oblique sputtering angle increases, in-plane anisotropy filed increases, H_{on} increases as well. This is due to the in-plane anisotropy increases, the magnetic reoriented field of the stripe domains increases. Fig. 1 Zero-field magnetic permeability spectrum and MFM images at (a-b) 0-configuration and (c-d) 1-configuration of film with oblique sputtering angle of 31^o. Fig. 2 Magnetic permeability spectra of imaginary part under applied magnetic field from 0 to 180 Oe in the case of (a) 0-configuration and (b) 1-configuration of film with oblique sputtering angle of 31^o. ET-07. Effect of absorption of hydrogen on the linewidth of the ferromagnetic resonance response of Co/Pd bilayer films.

T. Schefer[1,2] and *M. Kostylev*[1]
1. University of Western Australia, Perth, WA, Australia; 2. University of Basel, Basel, Switzerland

Hydrogen is expected to play a major role as a future energy carrier, ultimately replacing fossil fuels[1]. However, due to its high flammability it is mandatory to have control over its concentration and confinement at any stage of usage. Recently the magnetic hydrogen gas sensor (mHGS) has been proposed[2]. It relies on the shift of the ferromagnetic resonance (FMR) frequency or field in thin ferromagnetic (FM)/palladium (Pd) bilayer films upon absorption of hydrogen gas (H_2) by the Pd capping layer. This shift has been assigned to a change in the interface perpendicular magnetic anisotropy (PMA) due to changes to electron orbitals at the interface. While this sensing principle allows detecting H_2 over a wide sensing range[3], the amplitude of the FMR peak is inherently small due to the small thickness of the FM layer. Additionally to the shift in the resonance position H_{res}, an increase in the FMR amplitude as well as a decrease in FMR linewidth ΔH are always observed in the experiment. In this work, we try to separate the impact of H_2 on the resonance shift from the H_2-induced linewidth narrowing by varying the FM (Cobalt, Co) layer thickness t over a broad range. The Co layer is sandwiched between 10 nm of tantalum (Ta, seed layer) and 10 nm of Pd (capping layer). The stacks with varying t (t = 3, 5, 7, 10, 20, 30, 40, 50, 60, 70, 80 nm) were sputtered onto preheated (200°C) Si <100> wafers, where Ta and Pd were sputtered with dc magnetron sputtering and Co with RF sputtering. The differential broadband stripline FMR spectroscopy[4] measurements were taken employing an airtight chamber through which either nitrogen (N_2) or H_2 flowed with a constant flow rate of 800 SCCM. The recorded raw FMR traces were fitted with the real part of the first derivative of the complex Lorentz function, which gave us H_{res} and ΔH: $V=\mathrm{Re}(-A/(H-H_{res}+i\Delta H)^2)$. Here, V is the Lock-in amplifier signal, A the amplitude of the complex-valued Lorentz function and H the applied magnetic field. Fig. 1 demonstrates the obtained results. One sees that for thinner films, the change in H_{res} is well fitted with the $1/t$ dependence. This dependence is consistent with a reduction in the interface PMA with an increase in t. For the thicker films the behaviour is more complicated. The linewidth ΔH does not change significantly for the thinner films in the presence of H_2, while it decreases by over 20 % for 50 nm+ Co layers. This leads to a differential FMR amplitude change of over 50 %. This change can be used to sense H_2 with high concentration resolution over an impressive concentration range, as will be shown in our presentation. Fig. 2 displays an exemplary result of our concentration resolved measurements. The data presented in this figure were collected for the sample with t=70 nm. To enable this, we measured a time resolved differential FMR spectra at different H_2 concentrations. The external magnetic field and the microwave frequency are hold constant during the whole process and measurements of the FMR absorption amplitude are taken every few seconds. For the trace in fig. 2, the sample is exposed to three different concentrations (10, 25, 50 %) of H_2 sequentially. One sees that the absorption amplitudes for the three different concentrations are well distinguishable and that the signal recovers to its original level after evacuation of H_2 from the sample environment. This result demonstrates that monitoring the amplitude of the FMR response of 50 nm+ Ta/Co/Pd films in the presence of H_2 represents an alternative concept of an mHGS. It is characterised by a high sensitivity to H_2 concentration and much larger output FMR signal than for the sensing method which employs thinner Co layers and exploits the FMR peak shift for sensing. Potentially, the much larger FMR amplitude will considerably simplify signal processing electronics for future mHGS.

Co_2FeSi (CFS) Heusler alloy has attracted tremendous scientific attention in the emerging spintronics field, such as spin torque nano-oscillators, spin wave propagation and magnonics, due to the high saturation magnetic moment, high Curie temperature and low Gilbert damping [1]. In this work, we demonstrate angle dependence of static and dynamic properties of B2 ordered CFS thin film. The 60 nm thick CFS film was deposited on MgO (001) substrates by RF magnetron sputtering with a 3-inch CFS alloy disk as the target at room temperature. After growth, the stacks were *in situ* annealed for 1 hour in vacuum at 400 ^{o}C. The X-ray diffraction shows that the CFS film forms B2 structure. Figure 1(a) shows the in-plane measured M-H loops along the easy and hard axis. The high squareness of easy-axis M-H loop with full remanence was obtained. The extracted saturation magnetization (M_s) is 1205 emu/cm^3, which is smaller than the bulk value for B2 ordered CFS. The in-plane measurement azimuthal angel dependence of remnant magnetization ratio (M_r/M_s) for CFS film is shown in the inset of Fig. 1(a). The relationship, which can be well described by a cosine function, shows a two-fold symmetry, confirming an in-plane uniaxial magnetic anisotropy in the film. To investigate the magnetization reversal mechanism, the in-plane measurement azimuthal angel dependence of easy-axis coercivity (H_c) is shown in Fig. 1(b). It can be well fitted with Stoner-Wohlfarth model when the field orientation is close to the hard axis, showing the magnetization reversal is dominated by coherent rotation. When the field orientation is close to the easy axis, it is not fitted well with Stoner-Wohlfarth model, since the magnetization reversal is partially controlled by the domain-wall depinning according to Kondorsky model. The H_c value attains ~10 Oe for all angles, suggesting a soft-magnetic behavior similar to other Heusler alloys. The film was subjected to an in-plane microwave field *h* at various frequencies between 2 and 14 GHz, and an in-plane magnetic field *H* was applied perpendicular to *h* and swept from 0 to 2000 Oe. In the inset of Fig. 1(c), a typical spectrum measured at 12 GHz is given. It is notable that two resonance modes were observed in the spectrum. One appears at about H_{res}=1.0 kOe, and is identified as the fundamental FMR mode, which is characterized by a uniform magnetization precession through the film thickness. The other weak resonance, which is observed at the lower field, can be considered as the first exchange-dominatedperpendicular standing spin wave (PSSW) mode. The PSSW mode has a non-zero wave vector pointing perpendicularly to the thin-film plane and a thickness dependent spin-wave amplitude and phase. The typical field dependence of the FMR and PSSW modes at various frequencies for 60 nm CFS thin film is shown in Fig. 1(c). The magnetic anisotropy, H_k, extracted from the FMR mode, agrees well with that estimated from M-H loops. Exchange stiffness *A* can thus be extracted from the PSSW mode. In order to evaluate the damping factor, we also performed FMR measurements between 2 to 14 GHz. The frequency dependences of the FMR linewidth with the external field along in-plane easy and hard axes, are depicted in Fig. 1(d). The obtained values of Gilbert damping and inhomogeneous broading are 6.7×10^{-3}, 5.1×10^{-3} and 11.45 Oe, 24.29 Oe for easy and hard axes, respectively. The CFS film was then examined by in-plane angle-dependent FMR measurements at 8 GHz. The angular dependence of the resonance field is show in the inset of Fig. 1(d). The uniaxial anisotropy is clearly observed from this figure, agreeing well with that estimated from M-H loops.

ET-09. Voltage control of two magnon scattering and an enhanced ME coupling in multiferroic heterostructures.

X. Xue[1], *Z. Zhou*[1] and M. Liu[1]
1. Xi'an Jiaotong University, Xi'an, China

Driven by growing demands of fast, compact, and energy-efficient devices based on multiferroic systems, great efforts have been making to discover novel mechanisms and achieve tremendous magneotoelectric (ME) coupling effects. Electric field control of dynamic spin interactions is promising to break through the limitation of the magnetostatic interaction based ME effect. In this work, electric field control of the two-magnon scattering (TMS) effect has been demonstrated in $Ni_{0.5}Zn_{0.5}Fe_2O_4$ (NZFO)/Pb($Mn_{2/3}Nb_{1/3}$)-$PbTiO_3$ (PMN-PT) (001) multiferroic heterostructure. The angular dependence of ferromagnetic resonance (FMR) measurement has been performed by the electron paramagnetic resonance spectrometer. As shown in Fig. 1a and b, a large electric field modulation of magnetic anisotropy (-347 Oe) and FMR linewidth (275 Oe) is achieved at the TMS angle of θ_H=60°. Particularly, the TMS intensity is increased by 14.5% at room temperature. The TMS effect is an extrinsic magnetic damping mechanism that scatter the k=0 magnons excited by FMR into degenerate states of magnons having wave vectors $k\neq0$, offering a framework for voltage control of spin dynamics and further increase the ME interactions. The present work provides a promising paradigm for next generation voltage tunable electronic/spintronic devices such as RF/microwave devices, memories and spin wave logic devices.

Thin systems incorporating heavy metal/ferromagnet (HM/FM) stacks are currently under intensive research due to their potential applications in the field of spintronics. Indeed, various novel spin-related effects and phenomena could occur in these structures such as spin Hall [1] and inverse spin Hall effects [2], spin orbit torques [3] and interfacial Dzyaloshinskii-Moriya interaction (iDMI) [4]. In addition to the magnetic anisotropy, the damping constant is an important magnetic parameter in such structures as it determines the magnetization dynamics such as the speed of the magnetization switching. Therefore, the aim of this work is to use micro stripe ferromagnetic resonance (MSFMR) to investigate the Gilbert damping constant and the magnetic anisotropy as a function of the thickness of the CoFeB capped with Ir or Ru, where a special attention is given to the annealing temperature. For this, $Co_{20}Fe_{60}B_{20}$ thin films of different thicknesses have been sputtered on thermally oxide Si substrates and capped with 8 nm thick Ir or Ru layers. Both as grown films and samples annealed at 400°C are considered here. Vibrating sample magnetometer has been used to measure the CoFeB thickness dependence of the saturation magnetic moment per unit area in order to straightforwardly determine the magnetization at saturation (M_s) and the magnetic dead layer thickness (t_d). t_d are found to be 0.76 nm and 1.53 nm for the as deposited CoFeB/Ru and CoFeB/Ir, respectively. The magnetic dead layer is mainly due to intermixing at the interface of CoFeB with the capping layer. The larger magnetization value (M_s=1115±50 emu/cm^3) of CoFeB/Ir compared to that of CoFeB/Ru (M_s=930±50 emu/cm^3) is most likely due to the proximity induced magnetization in Ir. This corresponds to a change in film magnetization of 19% which is in good agreement with the reported values for Ir/Co [5] systems. Both M_s and t_d increase for films annealed at 400°C. The obtained values are 1185±50 emu/cm^3 (1110±50 emu/cm^3) and 2.93 nm (1.62 nm) for CoFeB/Ir (CoFeB/Ru). MSFMR measurements revealed that these systems present small in-plane uniaxial anisotropy with the magnetization easy axis direction depends on the sample. While the in-plane anisotropy field for the as grown films does not show a clear behavior versus the CoFeB thickness, clear linear behavior of this field versus the reciprocal CoFeB effective thickness can be observed for the annealed samples. This field decreases for samples annealed at 400°C and it is higher for CoFeB films capped with Ru with respected to those capped with Ir. Moreover, the effective magnetization varies linearly with the inverse effective thickness of CoFeB due to the perpendicular interface anisotropy. This surface anisotropy constant which was estimated to be 0.84 erg/cm^2 and 0.89 erg/cm^2 for the as deposited CoFeB films capped with Ir or Ru, respectively reinforces the perpendicular easy axis. It increases (decreases) slightly (drastically) for films annealed at 400°C and capped with Ir (Ru). The corresponding values for the annealed Ir and Ru capped films are found to be 1.07 erg/cm^2 and 0.57 erg/cm^2, respectively. Note also the existence of a high negative perpendicular anisotropy (reinforcing the in-plane easy axis), especially for the as deposited CoFeB/Ru films. This volume anisotropy decreases drastically from -1.83 $\times10^6$ erg/cm^3 (-0.6 $\times10^6$ erg/cm^3) to -0.4 $\times10^6$ erg/cm^3 (-0.21 $\times10^6$ erg/cm^3) when the CoFeB/Ru (CoFeB/Ir) are annealed at 400°C. MSFMR has also been used to investigate the CoFeB thickness dependence of damping parameter. For this, the field peak to peak linewidth has been measured as function of the driven frequency for an in-plane magnetic field applied along the direction giving the minimal linewidth. This direction is obtained from the investigation of the angular dependence of field linewidth for each sample. The obtained results revealed that the damping coefficient increases linearly with the reciprocal effective thickness of CoFeB most probably due to spin pumping. By considering that the total damping is given by $\alpha= \alpha_{CFB}+\alpha_{pump}$, where is the Gilbert damping of the bulk CoFeB and α_{pump} is the damping introduced by spin pumping effect due to Ir or Ru, the fitted data gives α_{CFB}=0.0027 and α_{CFB}=0.0013. The spin pumping contribution to the damping α_{pump} allowed determining the effective spin mixing of CoFeB/Ru and CoFeB/Ir estimated to be 12.93 nm^{-2} and 29.3 nm^{-2}, respectively. Note the higher value for CoFeB/Ir compared to that of CoFeB/Ru due to the higher spin orbit coupling of Ir. Moreover and in contrast to α_{CFB}, the spin mixing conductance increases for the annealed films at 400°C (the obtained values are 22.4 nm^{-2} and 43.85 nm^{-2} for CoFeB/Ru and CoFeB/Ir, respectively) traducing the enhancement of the spin pumping efficiency of the annealed films.

Magnetization dynamics induced by spin transfer torque (STT) in nanoscale magnetic structures result in a range of interesting phenomena, including magnetization switching, microwave oscillations, and the spin-torque diode (STD) effect. The STD effect can be used for the development of a new kind of microwave detectors [1]. Previous studies have demonstrated the STD microwave detectors have the potential to overcome the theoretical performance limits of their semiconductor counterparts at room temperature. For examples, Miwa et al reported a detection sensitivity of 1,2000 mV/mW by controlling their magnetization-potential profiles in magnetic tunnel junctions [2]. In our previous work [3], we have demonstrated a detection sensitivity of over 7×10^4 mV/mW in magnetic tunnel junction with perpendicularly magnetized free layer and in-plane magnetized reference layer at zero external magnetic field. The enhanced detection sensitivity is ascribed to the large-amplitude out-of-plane precession when the injection locking occurs due to the simultaneous application of d.c. and microwave currents. In this study, we investigated the effect of the perpendicular magnetic anisotropy (PMA) on the detection properties of STD. We found that the PMA at the interface of the CoFeB free layer with the MgO tunnel barrier is critical to improve the orbit of magnetization precession. At proper condition, by applying simultaneously a d.c. bias current to a STD, microwave emission induced by spin-torque is locked to an external microwave signal, leading to a drastically enhanced detection sensitivity in the locking regime. The optimized STD exhibited the detection sensitivity of 2.1×10^5 mV/mW in absence of the external magnetic fields, which is the highest sensitivity from a STD reported to date. The results suggest that the STD with injection locking technique is promising for next generation microwave detectors.

ET-12. Proximity effect induced enhanced spin pumping in Py/Gd at room temperature.

R. Bansal[1], N. Chowdhury[1] and P.K. Muduli[1]
1. Physics, Indian Institute of Technology, New Delhi, Delhi, India

Investigating the damping processes and the behavior of dynamic magnetic properties in ferromagnetic (FM) thin films has been an important key towards design and fabrication of different microwave and magnetic recording devices. Damping in a magnetic material can be enhanced due to spin pumping, in which magnetization precession in the FM layer produces a spin current that flows into the adjacent non-magnetic (NM) layer[1-2]. It is an interfacial effect and plays an important role in thin films. A recent theoretical work predicted that magnetic relaxation can be significantly enhanced when spin pumping is performed into a ferromagnet near Curie temperature (T_C) due to the fluctuation enhancement of the spin conductance across the interface [3]. This was qualitatively confirmed by Khodadadi *et al.* [4] in Py/Gd system at low temperature. Here, we discuss the relaxation mechanism in Py/Gd structure by means of broadband ferromagnetic resonance (FMR) technique at room temperature. We show that a portion of the Gd layer at the interface becomes ferromagnetically ordered at room temperature and become antiferromagnetically (AFM) coupled to the Py due to the magnetic proximity effect (MPE). The ordered Gd at the interface of Py/Gd acts as a spin sink and contributes to the increase in spin pumping. In this work, we performed FMR measurement on two series of samples consisting of Py (15nm)/Gd (*t*) and Py (15 nm)/Al (*t*), where *t* is the varying thickness of material from 0 to 16 nm. Py/Gd films were designed to study proximity induced magnetization in Gd due to neighboring Py. A series of Py/Al reference samples were used to distinguish proximity induced effect in Py/Gd films from other interface-related effects due to long spin diffusion length of Al compared to Gd. FMR measurements were carried out using a co-planner waveguide (CPW) based FMR set-up in the frequency range of 3-17 GHz. The raw FMR spectra were fitted using a derivative of Lorentzian line shape to determine the resonance field (H_R) and line-width (ΔH). Fig.1 shows the FMR spectra for Py/Gd samples at a fixed frequency of 10 GHz. The inset shows Gd-caused FMR resonance field shift (H_{shift}) as a function of t_{Gd}. This change in H_{shift} with t_{Gd} can be attributed to the MPE. The observed negative H_{shift} indicate a reduction of effective magnetization of the Py layer due to AFM coupling between the Py and the ordered interfacial Gd layer. We found that M_{eff} decreases with increase in t_{Gd} due to the AFM coupling between Py and ordered portion of the Gd layer. To further confirm that this is caused due to the MPE, not from other interfacial effects, we performed similar FMR measurements in a series of Py/Al samples. We did not observe any decrease of magnetization in Py/Al samples as shown in the inset of fig. 2(a). In these samples, the behavior of M_{eff} with t_{Al} is almost constant, indicating the absence of AFM coupling. The effective Gilbert damping parameter (α_{eff}) increases significantly with increase in t_{Gd} as shown in Fig.2 (b). An increase of 63.5% is observed in α_{eff} for Py/Gd bilayers as compared to Py alone. The inset of Fig. 2(b) shows the behavior of α_{eff} with t_{Al} for which we did not find significant enhancement of α_{eff}. We will show that a major contribution of this enhancement is due to the spin pumping effect into the ordered ferromagnet Gd layer which is near it's Curie temperature. This provides a qualitative confirmation of a recent theoretical prediction of spin sinking enhancement in this situation.

1. Introduction Recently attractions in nanomagnetism[1] is triggered by their fundamental physics as well as their huge potential applications in various fields of nanotechnology such as magnetic storage, memory, sensors, logic and communication devices. Bi-stable ferromagnetic cross-shaped nanoelements showed complex spin configurations[2] and subsequent report[3] proposed application of ferromagnetic cross-shaped elements as reconfigurable spin-based logic devices using spin-wave (SW) scattering and interference. The above results open a door for application of ferromagnetic cross structures as a building block of the above-mentioned devices, and hence, investigation of the static and dynamic magnetic properties of this structure with its size, inter-element interaction and variation of bias magnetic field strength and in-plane orientation has become very important. 2. Results and discussions Here, we report a systematic study of SW dynamics in $Ni_{80}Fe_{20}$ (Py) nano-crosses with varying arm lengths (200 nm $\leq L \leq$ 600 nm) while keeping edge to edge separation (S = 150 nm) fixed, fabricated by a combination of e-beam lithography and e-beam evaporation and measured using broadband ferromagnetic resonance technique. We have rigorously investigated bias field strength (H) and in-plane orientation (θ) dependent evolution of static spin configuration and magnetization dynamics in Py nano-cross[4] arrays of varying size (L). The bias field dependent ferromagnetic resonance (FMR) spectra for the nano-cross arrays with L = 600 nm and 500 nm at θ = 0° respectively are shown in Figures 1(b)-1(c) and surface plot with θ = 15° for L = 600 nm is shown in Figure 1(a). We have observed a remarkable variation in the SW dynamics with H which is also modified with size of nano-crosses including mode softening, mode splitting, mode crossover and mode merging. Particularly, SW mode softening strongly depends on the external bias field orientation. We also demonstrate that the mode splitting, mode crossover, mode merging and number of modes can be easily tuned by changing the applied bias field direction, which is further modified with size of the nano-cross element also. To understand the experimental results, we have performed micromagnetic simulations using OOMMF software, which reproduced the experimental results very well. Further, we simulated phase profiles of different SW modes using a home built code, from where we have characterized the observed SW modes. In Figures 1(e)-1(f) it is shown that how lowest frequency branch gets modified with the increase in bias fields. Here *n, m* corresponds to quantization number for backward volume mode and Damon-Eshbach mode, respectively. To understand the dynamics further, we have numerically calculated the magnetostatic field distributions in the nano-cross arrays (Fig. 1(g)). Line scan of this field reveals that with the decrease in arm length (L), the inter-cross interaction field as well as the internal field decrease monotonically as plotted in Figs. 1(h)-1(i). 3. Conclusions In summary, we investigated bias field strength and orientation dependent evolution of static magnetic configuration and magnetization dynamics in $Ni_{80}Fe_{20}$ nano-cross arrays of varying cross size using broadband ferromagnetic resonance technique. We observed a strong variation in the number of spin-wave (SW) modes and mode frequencies (f) with bias field magnitude (H) as well as in-plane orientation (θ). Simulated static spin configurations and SW mode profiles explain the rich variation of the SW spectra, including mode softening, mode crossover, mode splitting and mode merging. Such variation of SW spectra is further modified by the size of the nano-cross. Calculated magnetostatic field distributions supported the above observations and revealed the non-collective nature of the dynamics in closely packed nano-cross structures. The latter is useful for their possible applications in magnetic storage, logic and communication devices. We gratefully acknowledge the financial support from S. N. Bose National Centre for Basic Sciences (Grant no. SNB/AB/12-13/96) and Department of Science and Technology, Government of India (Grant No.SR/NM/NS-09/2011(G)).

1. State Key Laboratory of Control and Simulation of Power System and Generation Equipments, Tsinghua University, Beijing, China; 2. State Key Laboratory of Reliability and Intelligence of Electrical Equipment, Hebei University of Technology, Tianjin, China; 3. Municipal Key Laboratory of Advanced Technology of Electrical Engineering and Energy, Tianjin Polytechnic University, Tianjin, China

Abstract Body: On the basis of damping principle of vibration, the domain wall processes is investigated and modeled at low-to-medium frequencies in electrical steel sheets. Due to the energy dissipation chiefly descends from a micro-vortex current caused by domain wall motion, the coupled Landau-Lifshitz-Gilbert (LLG) and Maxwell electromagnetic diffusion equations are thus considered to describe the high-frequency characteristics. The overall core losses are eventually deduced in terms of separate contributions by domain wall processes and classical eddy current. Moreover, the calculation model can be extended to rotational excitation pattern. Hence, taking the typical electrical steel sheets as example, the novel core losses calculation model is analysed and compared with the total alternating core losses supplied by electrical steel sheets manufacturers and the 3-D rotating experimental core losses of sheets specimens which are carried out by using a 3-D magnetic properties testing system, and also achieve some beneficial conclusions. 1. Since the domain wall processes is essentially the magnetic moment rotation, then domain wall motion can be interpreted by solving LLG equation, that is [1, 2]: $\partial J/\partial t = -\chi J\times[H_{eff}+(\alpha/J_s)J\times H_{eff}]$, $|J| = J_s$ (1) where, $J = \mu_0 M$ represents the magnetic polarization vector inside the domain, M is the magnetization vector, μ_0 is the permeability of vacuum, $\chi = |e|/m_e = 1.76\times10^{11}$ $T^{-1}s^{-1}$ is the absolute value of the electron gyromagnetic ratio [3]; H_{eff} represents the overall effective field, which affects on the magnetic moments; $\alpha = \eta J_s$ is the qualitative dimensionless damping constant (Landau-Lifshitz damping coefficient), η is the damping coefficient of domain wall motion, J_s is the saturation polarization. The first term on the right side of Eq. (1) describes the magnetic moment precession around the effective field direction, while the second term is the damping motion towards the effective field. 2. As regard to the right sheet with the walls in Fig. 1, in effect of the high-frequency excitation field H, the wall moves to make on both sides of the domains contraction and expansion. Now, by applying Maxwell electromagnetic diffusion equation: $\partial^2 H_{vor}/\partial y^2 = \sigma\mu_0[\partial(M+H_{vor}+H)/\partial t]$ (2) where, σ is the electrical conductivity of magnetic materials and the vortex current field H_{vor} is directed to y-axis. At this point, such a response can be described in general terms by the solution of the coupled LLG (Eq. (1)) and Maxwell electromagnetic diffusion (Eq. (2)) equations. 3. According to the above derivation, the overall core losses per unit mass of electrical steel sheets are eventually deduced in terms of separate contributions by classical eddy current and domain wall processes, as follows: $P_{cl} = P_{cel}+\bar{P}_{mel} = (\sigma\pi^2 d^2/3\rho)f^2(B_m)^2+(\sigma\pi^2 d^2/4\rho)f^2(B_m)^2=(7\sigma\pi^2 d^2/12\rho)f^2(B_m)^2$ [W/kg] (3) where, P_{cl} is the overall core losses per unit mass of electrical steel sheets; P_{cel} is the classical eddy current loss per unit mass; $\bar{P}_{mel}$ is the mean micro-vortex current losses per unit mass; d is the thickness of the magnetic sheet; ρ is the mass density of magnetic materials; f is the excitation frequency; B_m is the peak flux density. 4. In order to validate the precision of the calculation model, the total alternating core losses supplied by electrical steel sheets manufacturers are used to compare with the calculation of Eq. (3), including cold-rolled GO electrical steel, NO electrical steel and hot-rolled electrical steel over wide range of excitation frequency [4, 5]. In addition, the model can be extended to rotational excitation pattern, so the 3-D rotational experimental core losses of typical electrical steel sheets carried out by using a 3-D magnetic properties testing system are also considered in the validity of the calculation model [6, 7]. The typical comparison result is shown in Fig. 2. Conclusion: Based on the basic equation of Micromagnetism (LLG equation), the vibration analysis of micro domain wall processes is carried on by applying excitation field at low-to-medium frequencies in combination with the field intensity spatial distribution of magnetic dipoles in this paper. By coupling Maxwell electromagnetic diffusion equations, the high-frequency micro-vortex current losses due to domain wall motion are deduced. Consequently, the calculation model of overall core losses are developed ultimately by means of the separate contributions of domain wall processes and classical eddy current. Precision and validity of the model are testified by several kinds of typical electrical steel sheets, including their alternating and 3-D rotational core losses. The modelling method of mean micro-vortex current losses and the characteristics analysis of the total core losses calculation model are helpful to engineering application. In addition, the investigation is a very important problem in the research field of Micro-magnetism and Magnetization Dynamics. This study can not only reveal the intrinsic characteristics of electrical steel sheets, but also provide reference for exploring origins of the core losses in magnetic materials in practice.

A magnetic Skyrmion is a chiral structure appearing in a magnetic thin film with Dzyaloshinskii-Moriya interaction (DMI) [1-4]. Because of its small size and the small threshold current for motion, it is expected to be used as an information carrier for a magnetic storage system [5-7]. The methods to manipulate the Skyrmion, nucleation, annihilation, switching of the core direction, motion, by external field, spin-polarized current and the others have been proposed. In this paper, we propose a method to switch the chirality of the Skyrmion by a pulse heat spot, and study it by simulation. The micromagnetic model was used and the motion of the magnetization in the thin film was calculated using the Landau-Lifshitz-Gilbert equation. The thin film model possessed dimensions of $256\times256\times1.4$ nm^3, and was further divided into rectangular prisms with dimensions of $0.5\times0.5\times1.4$ nm^3. Typical material parameters for perpendicularly-magnetized CoFeB thin films were used. These were a saturation magnetization M_s = 1600 emu/cm^3, a gyromagnetic ratio γ= 1.76×10^7rad/(s Oe), an exchange stiffness constant A = 3.1×10^{-6} erg/cm, an uniaxial anisotropy constant K_u = 16.2 Merg/cm^3, the Gilbert damping constant α = 0.1, and the DMI constant D = 0.6 erg/cm^2. Two types of Skyrmions with clock wise (CW) and counter clock wise (CCW) chirality were used as the initial states. In the simulation, a pulse heat spot with Gaussian shape was applied. The σ of the head spot (σ_h) was varied from 5 to 50 nm. The room temperature and the maximum temperature of the heat spot were set to be 300 and 550 K. The rise and fall time of the heat spot was assumed to be zero. The pulse length of the heat spot (t_p) was varied from 0.2 to 3.0 ns. Simulation was continued for 10 ns after to cut the pulse. The material parameters M_s, K_u, A, and D of each prisms were decreased as temperature was increased. Figure 1 shows the simulated time-resolved chirality switching by a heat spot. The CCW Skyrmion (fig. 1(a)) expands by the heat spot keeping the magnetization direction (fig. 1(b)). The Skyrmion shrinks after to cut the pulse, the magnetization rotates to the crock wise direction, and the CW Skyrmion appears (fig. 1(c)). The CW Skyrmion (fig. 1(d)) expands slightly by the heat spot, however the magnetization rotates to the counter clock wise direction (fig. 1(e)). The magnetization keeps to rotate to the same direction after to cut the pulse, and the CCW Skyrmion appears (fig. 1(f)). The Skyrmion breathes by these operations especially with large and long pulse. It annihilates with large breathing when it shrinks. Figure 2 show the diagram plotting the switching, not switching and annihilating of the Skyrmion structure on σ_h and t_p for CCW (fig. 2(a)) and CW (fig. 2(b)) Skyrmions. They show that there are conditions to switch both Skyrmions and there are also conditions to switch only one type of Skyrmions. The chirality of the Skyrmion can be specified by using the latter conditions. We investigate the switching of Skyrmion chirality dependence on the pulse heat spotσ_h and the pulse heat time t_p. It is found that there are the optimized conditions for Skyrmion chirality to be controlled, and that the changing of magnetization structure in Skyrmion during the pulse heating is different dependence on the initial Skyrmion chiral state.

EU-01. Magnetic properties of $L1_0$ FePt thin film influenced by strains stemmed from the polarization of PMN-PT substrate.

L. Liu[1], C. Hu[2], Y. Xu[1] and W. Rao[1]
1. Department of Materials Physics, and IEMM, Nanjing University of Information Science and Technology, Nanjing, China; 2. College of Materials Science and Engineering, Liaocheng University, Liaocheng, China

I. INTRODUCTION The perpendicular magnetic anisotropy(PMA) depending on structural domain orientation is vital to the performance of magnetic devices based on the $L1_0$ FePt thin films. In general, the out-of-plane ordered structural domains(OPOSDs) are desired in devices. However, the maximal volume of the OPOSDs can only reach 76 % [1]. One of the ways to increase the volume of OPOSDs is to change the strain states between the thin film and substrate. Experimental results [1, 2] showed that the large lattice mismatch between the thin films and substrates can cause tensile stress to the thin films, resulting in a large volume of OPOSDs and large PMA. Nevertheless, the experimental work [21] showed that the coercivities increase with the increase of the compressive strain in the thin film deposited on PMN-PT substrate. II. SIMULATION METHOD Phase field method is a powerful tool to simulate the magnetic properties in magnetic materials [4], In this work, based on the work [3], especially considering the role of magnetoelastic energy, the effect of the compressive strains on the PMA, magnetic domains evolution, in the $L1_0$ FePt thin film were studied in details by using the phase field model. III. RESULTS Fig. 1 shows the effect of compressive strain on the magnetic hysteresis loops and magnetic coercivities of the $L1_0$ FePt thin film. The area D in magnetic hysteresis of the $L1_0$ FePt thin film in Fig. 1(a) is enlarged shown in Fig. 1(b), which show that the magnetic coercivities increase with the decrease of compressive strains. Fig. 2 shows the magnetic domain structures corresponding to the point A, B, C, D, E, and F in the simulated hysteresis loops of the $L1_0$ FePt thin film with the strain of -0.06% in Fig. 1(a). The evolution of magnetic domain structure of the $L1_0$ FePt thin film under this strain shows that the magnetization changes from [001] single domain to multidomain and then from multidomain change to single magnetic domain at the reversible magnetization processes. The magnetic energies variations will be analyzed in future studies.

EU-02. Voltage controlled spin torque nano-oscillator based on magnetic skyrmion.

C. Song[1], C. Jin[1], H. Xia[1], J. Wang[1], J. Wang[1,2] and Q. Liu[1]
1. Key Laboratory for Magnetism and Magnetic Materials of the Ministry of Education, Lanzhou University, Lanzhou, China; 2. Key Laboratory for Special Function Materials and Structural Design of the Ministry of Education, Lanzhou University, Lanzhou, China

Magnetic skyrmions are topologically protected stable magnetization configurations, which exhibit to be a promising candidate for future memory and logic devices[1-4], due to their its topological stability, small size and low driving current[5-7]. One of the potential applications of skyrmion is nanocontact spin transfer nano-oscillators (STNOs)[8-9]. In this work, we propose a voltage controlled magnetic skyrmion STNO by using micromagnetic simulations. Here, a ring shaped voltage controlled magnetic anisotropy (VCMA) gate is applied on the skyrmion based STNO. It is found that the skyrmion size can be increased or decreased by applying a negative or positive electric field in the ring. Furthermore, the skyrmion dynamics can also be effectively modulated with applying ring-shaped VCMA gate. By tnning the current density, ring-shaped VCMA gate position and VCMA effect of the ring, the oscillarion frequency varies in a large range. This unconventional manipulation of magnetic skyrmions in STNOs allows a robust way of controlling frequency of skyrmions oscillator, and provides a new path to skyrmions based STNOs. Figure 1 depicts a schematic diagram of skyrmion based STNO device with a VCMA gate (white ring), which consists of free layer, a non-ferromagnetic space layer and a fixed layer. At the top and bottom of this device, there are two point-contact electrodes to ensure the spin polarized current flowing locally and perpendicularly, the radius of point-contact electrode is 10 nm. The ring shaped VCMA gate is applied on the free layer, and the spin polarization takes the form in the out-of-plane magnetized fixed layer along –*z*-direction. The magnetic free layer is assumed to be an ultrathin film with perpendicular magnetic anisotropy (PMA) and interfacial Dzyaloshinskii–Moriya interaction (DMI). Magnetic skyrmion is in the center of the free layer as a ground state, and it is gyrotropic in the free layer under the spin-polarized current. Figure 2 shows the oscillation frequency as a function of r for different K_{uv}. The skyrmion oscillation frequency is 430 MHz without VCMA effect in the nanodisk, which is represented by the black line in figure 2. When applying a current, the skyrmion reaches a steady motion and r_o is about 16 nm, and the radius r_s is about 10 nm in the rotation for all the cases. With applying a negative electric field, the PMA of the ring K_{uv} is reduced to 0.72×10^6 J/m^3, the frequency is still 430 MHz at $r = 15$ nm. While it reaches to 20.39 GHz at $r = 20$ nm. The inset shows the corresponding magnetization distribuions in this case. It indicates that the skyrmion is pinned with the edge of skyrmion expanding to the VCMA-gated region, and the inner magnetizations of skyrmion (red region) keep a steady precession under spin-polarized current. Increasing r to 25 nm, the oscillation frequency is 515 MHz, and it decreases to 475 MHz at $r = 30$ nm. It is noteworthy that the oscillation frequency decreases to a minimum value 335 MHz when $r = 35$ nm, and it is close to 430 MHz when $r = 40$ nm and 45 nm. When K_{uv} increases to 0.76×10^6 J/m^3, the frequency reaches a maximum at $r = 25$ nm with the value of 475 MHz, and a minimum at $r = 35$ nm with the value of 380 MHz. However, when applying a positive electric field with increasing to 0.84×10^6 J/m^3, the frequency decreases to 395 MHz with $r = 25$ nm, and then increases to the maximum 480 MHz at $r = 35$ nm. In the case of $K_{uv} = 0.88 \times 10^6$ J/m^3, the oscillation frequency reaches a minimum 360 MHz at $r = 25$ nm, and a maxmimum 525 MHz at $r = 35$ nm.

EU-03. Effects of Anisotropy Field and easy axis dispersions on squareness ratio for HDDR-processed NdFeB powders.

F. Akagi[1], T. Shirai[1] and R. Kariya[1]
1. Kogakuin Univ., Shinjuku-ku, Japan

I. INTRODUCTION NdFeB magnetic powders that are produced by a hydrogenation decomposition desorption recombination (HDDR) process consist of small grains with highly anisotropic energy [1-3]. Therefore, HDDR-processed NdFeB magnet powders are expected to have a high squareness ratio and high coercivity (H_c) to obtain the high maximum energy product ($BH_{\max}$) that is required in highly efficient motors of hybrid or electric vehicles. The squareness ratio is defined as the value of the magnetic field at 90% of the remanent magnetization divided by H_c. However, the squareness ratio is much lower than the expected value of 1.0, and the H_c is lower than a third of the average anisotropy fields. A previous study using a micromagnetic simulator has shown that when an anisotropy field (H_k) dispersion of grains was assumed to be a Gaussian distribution with a coefficient variation ($\sigma H_k/\langle H_k\rangle$) of 30%, the squareness ratio corresponded with an experimental value [4]. However, Nishio et al. showed that the H_k of a single crystal was 7600 kA/m [5]. Therefore, when the $\sigma H_k/\langle H_k\rangle$ is 30%, the $\langle H_k\rangle + 3\sigma H_k$ is unrealistically higher than the H_k of a single crystal. In this study, the H_k dispersion of the grains was assumed to be a horizontally flipped lognormal distribution, and the effects of the H_k dispersion of the grains on the squareness ratio were investigated by using a micromagnetic simulator. Moreover, Nishio et al. showed that an easy axis (c-axis) inclination angle was distributed within ±20° [6], so we also investigated the effects of the c-axis dispersion on the squareness ratio. II. CALCULATION METHOD AND MODEL We calculated the time change of magnetization for each grain using an EXAMAG LLG simulator [7]. The Landau-Lifshitz-Gilbert equation shown below was calculated by using the finite element method (FEM): $dM/dt = -\gamma(M\times H_{eff}) + \alpha/M_s(M\times dM/dt)$, (1) where M is magnetization, t is time, γ is the gyromagnetic ratio, H_{eff} is the effective field (which is the sum of the applied, static, anisotropy, and exchange fields), α is the damping constant, and M_s is the saturation magnetization. The calculation model of the NdFeB powder contained 64 grains, and each grain was a cube with a side length of 40 nm, including cube cells with a side length of 2 nm. The grain boundaries were 2 nm wide and the deterioration layers of the grain surfaces were also 2 nm wide [4]. The saturation magnetization (M_s) of the main phase was 1.61 T. The average H_k ($\langle H_k\rangle$) was 5000 or 6077 kA/m, and the coefficient variation of H_k ($\sigma H_k/\langle H_k\rangle$) was changed from 0 to 30%. The exchange stiffness constant was 1.0×10^{-11} J/m. The grain boundaries were assumed to be made from non-magnetic or soft magnetic materials. In the case of soft magnetic material, the M_s was 0.805 T, the H_k was 1 kA/m, and the exchange stiffness constant was 6.25×10^{-12} J/m. The H_k of the deterioration layer was 10% of the main-phase grain, and the M_s was the same as that of the main phase. The c-axis followed a Gaussian distribution with a standard deviation from 0 to 30°. III. RESULTS AND DISCUSSIONS Figure 1 shows the $\sigma H_k/\langle H_k\rangle$ dependence of the squareness ratio for the non-magnetic grain boundaries. As seen from this graph, there was only a small difference between the average H_ks of 5000 and 6077 kA/m, and each squareness ratio decreased with increasing $\sigma H_k/\langle H_k\rangle$. When the $\sigma H_k/\langle H_k\rangle$ was about 27%, the squareness ratio was close to the experimental value. Figure 2 shows the standard deviation of the c-axis dependence of the squareness ratio. The squareness ratio for the soft magnetic grain boundaries was substantially independent of the standard deviation of the c-axis and was far from the experimental value. This is because the magnetizations for the soft magnetic grain boundaries reversed rapidly due to a magnetic domain wall motion between the grains and the grain boundaries. On the other hand, the squareness ratio of the non-magnetic grain boundaries was much lower than that of the soft magnetic grain boundaries. The squareness ratio for the non-magnetic grain boundaries decreased and was close to the experimental value with increasing standard deviation of the c-axis. Therefore, the non-magnetic grain boundaries led to a low squareness ratio. However, Nd-enriched grain boundaries and grain boundaries comprised of ferromagnetic elements were experimentally observed [8]. As a result, some grain boundaries might be soft magnetic materials, and others might be non-magnetic materials that pin the magnetization reversal. In comparison, the squareness ratio of the non-magnetic boundaries was larger than the experimental value, although the standard variation was up to 30°. Therefore, the low squareness ratio cannot be explained by only the c-axis dispersion. The results show that both the H_k dispersion and the c-axis dispersion affect the squareness ratio. IV. CONCLUSION We investigated the effects of the H_k and the easy axis dispersions of the grains on the squareness ratio using a micromagnetic simulator. It resulted that both dispersions affected the squareness ratio, and the average H_k hardly contributed to the squareness ratio. It was also found that the non-magnetic grain boundaries led to a low squareness ratio. ACKNOWLEDGMENTS We thank Dr. Mishima of Aichi Steel Corporation for his advice on experimentally bonded magnets.

Introduction Spin-transfer torque (STT) magnetic random access memory (MRAM) with perpendicular anisotropy is expected to replace dynamic random access memory (DRAM) in high density nonvolatile memory applications. To realise high density MRAM, the write current has to be reduced while keeping high thermal stability $\Delta=K_uV/k_BT$[1]. Bi-layer structures, such as a magnetically hard-soft composite structure with Joule heating (EcC) [2], have been proposed to achieve these aims. Structures with three or more layers, such as the graded magnetic anisotropy medium structure [3], have been used for high density magnetic recording, and their application to MRAM has also been proposed to improve the switching efficiency. Recently, Zhang et al. [4] suggested that a tri-layer with a low Currie temperature (Tc) magnetic interlayer sandwiched between two hard magnetic layers could be used as a hybrid free layer (HFL) to solve the dilemma between writability and retention in MRAM. We previously proposed a new tri-layer with a low-Tc, hard magnetic interlayer between magnetically soft and hard layers, which has the possibility to be graded. In this work, we use numerical simulations with a Landau-Lifshitz-Bloch (LLB) model to analyze the switching characteristics of the new tri-layer and show that it has advantages over EcC in MRAM applications. The Model In our simulations, the micromagnetic simulator described in [5] was used. In this simulator, a Landau-Lifshitz-Bloch (LLB) model [6] with a Slonczewski STT term [7] was implemented to calculate STT-induced magnetization switching characteristics such as the switching probability, switching time and thermal stability factor. The model also takes account of the increase in temperature due to Joule heating during switching operations. The device diameter was fixed at 20 nm and the total thickness of the new tri-layer was 4 nm. As shown in fig. 1(a), the EcC structure consisted of two layers: one soft layer (2nm) and one hard layer (2nm), while the new tri-layer structure consisted of three layers: one soft layer (1nm), one low-Tc, hard interlayer (1nm), and a high-Tc, hard layer (2nm). The key material parameters of the structures are shown in fig. 1(b). The magnetic anisotropy K_u for each structure was chosen to satisfy $\Delta=60$ at room temperature. The same damping constant α, exchange stiffness A_{ex}, and interlayer exchange coupling A_{iec} were used for all structures. In our simulations, the magnetization evolution was calculated for 20 ns. Fig. 1(c) shows the write current I_c and temperature profile due to Joule heating [5]. The write current I_c was applied for 10 ns and was assumed to be uniform inside the structures. For the temperature profile, the device temperature increased for 1 ns with a temperature rise proportional to I_c^2, then remained constant for 9 ns, and finally decreased to the initial temperature over a period of 5 ns. Results Fig 2.(a) shows the write current I_c [υA] dependence of the switching probabilities at room temperature for the EcC and the new tri-layer structures. As shown in the figure, a smaller I_c can switch the magnetization in the new tri-layer when compared with the EcC structure. To demonstrate this current reduction more qualitatively, the critical switching current I_{c0} was estimated by fitting the inverse of the switching time $1/T_{sw}$ [1/nsec] and linearly extrapolating to the x-axis, as shown in Fig 2.(b). As shown in the table in fig. 2(b), the new tri-layer can reduce I_{c0} by 10% when compared with the EcC structure. The magnetic anisotropy of the second layer in the new tri-layer becomes smaller than that of the third layer due to Joule heating when the write current exceeds I_{c0}. The reduction in switching current may be considered to be partly caused by this faster reduction of magnetic anisotropy in the second layer. In this work, we compared the switching performance of EcC and the new tri-layer structure using a LLB model, and showed that the new tri-layer had a better switching performance. It is concluded that the new tri-layer is a more promising approach to reduce the write current while keeping the thermal stability. The tri-layer structures can realise various structures, such as graded anisotropy, to further improve the switching characteristics because they have a larger number of degrees of freedom for the magnetic properties. In the presentation we will discuss the temperature dependence of the switching probability and optimisation of the magnetic properties of the new tri-layer structure, and the effect of thermally assisted graded anisotropy on the write current reduction.

I. INTRODUCTION The discretization of the micro-structure of ribbon magnetic cores and laminated iron cores, i.e. by finite element method, would lead to a prohibitively large systems of equation. It is a huge difficulty for the modern computer to solve, even for the supercomputers. Surely, it is far away from being a routine task for engineers in the design and analysis of electrical devices. To overcome this unpleasant fact, homogenization methods have been developed. In 2003, Dular adopted FEM combined with the homogenization method to study a 3D magnetic field and the eddy currents in laminated stacks were taken into account[1]. Gyselinck presented a novel time-domain homogenization technique for laminated iron cores in three-dimensional (3-D) FE models for linear and nonlinear problems, respectively[2],[3]. However, the homogenization method is external equivalent. More often, it is desirable to capture the small-scale effect on the large scales, like the eddy currents, and magnetic distribution in the laminations for loss calculation. In order to capture the effects on the small scale, some researchers proposed their solutions. Duan proposed an improved extended finite element method (XFEM) for modeling electromagnetic devices with multiple nearby geometrical interfaces and discontinuities in electric fields [4], [5]. Meanwhile, Hollaus developed a 'multiscale finite element method' for the 2D, and 3D eddy current problem in iron laminates [6], [7]. The mesh is independent of the geometries for the XFEM and the multiscale finite element proposed by Hollaus. In a word, these methods are homogenization techniques relying on analytical expression or asymptotic expansions of fields, and mixed formulas based on finite element method. In this paper, we aimed to capture the magnetic distribution in the small scale of a ribbon magnetic cores through another multiscale finite element method (MsFEM) which is totally different from the one proposed by Hollaus. This MsFEM is first proposed by Hou for the elliptic problems in composite materials and porous media [8]. The magnetic distribution in each ribbon and the gaps between ribbons will be obtained. Hence, it is no longer to use some assumptions to get the losses since magnetic field is finely calculated. Observation on each single ribbon is possible for engineers. II. MATHEMATICAL MODEL The main idea of MsFEM is to construct finite element basis functions which capture the small scale information within each macro element. The small scale information is then brought to the large scales through the coupling of the global stiffness matrix. Thus, the effects of small scale on the large scale is captured. Like the XFEM, the mesh is independent of the geometries of the models, and several materials are might contained in each macro element. Compared to other multiscale modeling methods, basis function of MsFEM is numerical type basis function, which means that we do not have to find the expression of a numerical basis function, it is a more general method. What is more, MsFEM could be implemented based on the commercial simulation software packages. It is more flexible. In general, there are three major steps for MsFEM's implementation: basis function construction, global formulation, and downscaling analysis. Basis function construction is obtained by solving the local boundary problem with certain specified boundary conditions. The governing equations for the static magnetic field of the simulation model shown in Fig.1., Fig.1. (a)Simulation model, (b) and its mesh schematic diagram The specified boundary conditions for macro element E along x direction of Γ_1 is shown in (2). III. CONCLUSSION By adopting the MsFEM, the magnetic distribution in the each ribbon and the gap between the ribbons could be finely computed. We believe that it is much useful for loss calculation of the ribbon magnetic cores of high frequency transformer and iron cores of power transformers' design and performance analysis. Hence, methods resorting to some assumptions will be no longer needed for losses calculation.

1. College of Materials Science and Engineering, Beijing University of Technology, Beijing, China

I. INTRODUCTION The 3d transition metals such as iron, cobalt, and their alloys bear high saturation magnetization (M_s) and high Curie temperatures (T_C), which are necessary for the giant energy product and good thermal stability, respectively. For the nanowire of 3d transition metals, such as Co nanowires, the effective anisotropy field can be as much as 16.5 kOe by combining the shape anisotropy and magnetocrystalline anisotropy. However, such high coercivity has never been achieved, because there are much defects and the easy axis deviation from the length direction for the nanowires. Therefore, in this study, we investigate the influence of the defects and deviation of easy axis on the coercivity and magnetization reversal process via 3D micromagnetic simulations. II. METHOD The micromagnetic simulation on Cobalt nanowire is performed by OOMMF (the Object Oriented Micromagnetic Framework) which is based on the Landau-Lifhitz-Gilbert (LLG) dynamic equation [1]. The size of simulated mode is considered as a 10 nm × 10 nm × 200 nm prism. The error of the simulated results between the prismatic models and cylindrical is not more than 5% [2]. The magnetocrystalline easy axis deviates from the applied field H with the angle β, while the easy axis deviation of the defects is β_2. Based on the finite difference method of OOMMF, the nanowire has been divided into 1 nm × 1 nm × 1 nm cells. In the simulation process, a small angle of 0.6° between the applied field and the easy axis has been utilized to break the non-stable equilibrium states which would produce an overly large coercivity [3, 4]. III. RUSULTS AND DISSUSION The hysteresis loops of the nanowires with different easy axis deviation β are quite different as shown in Fig.1. The nanowire with β = 0° shows the good squareness and high coercivity of 12.15 kOe. The coercivity and remanence decreases linearly with the β increases. Meanwhile, the squareness of the hysteresis loops has been destroyed rapidly. The relationship between the coercivity and β is consistent with the results of coherent rotation[5]. The magnetization distribution also shown that the magnetization reversal mode is quasi-coherent rotation that the magnetic reversal nucleation is easy to occur at both the ends. Besides, we also calculated the magnetization process of Co nanowire with defects. Here, we just consider the situation that the easy axes of the defects deviate from the length direction. Fig. 2 shows the simulated hysteresis loops of nanowires with the defect in the middle and ends, respectively. For the nanowire with the defect in the middle, as $\beta_2 \leq 60°$,the defect has no effect on the coercivity of the nanowire. When β_2 is as large as 90°, the coercivity decreases from 10.7 kOe to 8.86 kOe. For the nanowire with the defect in the ends, as shown in Fig. 2(b), the coercivity decrease monotonously with the increase of β_2. IV. CONCLUSION The demagnetization process of a Co nanowire have been investigated with the easy axis deviation from the nanowire direction. As β inceases, the coercivity and remanence decrease gradually, which lead to the reduction of the maximum energy products. Besides, the defects occurring at different position also have effects on the magnetic property of Co nanowire. The nanowires is more sensitive to the defects in the ends than in the middle because the magnetization rotation starts from the ends of the nanowire. Thus, to obtained high coercivity permanent nanowire materials, we must ensure that the easy axis orient in the length direction and reduce the defects, especially reduce the defects in the ends of the nanowire.

EU-08. An optimal design of an electromagnetic actuator for targeting magnetic micro/nano-carriers in a desired region.

T. Le[1] and *J. Yoon*[1]
1. School of Integrated technology, Gwangju Institutue of Science and Technology, Gwangju, The Republic of Korea

I. INTRODUCTION Magnetic drug targeting (MDT) is a technique for transporting magnetic nanoparticles (MNPs) to, and concentrating them in, a desired location [1, 2]. MDT can increase the concentration of drugs in the desired region inside a body, therefore reduce the side effects of drugs in the rest of body. The focusing function of micro/nano-particles into a target region is prerequisite for the success of the MDT. However, a static magnetic field is unable to focus micro/nanoparticles [3]. To overcome this limitation, a new scheme using ferromagnetic rods and fast magnetic pulses was introduced in [4]. Our group also introduced a novel electromagnetic actuation scheme for concentrating spherical nano particles (SNPs), which are being extensively utilized in biomedical fields [5]. However, the targeting actuator requires a compact design with fast targeting efficiency. In this paper, the optimal design of the suggested actuation system for focusing micro/nano-particles is studied. Since maximizing the magnetic gradient within the workspace of the actuator can enhance the efficiency of the targeting and the capacity of device is limited in fact, the magnetic gradient is selected to be optimized to focus nanoparticles on a specified surface. The configuration and specifications of the optimized design for the actuator are presented, and its performance was examined through simulations in the COM-SOL™ Multiphysics software. II. Actuation scheme for Focusing Field Two independent actuation coils (ACC) can be oppositely placed, as shown in Fig. 1(a). By adjusting the distance of the two ACCs and/or changing the current of coils, a focusing region between two free field point (FFP) locations can be generated on the *x*-axis. The proposed scheme can focus the SNPs in the *x*-axis. We propose a focusing scheme for a surface region by combining two focusing actuators for line segment. The *x*- and *y*-axis coils will be operated alternately with the time function (TF) of the currents shown in Fig. 1(b). By applying TF, the SNPs can be pushed from the four sides of the surface region and concentrated into a target surface region. The SNPs will be focused on the *x*-axis and *y*-axis; the SNPs tend to emerge toward both sides of the *z*-axis. Thus, to focus on one side of the surface region, the particle sample should be placed on one side (positive or negative) of the *z*-axis. III. Design and optimal system The proposed system consists of 8 separate circular coils as Fig 2(a). To investigate the influence of coil parameters on the magnetic field, the simulations are performed using the COMSOL Multiphysics software. To simplify the simulations and data analysis, one pair coil is considered for optimization in this paper. The structural parameters of the coils are shown in Fig. 2(a). In the simulations, the coil width w_1, w_2, coil height h_1, h_2, and wire diameter d_w are assumed to be independent parameters. To minimize the size and use one cooling system for both coils, the internal diameter d_i, d_o was fixed as 30 mm which are enough space for a frame and cooling systems, and the edge distance between two coils d_c equals h_1. The width of focusing region *wsp* was fixed as 30 mm which can cover a mouse brain for drug targeting. The relations between these design parameters and the independent variables were as follows: $d_0 = d_i = 30$ mm; $h_1 = 20 \div 140$ mm; $w_1 = 20 \div 140$mm; $h_2 = 20 \div 140$ mm; $w_2 = 20 \div 140$ mm; $d_c = h_1$; $wsp = 30$ mm; $d_w = \{0.32;0.4;0.51;0.64;0.81;1.02\}$ mm; The wire turns of the coil can be calculated as: $T_j = kw_jh_j/d_w^2$ where k is the winding factor (k=0.85÷0.95) and j = 1, 2 is corresponding to the inner and outer coils. The objective function is the average value of magnetic field gradient $\nabla H_x(h_1,w_1,h_2,w_2,I_1,I_2)$ in the area $-wsp/2 \le x \le 0$; $-wsp/2 \le y \le wsp/2$; *Design constraint 1*: For generating the focusing region *wsp* * *wsp*. The constraint assures a pushing force. The constraint is identical to the right focusing region. $\nabla H_x > 0$ with $-wsp/2 \le x < 0$ and $-wsp/2 \le y \le wsp/2$; $\nabla H_x = 0$ with $(x,y)=0$; $\nabla H_x < 0$ with $0 < x \le wsp/2$ and $-wsp/2 \le y \le wsp/2$. *Design constraint 2:* For power, voltage and current conditions of the proposed DC supply (AMETEK SGA 600/17, 10 kW). $0 < P_j \le 10$ kW; $0 < V_j \le 600$ V; $0 \le I_j \le 17$ A where the P, V, and I are the power DC, voltage, and current of the coil, respectively. The optimal problem is solved by using the COMSOL Optimization module. The coordinate search method is utilized as an optimization method to maximize the objective function [6]. The final optimal result can be obtained at d_w = 1.02 mm with the highest objective function.

IV. Simulation Results The optimized actuator can generate a focusing area with 3*3 cm, which was not possible from the original design [5]. A cylinder-shaped container (height 1 cm and radius 1.5 cm) was initially used for the simulations of targeting, as shown in Fig 2(b)(c)(d). The container was filled with blood environment [5]. The SNPs diameter is 1000 nm. In the simulation, 2000 particles of 1000 nm diameter are distributed uniformly in the cylinder. Their trajectories according to the magnetic force were captured after 1200 s with f = 0.01 Hz ($T_x = T_y$). The optimized actuator can concentrate SNPs into the center of the desired surface region (0.4*0.4 cm) as shown in Fig. 2 (d) with an acceptable targeting time for drug delivery.

EU-09. AC Loss Database Built with Numerical Multi-scale Model and Status Prediction of a 150 kJ SMES.

Z. Zhang[1]
1. State Key Laboratory of Advanced Electromagnetic Engineering and Technology, School of Electrical and Electronic Engineering, Huazhong University of Science and Technology, Wuhan, China

Abstract—In the process of dynamic power compensation of superconducting magnetic energy storage system (SMES), AC loss is produced inevitably, which will influence the thermal stability of the SMES. In this paper, we firstly use a fast-numerical model, multi-scale model, to analyze the AC loss of a 150 kJ high temperature superconducting (HTS) SMES, and arrange the AC loss under different working conditions into a database. Then, based on the AC loss database, we build a neural network model to provide a real-time prediction of AC loss and thus to adjust the cooling power accordingly. This AC loss data base and neural network system will help keep the SMES magnet thermally stable and prevent the SMES from overload working condition. *Index Terms*—AC loss database, multi-scale model, neural network model, SMES magnet I. Introduction AC loss is one major heat source in the SMES magnet which has great influence on the dynamic thermal stability. However, AC loss calculation of large-scale HTS SMES is a very challenging task, especially in working condition for power compensation when the current load is irregular and unpredictable. The multi-scale model can dramatically speed up the AC loss calculation and verified to have relatively good accuracy. So, the multi-scale model is particularly suitable for building an AC loss database. In this paper, we firstly introduce the modeling methodology of the multi-scale model for AC loss calculation of a 150 kJ HTS SMES magnet. and calculate the AC loss of the magnet under several working conditions, including a series of maximum power working conditions and a series of dynamic power compensation working conditions. Secondly, all these AC losses are arranged into a database, which is used train the neural network model. Thirdly, we use a specific maximum power output working condition to test the accuracy of the neural network model. II. Multi-scale Model and AC Loss Database The 150 kJ SMES magnet was wound with the two types of HTS wires, the BSCCO tape and the YBCO tape. The magnet consists of 12 BSCCO double-pancake coils and 6 YBCO double-pancake coils. Due to the critical current characteristic of the two tapes, the BSCCO coils are divided equally into two groups, placed at the ends of the magnet, and 6 YBCO coils are placed in the middle. The main idea of multi-scale model is described in detail in [1], [2]. The multi-scale model is featured with high calculation speed and low computation complexity. It is suitable for AC loss calculation of large-scale HTS magnet especially when the current load of the SMES magnet is complex. We use the iteration method in the multi-scale model for background field estimation. The diagram of the multi-scale model is shown in Fig. 1. The 150 kJ HTS SMES system is developed in authors' laboratory [3] and its maximum power is 100 kW. AC loss is calculated under two series of working conditions, one is the maximum power working condition where the initial current of the magnet varies from 0.2 I_c to 0.8 I_c, the other is the dynamic power compensation working condition where the SMES is used to stabilize the output power fluctuation of the hydropower station. All these AC loss curves are arranged into a database. III. Neural Network Model Neural network is widely used in nonlinear system for its good function approximation ability, and dynamic NARX neural network can accurately model the time domain problem. The neural network model is suitable for predicting the AC loss of the HTS magnet, which is nonlinear and dynamic [4]. The steps of the neural network model are as follows. (1) Set the exchange power P_{SMES} and the initial current load I_0 of the SMES as the input variable, and the AC loss as the output variable. (2) Use the AC loss database to train the neural network model, and obtain an optimized weight coefficient W. (3) When the training is done, test the accuracy of the neural network model with a certain power compensation working condition. IV. Results and Discussion With the neural network model, we can predict the AC loss of the HTS magnet rapidly and adjust the cooling power accordingly, and thus to keep the thermal stability and prevent the magnet from overload working condition. To test the neural network model, we charge the magnet to I_0 = 150 A and set the exchange power to ± 100 kW. Each power command is maintained for 10 ms. AC loss calculated with H-formulation model, multi-scale model and neural network model is shown in Fig. 2. The multi-scale model speeds up AC loss calculation by 15 to 20 times and restrict the error under 10%. Based on the AC loss database, the neural network model provides a real-time calculation result, which has similar accuracy with the multi-scale model.

In this paper, a combined rational and power functions are used to represent magnetization and *B-H* curves of high magnetic permeability ferromagnetic materials. The proposed functions cover wide range of magnetic flux density values, *B* and magnetic field strength values, *H* from very low values of magnetic fields to highly saturated magnetic fields. High magnetic permeability materials have numerous industrial applications such as magnetic sensors, high efficiency transformers, magnetic recording heads and magnetic shields [1]. Analytical representations of the *B-H* curve of magnetic materials are used for magnetic modeling, numerical analysis and design process. It gives apparent and fast picture of maximum magnetic relative permeability and magnetic saturation without *B-H* data table. Several publications have shown different analytical functions for *B-H* curve modeling such as rational function [2] and [3]. The modeled magnetic materials were silicon steel laminations and solid irons and steels in [2] - [4], which have small magnetic permeability especially at low magnetic fields. Rational functions and power functions are combined for modeling of very high permeability *B-H* curves. In order to calculate analytical functions for *B-H* curve, magnetization parameter, *J* versus magnetic field strength is represented by the proposed function: $J = B-\mu_0 H$ and *J* is constant when $H\rightarrow\infty$. The main difficulty to find analytical function for *B-H* curve or *J-H* curve of high permeability material is very sharp changing of relative magnetic permeability at very low magnetic fields. It is problematical to use conventional rational functions or conventional power functions. The proposed function is as following: $F(x)=(a.x^b+ c.\ x^d+ e.\ x^f)/(1+ a'.\ x^b+ c'.x^d+ e'.x^f)$ (1) where, *x* is variable and *a*, *a*', *b*, *c*, *c*', *d*, *e*, *e*', *f* are the function constants which are calculated by the curve fitting process. Large difference between magnetic field strength, *H* at maximum permeability point and magnetic field strength at high saturation points creates complexities to calculate function constants. In order to overcome this problem and improve curve fitting performance, powers of J^m and H^n are used for curve fitting instead of *J* and *H*. The parameters *m* and *n* are positive numbers, which are mostly less than 1. H^n and J^m are variable *x* and function *F*(*x*) in (1), respectively: $J^m=(a.(H^n)^b+ c.(H^n)^d+ e.(H^n)^f)/(1+ a'.(H^n)^b+ c'.(H^n)^d+ e'.(H^n)^f)$ (2) Three high magnetic permeability materials are chosen from [5] and [6] and curve fitting method is used [7] to calculate the function constants. The results of calculation are shown in Fig. 1 - Fig. 2. It is shown that the proposed functions correctly model *B-H* curve of high permeability materials. - The normalized rms error of *B* and μ_r for Moly permalloy are 0.27 and 0.55, respectively. - The normalized rms error of *B* and μ_r for Supermalloy are 0.28 and 1.55, respectively. - The normalized rms error of *B* and μ_r for Mumetal are 0.20 and 0.64, respectively. The calculated errors between *B-H* data [5] and curve fitting function results confirm high precision of the proposed method. 1- The calculated function constants for Moly Permalloy - *a*=-2.679, *a*'=-0.8315, *b*=28, *c*=2.758, *c*'=0.9487, *d*=27.74, *e*=0.08104, *e*'=0.09077, *f*=39.48, *m*=0.56, *n*=0.07 2- The calculated function for Supermalloy - *a*=17.37, *a*'=19.92, *b*=85.01, *c*=0.52, *c*'=0.2364, *d*=11.73, *e*=0.8789, *e*'=6.982, *f*=73.74, *m*=0.56, *n*=0.07 3- The calculated function for Mumetal - *a*=0.04578, *a*'=0.0576, *b*=33.42, *c*=0.617, *c*'=0.469, *d*=15.65, *e*=-0.3419, *e*'=-0.3305, *f*=22.79, *m*=0.56, *n*=0.07

1. National Institute of Research and Development for Technical Physics, Iasi, Romania

Results on the influence of sample dimensions, specifically nanowire length, L, and diameter, D, on the magnetization processes taking place in cylindrical amorphous nanowires prepared by rapid quenching from the melt are reported. Nanowires with various compositions - $(Co_{0.94}Fe_{0.06})_{72.5}Si_{12.5}B_{15}$ and $Fe_{77.5}Si_{7.5}B_{15}$ - have been investigated in order to correlate their magnetic behavior with the dimensions, mainly to reveal the role played by the large aspect ratio of these novel nanowires, which can exhibit significant lengths, in their overall magnetic behavior. The approach taken was to simulate first the axial hysteresis loops of amorphous nanowires with different lengths, whilst keeping their diameter constant. The simulations have been performed in the micromagnetic approximation employing finite element discretization. This method allowed us to perform a unique study of the magnetization reversal process within this new type of cylindrical nanowires, starting from a fully saturated state ($+M_S$) with the nucleation of a domain with reverse magnetization, continuing with the depinning and propagation of the newly formed 180° domain wall until it reaches the opposite end of the nanowire, which is again fully saturated in the opposite direction ($-M_S$). The usual inductive hysteresis loops (experimental) are bypassing nucleation, since there already are end domains with reversed magnetization due to demagnetization, and magnetization reversal only consists in the depinning and propagation of the preexistent 180° domain wall. The results of micromagnetic simulations, illustrated in Figure 1 for the case of $(Co_{0.94}Fe_{0.06})_{72.5}Si_{12.5}B_{15}$ amorphous nanowire samples, which exhibit nearly zero magnetostriction, reveal the fact that the remanence to saturation ratio M_R/M_S increases with the nanowire length to diameter ratio L/D. This dependence shows directly the critical effect of shape anisotropy, which also increases with the L/D ratio (aspect ratio). The relatively large coercivity of the calculated high-field loops is the result of the magnetization reversal mechanism described above, which begins with the nucleation of a reverse domain, requiring thus a quite large applied field. The inset of Figure 1 shows the region near the switching field for every value of the sample length. From the results illustrated in the inset, one can clearly observe that the remanence to saturation ratio (M_R/M_S) varies monotonically with the sample length, showing that it is easier to nucleate domains with reversed magnetization in the shorter samples. In order to thoroughly understand the mechanisms of magnetization reversal, the visualization of the orientation of the magnetic moments within the sample at various stages is extremely helpful. Figure 2 shows the orientations of the magnetic moments for an amorphous nanowire sample with 2.7 mm in length and the diameter of 90 nm at various stages of the hysteresis loop. Magnetic moments are represented by red arrows when pointing in the direction of the applied field and by blue arrows when pointing in the opposite direction. The magnetization reversal process begins from both ends of the nanowire, with a small delay, the two domain walls propagating towards the middle of the wire. Here, the two domain walls collide, canceling out each other. Such behavior has been previously emphasized experimentally in the case of thicker amorphous glass-coated microwires subjected to large applied fields [1]. We have also simulated the axial hysteresis loops for amorphous nanowires with various diameters, whilst keeping a constant sample length. The results confirm that M_R/M_S increases with L/D. The same result has been also confirmed experimentally, by means of inductive hysteresis loop measurements. Thus, shape anisotropy and the demagnetizing field play a key role in the magnetic behavior of rapidly solidified nanowires. Moreover, the correlation between the simulated loops and the experimental ones allows us to get a deeper insight into the magnetization reversal mechanism, and to analyze the two separate stages of axial magnetization switching, i.e. the nucleation of new domains with reversed magnetization, as indicated by the variation of the remanence to saturation ratio with the nanowire dimensions, and the propagation of the domain wall between the newly nucleated domains or pre-existent end domains and the rest of the nanowire, as shown by the changes in the value of the experimental switching field. The results are key for understanding and controlling the magnetization processes in these novel nanowires, with important application possibilities in new miniaturized sensing devices. Thus, it is possible to tailor a nanowire's anisotropy and magnetic characteristics (switching field, remanence, coercivity) by changing its dimensions (diameter and/or length).

To achieve high magnetic recording density, the magnetic recording head of the hard disk drive is the key element [1]. Therefore, the quantification of spatial variation in recording head's magnetic field and field gradient is very important and provide useful information to the design goals, which is critical for the development of new recording heads [2]. In this regard, magnetic force microscopy (MFM) is recognized as one of the most widely used technique for imaging the stray magnetic field distribution at the microscopic level with high lateral resolution [3]. In literature, there are few investigation reported in order to improve the MFM performance for measurement of the stray magnetic field from the recording head [3, 4]. However, despite the impressive performance and widespread use of the MFM, there are important probe-related limitations that need to be overcome to realize its full potential. From the MFM images it is not easy to demonstrate the magnetic field distribution because of artifacts due to shape, size, and tip hysteresis [1]. To conquer these limitations in MFM images, the superparamagnetic (SP) tip is an attractive candidate due to no hysteresis over wide operating field range that results in MFM images without tip memory effects [5]. Motivates by these backgrounds, here we have fabricated 100 nm high performance Co-GdO$_x$ SP tip and demonstrated the magnetic field energy observation from the magnetic recording head by using Co-GdO$_x$ SP tip and self-developed alternating magnetic field microscopy (A-MFM) [5]. In A-MFM, AC magnetic field is used to change MFM tip moment periodically. The interaction between the tip moment and magnetic field from head causes the change of effective spring constant of a cantilever. Frequency modulated (FM) cantilever oscillation occurs in accordance with the following equations; $m(d^2z(t)/dt^2)+m\gamma(dz(t)/dt)+(k_0+k_{eff}\cos(\omega t))z(t) = F_0 \cos(\omega_0 t)$, (1) Here the cantilever oscillates in the z direction. In narrow-band FM, the intensity of the side-band spectra is proportional to the derivative of AC magnetic force and magnetic field detection is achieved by the following equation, $k_{eff} = \partial F_z(t)/\partial z$. When the change of effective spring constant is smaller than the intrinsic spring constant ($k_{eff} \ll k_0$) narrow-band FM with one pair of side-band spectra occurs in the following equation, $z(t) = (F_0/m\gamma\omega_0) \sin(\omega_0 t+\Delta\theta) + (F_0 k_{eff}/(2(m\gamma\omega_0)^2) (\cos((\omega_0+\omega)t+\Delta\theta) + \cos((\omega_0-\omega)t+\Delta\theta))$, (2) The, A-MFM signal is obtained by a lock-in amplifier using frequency demodulated output of a PLL. The concept of high-resolution magnetic field energy imaging technique is demonstrated by high initial susceptibility ($\chi_i = 5.15 \times 10^{-7}$ H/m) Co-GdO$_x$ SP tip for perpendicular magnetic recording (PMR) head. The magnetic moment of the SP tip m_{tip} is parallel to head magnetic field and is proportional to its strength i.e. ($m_{tip} = \chi H$) and each grain behave as the magnetic dipole. the magnetic force on dipole type Co-GdO$_x$ SP tip can be expressed by taking integral over tip volume as, $F_z(t) = \partial/\partial z(\int m_{tip}(t)\bullet H(t)dV) = \partial/\partial z(\int \chi H(t)\bullet H(t)dV) = \chi \int(\partial(H(t))^2/\partial z)\, dV$, (3) Therefore, magnetic field energy $(H(t))^2$ is measured by the SP tip. The distribution of magnetic energy gradient from the PMR head is imaged by 100 nm Co-GdO$_x$ SP tip and compared with the magnetic field imaging by 20 nm FePt-MgO hard magnetic (HM) tip (coercivity (H_c) ~15 kOe and magnetization (M_s) ~ 680 emu/cm^3). Figure 1(a) shows the A-MFM amplitude image measured on magnetic recording head by Co-GdO$_x$ SP tip. The dotted line in Fig. 1(a) indicates the actual topographic (Physical) size of the main pole and trailing shield of the recording head. Further, the line profile measured from the amplitude image of Co-GdO$_x$ SP tip is shown in Fig. 1(b). Here, the FWHM of the A-MFM amplitude peak (Fig. 1(b)) measured for the Co-GdO$_x$ SP tip is 77 nm, clearly indicate the higher resolution for the Co-GdO$_x$ SP tip. Fourier analysis of the A-MFM amplitude image revealed that the spatial resolution of 13 nm is achived by Co-GdO$_x$ SP tip which is higher than the state of-the-art FePt-MgO HM tip of 17 nm resolution in the present study and the other MFM tips reported in literature. The Co-GdO$_x$ SP tip consists of nano-size superparamagnetic Co particles surrounded by the non-magnetic GdO$_x$. The physical model for the Co-GdO$_x$ SP tip is shown in the Fig. 1(d). The magnetic moment of each grain in the Co-GdO$_x$ SP tip depends on the strength of magnetic field, results in inhomogeneous magnetic charges distributed along the tip volume as shown in Fig 1(d). Therefore the tip volume near the tip end mainly contributes to the magnetic field energy imaging as shown in Fig. 1(d). The transfer function of the Co-GdO$_x$ SP tip against a single magnetic charge source located at the origin (x, y, z) = (0, 0, 0) is given by considering as dipole for the SP tip. $\int\chi(\partial^2(H_{AC}(\approx 0, \approx 0, z))^2/\partial z^2)\, dV = \int((5\chi)/(4(\pi\mu_0)^2))\,(1/z^6)\, dV$. From this transfer function equations, it is clear that magnetic field energy imaging by SP tip is more dependent on the tip sample separation distance ($1/z^6$) as compared to the magnetic field imaging ($1/z^3$). Thus the fabricated Co-GdO$_x$ SP tip opens an opportunity for the development of advanced high-resolution magnetic energy based imaging methods and development of the high-resolution MFM tips.

EV-02. Rotatable magnetic anisotropy in Fe-based thin films with stripe domains by Field-Dependent Magnetic Force Microscopy.

P. Tiberto[1], G. Barrera[1], F. Celegato[1], M. Cialone[2], M. Coisson[1] and P. Rizzi[2]
1. INRIM, Torino, Italy; 2. Chemistry, Università di Torino, Torino, Italy

Fe-based thin films are characterised by critical thickness above which the in-plane magnetisation is replaced by a dense stripe domain configuration [1], originating from internal stresses quenched during film growth that can be progressively released by means of relaxation thermal treatments. Such systems are generally characterised by a transcritical, in-plane hysteresis loop shape and an in-plane component of the stripe magnetisation that can be aligned to any direction in the film plane, provided that a strong enough in-plane magnetic field is applied (rotatable anisotropy). Stripe domain rotation have been studied in the two Fe-based compositions being characterised by different anisotropy values: a) $Fe_{70}Pd_{30}$ with different thickness (50-600 nm) deposited by electrodeposition on Si(100)//Si02//Cr//Au substrate; b) $Fe_{78}B_9Si_{13}$ sputtered on Si substrate (thickness ranging from 100 to 800 nm). Both alloys display stripe domain structure above a critical thickness originated by quenched stresses at the magnetic film/substrate interface. Critical thickness values are different for the two Fe-based compositions and this can be ascribed to the different deposition tecniques exploited. As an example, room-temperature hysteresis loop of a $Fe_{70}Pd_{30}$ sample having thickness higher than 300 nm measured by means of a vibrating sample magnetometer (VSM) is shown in Fig. 1a. The typical fingerprint of a transcritical loop is visible. In the inset, the corresponding MFM image at the magnetic remanence is reported showing that the magnetisation of the film is organised into parallel stripes alternately tilted upwards and downwards. By exploiting a recently developed field-dependent MFM technique [2,3] coupled with a novel analysis of the acquired data, we have been able to investigate the orientation of the magnetisation in the stripes as a function of the applied field, and their rotation towards saturation. The field evolution of the stripes for increasing field values is followed by applying a magnetic field perpendicular to stripe orientation (horizontal direction). The intensity of the magnetic field applied during the acquisition of MFM images following the procedure described in [2,3] is shown in Fig. 1b. Conversely, the field-dependent MFM image of the same sample during application of an in-plane field along the horizontal direction in Fig.1c. After a threshold field, the MFM contrast changes indicating that the stripes, initially orthogonal to the scan direction of the tip, rotate along the field direction, resulting parallel to the scan direction. The rotation field turns out to be connected with the change of slope in the transcritical loop indicating its link with the perpendicular magnetic anisotropy that is also progressively reduced. For both Fe-based compositions, the detailed field evolution of the magnetisation in the stripes is investigated by direct comparison of vector measurements made by VSM and field-dependent MFM, as a function of the magnetic anisotropy. The origin of the threshold field, whose amplitude is independent on the field direction in the sample plane, is discussed as well to rule out the role of the two deposition techniques inducing microstructure characterised by different stress.

Abstract— Resistive dissipation in superconductors is a direct consequence of vortex motion, that causes a reduction of transport efficiency, limits the coherence times for quantum computation, and generally introduces noise. Such unwanted effects can be limited by adding vortex pinning (structural or magnetic) into the superconductor. Here, we will be focusing on the magnetic pinning exerted on vortices by a ferromagnetic layer, in superconductor/ferromagnet (S/F) heterostructures only magnetically coupled, where F is in the magnetic-stripe regime (the magnetization alternates its direction by crossing adjacent domains). We used low temperature magnetic force microscopy (MFM) to image both ferromagnetic domains and superconducting vortices in Nb/Py (Permallloy-$Ni_{80}Fe_{20}$) heterostructures. By tuning Nb and Py thickness, we observed spontaneous formation of vortices in Nb thin films, due to the magnetic stray field coming from Py itself, as well as clusters of vortices when in presence of magnetic domain bifurcations. Our findings suggest that stripe magnetic topology is useful to minimize vortex motion and enhance the critical current value, by pinning vortices and organizing them in ordered chains along the stripes. Moreover, vortex confinement and jamming, producing clusters, are eventually induced in presence of defects in magnetic domain arrangement. Many of the potential applications of superconductors in electronic devices demand high current densities with minimal losses, requiring a mandatory pinning of vortices. In the last decade several studies have focused on the influence of different types of pinning centers on the dynamics of superconducting vortices [1-7]. Among them, magnetic pinning in magnetically coupled S/F heterostructures, appears to be stronger than other mechanisms [4,8]. Particularly, an enhanced pinning has been reported due to vortex coupling with ordered magnetic structures, such as stripes and dots [9-11]. Nevertheless, unconventional vortex configurations such as vortex chains, vortex clusters as well as multi-vortex and giant vortex phases can also be induced by a strong magnetic or geometric confinement potential [12-16]. In this work, we used low-temperature MFM to investigate S/F heterostructures composed of Py as the magnetic material and Nb as the superconductor, with several Py and Nb thickness, separated by a thin SiO_2 insulating layer to prohibit proximity effects. A thick Py film presents peculiar arrangement of magnetic domains, made by stripes with canted magnetization vectors, mainly oriented along the film plane, but with small alternating up-and-down out-of-plane components. Moreover, its Curie temperature T_C is much greater than the superconducting critical temperature T_S, ensuring a field cooling of Nb in a spatially nonuniform magnetic field, giving place to vortices with opposite polarities, namely Vortices and Antivortices (V and AV). We investigated the conditions for nucleation of spontaneous V-AV structures as a function of thickness of superconducting films as well as magnetic domain width. We compared our results with those of existing theoretical models and provided an estimate of the threshold of the local out-of-plane component of the magnetization for different Py film thickness. In this sense, the MFM imaging of spontaneous V-AV in Nb/Py bilayers, for different Nb and Py thickness, is also proposed as an indirect but quantitative method to estimate the out-of-plane magnetization value of our F layers. Moreover, the periodic out-of-plane stray field coming out from Py surface plays the role of magnetic cofinement potential for vortices, forcing those to align in chains along the domains (Fig. (a)). When in presence of intrinsic topological defects of the magnetic template, called *bifurcations*, we found a peculiar distribution of superconducting vortices. In such cases, we demonstrated that a bifurcation can naturally lead to unusual vortex distribution, and eventually to the formation of vortex clusters, without any need of invasively engineering the shape of the sample via lithography or self-assembly (Fig. (b)). MFM measurements clearly show that a bifurcation, where two magnetic stripe domains converge and coalesce in a single one, leads to a local enhancement of the out-of-plane stray field. As imaged by MFM, this enhancement induces vortex clusters. We infer that such a phenomenon can be also explained by taking into account the role of the bifurcation magnetic topology. Indeed, while each vortex inside an infinite chain would feel the same net repulsive force, which leads to a constant intervortex distance, an unbalanced force is felt by vortices close to magnetic channel interruptions (stripe endpoint or bifurcation core). For instance, the vortex at the stripe endpoint feels a long-range repulsive interaction due to the semi-infinite vortex chain on one side, while on the other side only the Lorentz force would keep it away from the domain wall. In such a case a reduction of the inter-vortex distance close to the magnetic stripe endpoint is expected. The bifurcation topology indirectly affects the vortex distribution at the nearest neighbour domains as well. Indeed, our experimental results show that hexagonal vortex lattice is achieved at the matching field [19] wherever the stripes are straight and regular, as expected. On the other hand, around the dislocations the inter-vortex distance is affected by the stripe curvature, leading to a modulation of the vortex-vortex spacing.

The imaging of small magnetic microstructures, such as chiral skyrmions or magnetic bubbles, is of current interest in spintronic and spin-orbitronic research. If such an object is smaller than the optical resolution limit, direct observation demands sophisticated imaging techniques based on electron-, x-ray spectro-, or scanning probe microscopy, all of them with limitations in the expense and complexity of the method or limitations in their dynamic capabilities. Magneto-optical Kerr microscopy, on the other hand, is an in-house technique that offers high versatility without restrictions in dynamic imaging, field compatibility etc.. Recently the method was applied to the imaging of micron-sized "skyrmionic" bubble domains in metallic film systems [Jiang2015, Jiang2017]. Skyrmion research, however, aims at objects smaller than 100 nm in size, which is well below the resolution limit of Kerr microscopy that can be estimated to be about 180 nm at best according to the Abbe criterion. In this contribution we present a methodology for the processing of magneto-optical images, which allows simultaneously to suppress the noise and to enhance the resolution of domain images beyond the mentioned limit, thus making Kerr microscopy attractive for skyrmion research. We start with the determination of the point spread function (PSF) for the specific m/o setup, because despite the existence of so-called blind deconvolution methods (see, e.g., [Caron2002]), the knowledge of this function strongly increases the deconvolution quality. To measure the width of a PSF, we fit a line scan across a domain wall (DW) image obtained on a NeFeB sample. Due to the high magnetocrystalline anisotropy of this material, the DW width is well below 5 nm, so that this wall can be considered to be infinitely thin from the Kerr microscopy 'point of view'. For this reason, fitting of the magneto-optical profile along the corresponding line cut using an error function, we can directly extract the PSF width of the given Kerr setup. For the processing of the image of interest (as an example, see panel (a) in Fig. 1), we first apply the Wiener filter $W(k) = H^{*}(k)/(|H(k)|^2 + K(f))$ with a Fourier transform of the convolution kernel $H(k)$ evaluated using the obtained PSF width (see above). The frequency-dependent function $K(f)$, representing the noise-to-signal ratio, can in principle be extracted from standardized magneto-optical images, but in this study it is held constant; its value is adjusted to avoid an excessive noise amplification arising for too small values of this threshold. The result of this operation is a deconvolved image without white noise, but with clearly seen artificial features (Fig. 1b); this image is then passed to the next step. Finally, the wavelet denoising [Gonzalez2008, Neelamani2004] is applied. After comparing various wavelet types, we have found that best results are obtained using the so called Haar wavelet system [Porwik2004], as this system is best suited to approximate the images with sharp domain boundaries often encountered in magneto-optics. The appropriate choice of the decomposition level by the wavelet transform allows to reduce the noise level of the image significantly without losing its fine details (Fig. 1c). Test results obtained on artificial images and results obtained on various types of domain structures in real magnetic samples (Fig. 2), which demonstrate a substantial resolution improvement of our Kerr microscopy technique, are presented.

X-ray spectroscopy is one of the essential experimental methods in materials science to probe electronic structures of materials. As a derived method, X-ray magnetic circular dichroism (XMCD) spectroscopy is frequently used to investigate microscopic magnetic properties of magnetic materials. In these days, we have revealed that adaptive design of an XMCD experiment by a Gaussian process (GP) modeling, one of a machine-learning technique, can improve the efficiency of a measurement [1,2]. In that study, we supposed an ideal experimental condition that measurement data does not include noise. GP modeling predicted spectra by learning of experimental data points. We revealed that magnetic moments with required accuracy could be evaluated from predicted spectra. Convergence of the measurement was determined by the values of the magnetic moments. In this study, we applied GP modeling to X-ray absorption spectra (XAS) with various signal-to-noise (S/N) ratios to develop general versatility of the GP modeling of X-ray spectroscopy. Convergence of the measurement was determined by similarity measure between the GP-predicted XAS and simulated XAS. X-ray absorption spectra were simulated using CTM4XAS [3]. Sm $M_{4,5}$ XAS were calculated for Sm^{3+} ion. Total data points were set to 201 that is similar to typical XAS experiments. Gaussian process modeling was performed using a DiceKriging package for R [4]. Adaptive design of XAS experiment was implemented as follows. (1) 20 data points were extrapolated from an XAS spectrum as initial data points. (2) Predicted XAS spectra and its variance were calculated by GP modeling with the learning of initial data points. (3) Energy point of the maximum variance σ was chosen as a next data point to measure. (4) Gaussian process modeling predicted an XAS spectra again including new data point. (3) and (4) repeated 500 times by permitting multiple measurements on same energy points. Furthermore, we investigated another strategy that including a prior distribution to improve the efficiency of adaptive design of the experiment. The inclusion of prior distribution means that one can use prior knowledge about general view of a spectrum, i.e., energy ranges, peak positions and so on in an actual situation. In this study, the prior distribution was set to the noiseless XAS. Prior distribution was considered in (3); thus, the energy point with the maximum $\sigma + k \times prior$ was chosen as a data point to measure. This prior increase preference of sampling around peaks. Coefficient k was set to 0.05 in the present study. A similarity between GP-predicted XAS and noiseless XAS was evaluated to determine convergence of measurement and prediction. We used Pearson correlation coefficient (PCC), a similarity metric robust for noisy XAS, as a similarity measure [5]. Pearson correlation coefficient takes a value between +1 and -1. In the present study, the more similar the GP-predicted XAS to the noiseless XAS, the more approaching the PCC value to +1. Figure 1 shows simulated X-ray absorption spectra of Sm^{3+} with different levels of signal-to-noise (S/N) ratio. Gaussian noise is artificially added to the noiseless XAS. The S/N ratio is defined as a ratio between an M_5 peak intensity and a square root of a variance of a Gaussian distribution. Figure 2(a) shows the similarity between GP-predicted XAS and simulated-noiseless XAS versus number of measurements. Circles and lines represent results for without and with a prior distribution, respectively. For results without the prior distribution (full circles in Fig. 2), high S/N spectra (i.e., S/N = 1000, 200, and 100) converges with fewer numbers of measurements as an overall trend. In particular, similarity for S/N = 1000 and 200 converges to almost 1 in below 100 measurements. On the other hand, similarity for S/N = 20 converges to almost 0.98 with about 300 measurements. Similarity for S/N = 10 does not converge in the present result. For results with the prior distribution (lines in Fig. 2), similarities for S/N = 1000, 200, 100, and 20 become closer to 1 with much fewer measurement as compared to the results without the prior distribution. In particular for high S/N spectra (S/N = 1000, 200, and 100) converges less than 50 measurements as shown in Fig. 2(b). These results indicate the GP-predicted XAS spectra with fewer data points are very similar to the "true" spectrum with 201 data points (noiseless XAS in Fig. 1). The method is reliable for XAS with S/N larger than 100 with including the prior distribution in the range of the present study. In conclusion, we investigated the application of the GP modeling and similarity measure to improve the efficiency of XAS experiments. The results indicate that the GP modeling for XAS experiment is useful to decrease data points to be measured. Moreover, the efficiency of the GP modeling is improved by including the prior distribution in adaptive sampling. The present method reduces experimental costs and realizes high-throughput characterization of magnetic materials.

Determining magnetic properties of nanostructured materials is a key issue for designing functional nano-devices for information storage, sensor technology, or medical diagnostics. Recent development of new magnetic nanopatterns raised the need for advanced tools to quantify lateral heterogeneous magnetization states. Addressing this demand, we have introduced two new X-ray scattering approaches, namely nuclear grazing incidence small angle scattering [1] and nuclear surface diffraction [2]. Both techniques employ resonant off-specular scattering to allow for a unique insight into complex lateral magnetization states of nanopatterned systems. In the last decades, various synchrotron based X-ray scattering techniques have proven to be essential for nanoscopic magnetic characterization of ultra-thin films and multilayers. Experiments benefitted from the high sensitivity of polarized X-rays to magnetic moment orientations and their relatively large penetration depth. Recently, a new field of research has emerged, which focusses on the lateral magnetization state of nanopatterns like spin ice and skyrmion lattices or magnetic nanostructure arrays with tilted or curved surface morphology. Their heterogeneous magnetization state within the sample plane hinders a characterization with X-rays via specular scattering which yields integral magnetic information only. We developed two new scattering approaches, which overcome this limitation and allow disentangling of magnetic contributions from selected parts of magnetic nanopatterns. In the first experiment we demonstrated how the resonant analogue of the widely applied grazing incidence small angle X-ray scattering (GISAXS) can be used to disentangle nanomagnetic information from a sample with facetted surface morphology. For this purpose, we sputter-deposited iron at non-normal incidence onto a nanofacetted sapphire template to form a continuous magnetic film with periodically varying thickness (Fig. 1). Performing non-resonant GISAXS on this sample in-situ allows to precisely follow the structural growth of the nanostructured film. Thickness oscillations with decreasing period become visible during deposition along the two scattering rods oriented perpendicular to both facet nanosurfaces. To correlate this structural information with the nanomagnetic state of the sample we additionally recorded the time dependent nuclear resonant scattering (NRS) signal of iron in the same GISAXS configuration (Fig. 1b). To separately extract the magnetic signal from both types of nanostripes we did not collect the NRS signal along the specular scattering direction but on both scattering rods. This allowed us to follow the evolution of magnetic order in the nanostripes during the deposition run. In subsequent magnetic field cycles we found an unexpected heterogeneous nanomagnetic behavior: The magnetic moments in the thinner nanostripes tend to follow the external magnetic field much stronger than the thicker ones and show a different magnetic hysteretic behavior in general (Fig. 1b, bottom). This observation on the nanoscale became only possible using this new resonant GISAXS approach which can be generally applied to magnetic nanopatterns with 3D morphology. In the second experiment we applied nuclear resonant surface diffraction as a new technique for the characterization of lateral magnetic order in magnetic nanopatterns. For this purpose, we fabricated a custom-made permalloy nanograting, which was intended to undergo a ferromagnetic-antiferromagnetic transition upon field cycling. The non-resonant scattering signal in the GISAXS configuration shows a diffraction pattern from which the morphology of the nanograting was determined with sub-nanometre precision. To be sensitive to the lateral magnetization state we collected the nuclear resonant diffraction pattern via horizontal line scans (Fig. 2b). It turned out that during magnetic reversal strong pure magnetic superstructure peaks (red arrows) are formed, which are caused by an antiferromagnetic superstructure in the grating with a lateral correlation length of twice the structural one. The angular position, relative strength and field-dependent intensity of these superstructure peaks enabled us to precisely study the nanoscale magnetic reversal. The experiment thus successfully demonstrated that nuclear surface diffraction is technically feasible and could offer a completely new insight into a wide range of nanomagnetic sample systems.

[1] Disentangling magnetic order on nanostructured surfaces, D. Erb, K. Schlage, L. Bocklage, R. Hübner, D. Geza Merkel, R. Rüffer, H.-C. Wille, R. Röhlsberger, Phys. Rev. Materials 1, 023001 (2017) [2] Nuclear Resonant Surface Diffraction of Synchrotron Radiation, K. Schlage, L. Dzemiantsova, L. Bocklage, H.-C. Wille, M. Pues, G. Meier, and Ralf Röhlsberger, Phys. Rev. Lett. 118, 237204 (2017)

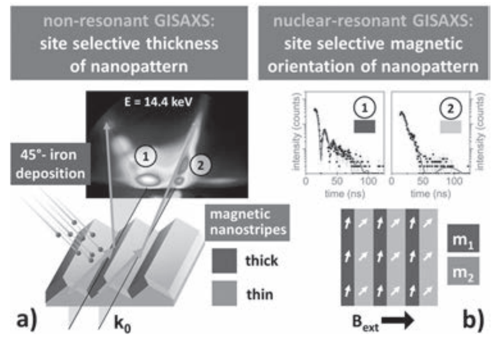

Fig. 1. Nuclear resonant GISAXS is applied to monitor the formation of a magnetic nanopattern with periodically varying thickness. (a) Conventional, non-resonant GISAXS allows to follow the growth of both types of nanostripes via detection of diffuse thickness oscillations along scattering rods. (b) Nuclear resonant time spectra detected at both GISAXS scattering rods (position 1 and 2) allow to precisely disentangle their heterogeneous magnetic moment orientations during growth and subsequent field dependent reversal.

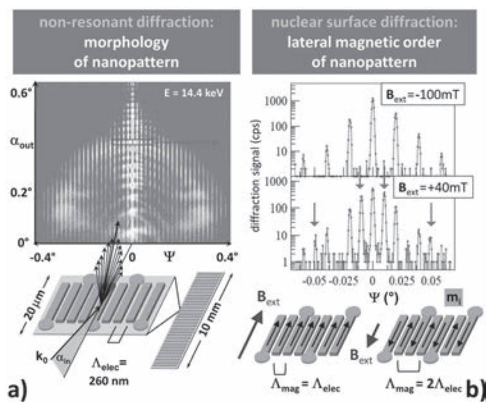

Fig. 2. (a) Non-resonant surface diffraction on a grating of magnetic nanostripes results in formation of a scattering pattern from which the morphology of the nanostructure can be determined with sub-nanometre precision. (b) Nuclear resonant surface diffraction is in addition sensitive to the lateral magnetic ordering in the grating. During field-dependent reversal of this nanograting, pure nuclear superstructure peaks (red arrows) appear, which identify a ferromagnetic-antiferromagnetic transition on the nanoscale.

EV-07. Spin-orbit torque magnetometry by wide-field magneto-optical Kerr effect.

T. Tsai[1] and C. Pai[1]
1. Materials Science and Engineering, National Taiwan University, Taoyuan City, Taiwan

Magneto-optical Kerr effect (MOKE) is an efficient approach to probe surface magnetization in thin film samples. Here we present a wide-field MOKE technique that adopts a Köhler illumination scheme to characterize the current-induced spin-orbit torques (SOTs) in micron-sized and unpatterned magnetic heterostructures with perpendicular magnetic anisotropy. Through a current-induced hysteresis loop shift analysis, we quantify the SOT efficiency of Ta-based heterostructures to be ξ_{DL}=0.08. We also find that the estimated SOT efficiencies strongly depend on the probing area-of-interests for Hall-cross devices. This issue can be resolved by considering the shunting of current in devices with Hall-cross geometry. The proposed wide-field MOKE approach therefore provides an instant and direct characterization of SOT, without the need of any further interpretation on electrical signals.

In recent years, the First-Order Reversal Curve (FORC) method has gained increasing interest for exploring magnetic phenomena in natural and synthetic multicomponent magnetic materials, such as interaction and coupling phenomena in particle and film systems [Roberts2014]. The method consists of the measurement of minor hysteresis curves, starting by saturating the sample, decreasing the field to a reversal field, then sweeping the field back to saturation in regular field steps. This process is repeated for many values of the reversal field, yielding a series of FORCs. The FORC distribution function [Mayergoyz1986] is then obtained by the calculation of a second-order mixed derivative of the output variable with respect to the reversal and measuring field values. The interpretation of FORC plots has been historically based on the classical Preisach model, in which hysteresis is assumed to be associated with a collection of single square irreversible curves, called mathematical hysterons. The connection between hysterons and the physically relevant reversal events governing the FORC plots, such as switching by domain wall motion or rotational processes, is often non-trivial and needs refined models in order to evaluate such diagrams. FORCs are commonly measured by vibrating sample-, SQUID- or alternating gradient magnetometry. All these methods suffer from being time consuming with FORC acquisition times well above one day if a high field resolution is required. Recently, it was shown that MOKE (Magneto-Optical Kerr Effect) magnetometry can significantly reduce the measurement time by keeping a high field resolution [Gräfe2014]. In this presentation, we extend this method by implementing MOKE-based FORC magnetometry in a wide-field Kerr microscope. The Kerr image intensity of selectable areas on the sample is used as magnetization signal [Soldatov2017]. At the same time the magnetic domains along each FORC can be recorded, allowing to directly see the relevant magnetization process that is responsible for the curve. The benefit of supporting FORC analysis by domain imaging was already appreciated previously, see e.g. [Beron2012, Ma2014, Gräfe2016]. In those studies, however, the imaging and FORC experiments were performed in different setups. Our approach of in-situ measurement and imaging in the same setup provides the possibility to understand both, the FORC distribution and the magnetization processes, thus offering the prospect to propose realistic models for complex magnetization reversal mechanisms. In our presentation we will show combined experiments on interacting (see figure) and isolated thin film elements, magnetic film systems with perpendicular anisotropy and extended specimens such as amorphous ribbons.

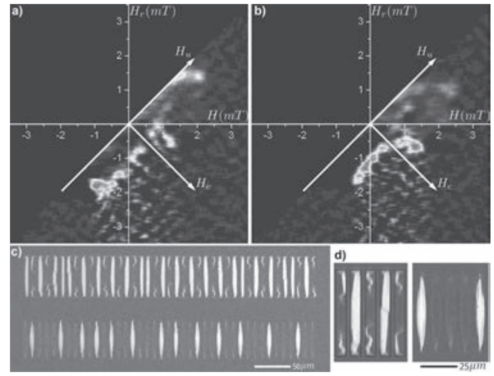

Fig. 1. FORC diagrams of interacting Permalloy elements of rectangular (a) and pointed (b) shapes with a thickness of 240 nm. The Kerr image in (c) shows typical domain states of both types of elements along one of the FORCs at zero field. Whereas the pointed elements (lower row) appear completely saturated before and after switching, at the blunt ends of the rectangular structures (upper row) closure domains are formed. They reduce the stray field, which is reflected in subtle differences in the FORC plots. Image (d) shows a magnified view of some of the elements. The FORCs were measured on the whole row of each element type.

EV-09. Improvement of the measurement method of rock magnetic properties based on the scanning SQUID microscope with an in-situ magnetization/demagnetization field.

J. Du[1,2], Q. Wang[1] and *T. Song*[1,2]
1. Institute of Electrical Engineering, Chinese Academy of Science, Beijing, China; 2. University of the Chinese Academy of Sciences, Beijing, China

The magnetic properties of geological samples provide significant information about the Earth, which can reflect the evolution of the continent and the oceans [1, 2]. A scanning SQUID microscope with an in-situ magnetization/demagnetization field (Fig1) had been developed by us [3], which can obtain not only the distribution of the magnetic field but also the remanent curves of a wafer sample at each point. In this paper, we developed an improved method to measure the remanent curves of rock magnetic properties. The remanent curves at each point can characterize the magnetic properties of the samples. But selecting all the points on the sample for measurement would consume a lot of time; randomly selecting some points to measure would lose important information. For the above problems, we proposed a measurement method to choose the characteristic point. At first, we mapped the distribution of magnetic field of a wafer sample which need to be measured, and the extreme points in the distribution of magnetic field were obtained by the contour map of magnetic field. Because the extreme value of the magnetic field generally appears above the position of the magnetic particles, and the field value in the vicinity of the magnetic particles is gradually reduced, we selected the extreme points in each area as the points to measure the remanent curves which are marked with red solid circle in the Fig. 2. Then the sample moving platform could move the sample to place the point to be measured below the probe. Based on the magnetization/demagnetization field the remanent curves were obtained. Using the method, the magnetic properties of geological samples could be rapidly measured. Relative to the random selection and all selection, this method of selecting points to be measured based on the distribution of magnetic field can save measuring time without losing feature information. This work was supported by the National Science & Technology Support Program of the Ministry of Science and Technology of China (2015BAI01B07).

EV-10. Implementation of 16-channel AMR sensor array for quantitative mapping of two-dimension current distribution.

G. Huang[1] and *J. Jeng*[1]
1. Mechanical Engineering, National Kaohsiung University of Applied Sciences, KAOHSIUNG, Taiwan

In recent years, the development of system-on a-chip (SoC) magnetic sensors makes it possible to mass-produce the miniature vector magnetometers with stable quality, e.g. Hall Effect and anisotropic magnetoresistance (AMR) magnetometers [1]-[3]. For applications in quantitative magnetic source imaging, it is necessary to map the field distribution with high accuracy. The traditional field scanner employs a single magnetometer [4],[5], which may take hours to map the magnetic field at a high spatial resolution. The multi-channel magnetic imaging system based on linear array of AMR sensors [2] can achieve a higher scanning efficiency. However, the feature size of 10 mm for the sensor made the center-to-center distance between sensors as large as 15 mm, which limits the achievable spatial resolution. In addition, the sensor operation requires external driving and analog-to-digital circuits, which results in high complexity and high total cost when the number of channels are increased. In this work, we investigated a magnetic source imaging system based on a 16-element array of SoC AMR sensors to reduce the complexity in system construction. The magnetic field was mapped in a one-way scan and the current distribution was subsequently obtained within one second by using the calculation program to solve the magnetic inverse problem. The accuracy of current amplitude was analyzed and the parameters affecting the spatial resolution were discussed. The 16-element sensor array consists of the IST8308 AMR vector magnetometers from iSentek Inc. [3]. The maximum dynamic range is ±500 μT and the maximum data rate is 200 Sa/s in the high sensitivity mode. The small package size of 3 mm for the sensor reduces the center-to-center distance of adjacent sensors to 6 mm. The total length of the 16-element sensor array is 90 mm. The sensors communicate with the Arduino Nano microcontroller unit via I^2C interface. The real-time data are transmitted via a Bluetooth Module to a desktop computer for processing and display. The object under test was moved during scanning with an X-Y scanning stage of 0.002-mm resolution. The scanning time is only 20 seconds for a 100-mm scanning range, which covers an area of 90 mm×100 mm. To probe the accuracy for current mapping, a pair of anti-parallel long straight conductors of known current is used as the specimen. The experiment was conducted at three different heights of 2.5, 3.5, and 4.5 mm at various current of 0.25, 0.5, 0.75, and 1 A. After each adjustment of height changes, the map of background magnetic field was recorded for subtraction from the observed field distribution. The size of raw field data is 16×256 points. Before the current-inversion calculation, the size of measured field data is expanded to 256×256 points, as shown in Fig. 1a, by linear interpolation between the data points taken by adjacent sensors. The typical field map for z = 2.5 mm and current of 0.5A different is shown in Figure 1a. The algorithm used for retrieving the current distribution is the Fourier transform [4], for which the source current density was solved by assuming that the distribution is periodic on the same plane of constant height [4],[5]. The calculated current density distribution, as shown in Figure 1b, is obtained by using the Fourier algorithm as follows [5]: $j_x(k_x, k_y)=-(2*i/(u_0*d))*(k_y/k)*(e\wedge(k*z))*b_z(k_x, k_y, z)$ and $j_y(k_x, k_y)=(2*i/(u_0*d))*(k_x/k)*(e\wedge(k*z))*b_z(k_x, k_y, z)$. Figure 2 shows the retrieved current magnitude along the long conductors carrying a current of 0.5 A. The data are taken on the sensing planes of different heights. It is found that the full width at half maximum of current trace is about 3.9 mm and 3.1 mm respectively for the top (forward) and bottom (backward) conductors. The current amplitudes in Fig. 2 are calculated by definite integral from the current density distribution in Figure 1b. The current amplitudes observed by our system at three different heights were close to source amplitude of 0.5A with the error within 4-6%. Moreover, at the same height, the calculated current values of two long straight conductors were similar with a non-uniformity less than 3%. The results indicated that, by using our non-contact field mapping and source current calculation method, the current density as well as the current amplitude could be determined quantitatively at high efficiency. The Fourier algorithm is currently restricted by several conditions. It can only solve the problem of the two-dimensional inverse problem, which excludes the cases with a tilt sensing plane and three-dimensional current distribution. Further work to include the inversion algorithm, e.g. minimum norm estimation, which is compatible with three- dimensional current distribution, will help improve the quality of source current mapping. The developed magnetic source imaging system is useful for detection of current leakages and shorts of printed circuit [6]. This work is supported by the Ministry of Science and Technology of Taiwan under Grant No. MOST 106-2221-E-151-025.

The ability to visualize the biological processes in real time rather than observing it at discrete point of times has a promising potential application in observing tissue regeneration. The prospects of live cell imaging is increasing to observe changes in anatomy during cell differentiation, studying the cell signaling- molecular analysis of cell processes, sensing transgene activity and therapeutic applications including targeted drug delivery. Studying these cells in real time helps us to record invaluable data whose knowledge holds great importance in understanding several aspects of cell functions at both microscopic and macroscopic level. Ability to trace cells in real time requires cell labeling using suitable markers (that may be injected or Endocytose) which tremendously improves cell visualization. Various cell labeling techniques have been attempted successfully in the past for live cell imaging. Some procedures targeted to label the cells directly, whereas it is also possible to view cell functions by tracing labeled giant vesicles made of double lipid layers endocytosed in living cells. Using photonic crystals which have brilliant light reflective properties that respond rapidly to magnetic field has never been tried before. Guanine crystals are optical nanoparticles present abundantly in the scales of fish skin and other color changing animals. These guanine crystals respond rapidly to light and align parallel to an applied magnetic field. We have observed that the optical and magnetic properties of synthetically available guanine nanoparticles behave similarly to biogenic guanine crystals. Our target was to encapsulate synthetically available guanine nano-particles inside giant vesicles and subject them to strong light source and magnetic field. Figure 1 shows bilayer lipid giant vesicles encapsulated with guanine nanoparticles. Under dark field microscopy, we observed that a cluster of guanine particles accumulated and were encapsulated into the giant vesicles successfully. When this giant vesicle was subjected to an external light source, guanine nanoparticles shine brilliantly and reflect light in a direction opposite to the light source, and magnetic field caused flickering of guanine nanoparticle. Additionally, this strong illumination of the flickering guanine nanoparticles in turn caused strong illumination of the giant vesicle itself into which they lay encapsulated, making it look like an iridosome similar to those found in natural cells in skin of color changing animals. These brilliantly illuminated giant vesicles marked with encapsulated guanine nanoparticles can be entirely endocytosed into living cells. Further, the location of the cells carrying giant vesicle-guanine nanoparticle complex could possibly be traced with MRI to track the exact real-time location of the cell; thus holding a promising potential application for live cell imaging to study changes in cell anatomy during tissue regeneration and wound healing around dental implants. Moreover, visualizing the response of tissues around the dental implant to invading bacteria could be studied. Fig. 1. Under dark field microscopy with an external light source, the encapsulated guanine nanoparticles into giant vesicles resulted in brilliant illumination of giant vesicle. Additionally, it can be noted that the flickering guanine nanoparticle in the vesicle reflected bright light in a direction opposite to the light source and caused bright illumination of the giant vesicle like an iridosome.

EV-12. Modifying coercivity via growth rate on domain wall pinning (001) FePd thin film.

C. Hsiao[1], H. Chang[2] and *C. Ouyang*[1]
1. Materials science and engineering, National Tsing Hua University, Hsinchu, Taiwan; 2. National Chung Cheng University, Chia-Yi, Taiwan

Perpendicular magnetic anisotropy (001) oriented FePd films epitaxially grown on MgO(100) substrates(as shown in Fig.1) with high order parameters(S=0.94) and large out-of-plane coercivity have been demonstrated. Stacking faults induced by strain relaxation are closely related to out-of-plane coercivity ($H_{c,\wedge}$) of FePd films prepared at various temperatures through examining all defects related to coercivity variations based on statistical simulations. Through climbing dissociation of total dislocation, the stacking fault densities($r_{S.F.}$) are promoted(as shown in Fig.2), resulting in distinguished promotion in out-of-plane coercivity. $H_{c,\wedge}$ drops significantly via raising or decreasing growth rate, indicating $r_{S.F.}$ is affected strongly by deposition parameters. This result suggests the coercivity can be manipulated via controlling stacking fault density in FePd film, which may pave a way for future magnetic devices.

Abstract: The research on the performance of ultra-high magnetic field radio frequency (RF) coils is one of the main aspects in the research of ultra-high field magnetic resonance imaging (MRI)system. In this paper, a ^{1}H /^{31}P dual-tuned multi-channel RF coil for the ultrahigh magnetic field 7T MRI was proposed. The performance of the proposed coil is evaluated by using numerical co-simulation approach. The result demonstrates the feasibility of the proposed double-tuned RF coil in the applications of 1H/31P ultrahigh magnetic field. 1.INTRODUCTION The improvement of RF coil performance is the most challenging topic in ultrahigh field MRI, particularly in the heteronuclear MRI where double nuclei are often involved. It is important to study the performance of ^{1}H /^{31}P double tuned RF coils to study metabolism of living systems[1]. In multi-channel dual-tuned RF coils, a technical challenge is to achieve sufficient electromagnetic coupling between adjacent channels and between non-adjacent channels[2]. In this work, we propose to design an 8-channel dual-tuned coil for ^{1}H/^{31}P imaging at 7T. The dual-tuned RF circuit of the dual-tuned coil can make it difficult to obtain optimal tuning and matching with high efficiency at both frequencies. The field distribution and tuning/matching conditions of the RF coil are modeled separately by EM and RF simulation[3].Through simulation, EM fields and SAR can be investigated to ensure imaging quality and patient safety[4]. Therefore, in this work, we used field-circuit co-simulation to model and field analyze dual-tuned coils[5] to evaluate the performance of the proposed dual-tuned RF coil imaging. The parameters evaluated coils performance include the homogeneity for B1+ field and specific absorption rate(SAR) value. 2. METHOD The 4-channel by 4-channel double-tuned coil design was used to image ^{1}H with a four-channel dipole array and ^{31}P with a four-channel Loop array. Sufficient decoupling of adjacent channel was achieved by using loop-overlapping approach. The dipole coils were placed in the center of the loop coils to minimize the coupling between the two coils [6]. The diagram of the double tuned structure is shown in Figure1(a). The loop size was 180×168 mm. The line width was 6 mm, and dipole size was 240×8 mm. The coil conductor was made of copper wire. The overlapping area of adjacent loops was 34.7 mm. The length of the single-side adapted dipole antenna was 117 mm, the distance between the two sides is 6 mm, placed in the center of the loop coil. These coils surrounded a cylinder with an outer diameter of 185 mm. The load was a cylindrical saline phantom with a diameter of 150 mm and a length of 200 mm. Its permittivity was 78, permeability was 0.99, conductivity was 0.6 S/m. The present study was modeled using a commercial CST software (Computer Simulation Technology, Darmstadt, Germany) and laboratory matrix codes were used to analyze and calculate B1+ field data and SAR derived from CST.The coil was modeled in a microwave studio (MWS). In joint simulation, all lumped elements were replaced by discrete excitation ports with impedance of 50Ω instead of the integrated elements on each of the loop coils. Other parameters were set in accordance with those of electromagnetic field simulation. As shown in Figure1(b). The number of mesh cells was about 510000 and boundary conditions were set to be omnidirectional. With time-domain solver, the steady-state accuracy limit was set to -40dB.The coil was tuned by changing the capacitance and inductance in RF circuit and combining individual B1+ fields based on tuning data for the external port to obtain the B1+ field. Since the four-channel coil was cylindrically shaped, four-channel orthogonal excitation was achieved during the emission mode. Therefore, the on-field phase was set to 0°, 90°,180°, and 270°in turn. When calculating the B1+ field results, the received power field was normalized to 1w. SAR post-processing results were normalized to 1W of input power. A graph of SAR was calculated using the average of 10g. The local SAR value (average of any 10 g tissue SAR) generated by the RF signal in the MRI system cannot exceed 10W/Kg. B1+ field uniformity calculated as follows: B1+homogeneity=($B1+_{Max}$ -$B1+_{Max}$)/(2×B1+Average) 3. RESULT The SAR distribution of ^{1}H and ^{31}P in xz plane are shown in Fig.2(a)and(b), respectively. The B1+ distribution of ^{1}H and ^{31}P in xz plane are shown in(c)and(d). In the center of interest area, distributions of B1+ and SAR show a desired pattern with high intensity B1+ and weak SAR, ensuring sensitive yet safe imaging acquisition. B1+ field distribution is symmetrical and uniform. B1+homogeneity of ^{31}P is 0.6, B1+homogeneity of ^{1}H is 0.65. Therefore, the proposed double-tuned coil design is feasible for ^{1}H/^{31}P imaging applications at the ultrahigh field of 7T. 4.DISCUSSION From the simulation results, the proposed ^{1}H /^{31}P double tuned multi-channel RF coil design for the UHF MRI system has good performance. This coil design method should be a feasible and efficient technique in designing high frequency double-tuned RF coil arrays for heteronuclear metabolic MR imaging at ultrahigh fields. However, the coupling between non-adjacent channels needs to be further improved. To address this issue, one possible solution would be the use of the magnetic wall or ICE decoupling technique[7].

EV-14. Effect of synthesis method on particle size and magnetic and structural properties of Co-Ni ferrites.

S. Sharmin[1], M. Kishimoto[1], E. Kita[1], H. Latiff[1] and H. Yanagihara[1]
1. Applied Physics, University of Tsukuba, Nagareyama, Japan

Introduction Spinel type ferrites are considered to be key materials for advancement in electronics, magnetic data storage, ferrofluid technology and many bio-inspired applications. Their magnetic properties, such as anisotropy, coercive force, and saturation magnetization are affected by various factors such as particle size and shape, crystal structure, and composition [1]. Co-Ni spinel ferrite particles have been studied mainly for the purpose of increasing saturation magnetization, even though the coercive force showed a tendency to decrease with the substitution of Ni. In the present study we have discussed the magnetic properties, Mössbauer parameters, particle sizes and cation distribution in Co-Ni spinel ferrites synthesized via a succession of chemical co-precipitation, hydrothermal treatment, and etching in hydrochloric acid (HCl). Experiment Co-Ni spinel ferrite nanoparticles were synthesized through the following processes. First, 0.02 mole of $FeCl_3$, 0.005 mole of $CoCl_2$, and 0.003 mole of $NiCl_2$ were dissolved in 20 mL of water, to obtain a 2.5 times molar ratio of Fe^{3+} against ($Co^{2+} + Ni^{2+}$). The solution containing Fe^{3+}, Co^{2+} and Ni^{2+} was added to an aqueous solution of 0.228 mole of NaOH to prepare the co-precipitant while stirring at room temperature. Then, the suspension containing the co-precipitant composed of Fe^{3+}, Co^{2+} and Ni^{2+} ions was treated hydrothermally using an autoclave at 180 °C for 2 h to grow Co-Ni spinel ferrite particles. After the hydrothermal treatment, the suspension containing Co-Ni spinel ferrite particles was washed with pure water until a neutral pH was reached. The suspension containing hydrothermally treated particles was then furthermore divided into several parts with equal volume, and each suspension was etched in 40 mL of HCl solutions diluted with water at concentrations from 2.0 to 6.0 mole/L for 2 h. The dimensions of the synthesized materials was examined by transmission electron microscopy (TEM). The Mossbauer spectra were collected at room temperature and at helium temperature (4.2K) using a constant acceleration Mossbauer spectrometer. The samples produced by chemical co-precipitation and hydrothermal treatment are denoted by AP and HT respectively, while the samples produced as a result of etching are indicated by ET2 (HCl solution 2.0 mole/L), ET4 (4.0 mole/L), and ET6 (6.0 mole/L). The magnetic properties were measured using a vibrating sample magnetometer (VSM) under a maximum magnetic field of 1353 kA/m (17000 Oe). Results and Discussion TEM images showed that the co-precipitant (AP) consists of fine particles of a few nanometers in size. When the co-precipitant was hydrothermally treated (HT), there was remarkable particle growth of the co-precipitant to almost cubic shape approximately 30–40 nm in size. A large quantity of fine particles were also present. However, after etching, the fine particles were almost all removed. Figures 1(a), (b) and (c) show the M-H curves of the co-precipitant, hydrothermally treated co-precipitant particles and the ET4 sample respectively. Table 1 shows the saturation magnetization (M_s) and coercive force (H_c) obtained. (Co-Ni) Fe_2O_4 can be described as a cubic close-packed arrangement of oxygen ions with Co, Ni and Fe^{3+} ions at two crystallographic sites. The analysis of room temperature Mössbauer spectra of the samples indicates that it comprises two subspectra; one for tetrahedral (A) site and the other for octahedral (B) site. On the premise that all of the Fe^{3+}, Co^{2+}, and Ni^{2+} metal ions, with the molar ratio 20:5:3, were used to form the spinel ferrite and that Co^{2+} and Ni^{2+} ions (M^{2+}) preferentially occupy B-sites while Fe^{3+} occupies the A-site, the composition should be $Fe^{3+}_{1.0}(Co^{2+}_{0.526}Ni^{2+}_{0.316}Fe^{3+}_{1.105\Delta 0.053})O_4$. Here, $_\Delta$ indicates vacancy. From room temperature Mössbauer spectra, we found that the nanosized AP sample is partly paramagnetic at room temperature, as evidenced by a central quadrupole doublet attributed to the superparamagnetic relaxation effect of nanometer-sized particles which is observed when relaxation time becomes significantly less than the Mössbauer effect observation time i.e. ~99 ns. The effects of superparamagnetic relaxation were offset by reducing the sample temperature to 4.2 K. The Mössbauer parameters (hyperfine field, H_{eff}, isomer shift, IS, and relative area) for the AP, HT, ET2 and ET4 samples at liquid He temperature are given in Table 1. We see that the ratio A/B changes as particle size is increased indicating that the cation distribution is changed as a result of the size and synthesis method. The ratio A/B is almost 1 in ET samples. Summary: Co-Ni spinel ferrite particles were synthesized via chemical co-precipitation, hydrothermal treatment, and etching in HCL solutions. A maximum coercive force of 519 kA/m and saturation magnetization of 60.4 Am^2/kg was obtained by after etching in HCl with a concentration of 4.0 mole/L.From the Mossbauer data, we can conclude that there are no Fe^{2+} ions as the obtained ISs are close to the typical value for Fe^{3+} ions, 0.36 mm/s. The reduction in particle size and the defects introduced in particles by etching are expected to have contributed to the high coercive force exceeding 500 kA/m.

EV-15. Effect of Sputtered Flux Direction on Damping Properties in Magnetic Bilayers.

S. Nayak[1], S. Mallick[1], B.B. Singh[1] and *S. Bedanta*[1]
1. LNMM, School of Physical Sciences, NISER, Bhubaneswar, India

The magnetic hard/soft bilayers have been studied widely due to high saturation magnetization (M_s) and magnetic anisotropy compared to its constituent layers [1]. These bilayers with high energy product $(BH)_{max}$ value have the application in various devices, permanent magnets, etc [2-6]. The material with high magnetic anisotropy has the application in high density recording devices [7]. Therefore, various deposition methodologies and conditions have been utilized to tune the value of magnetic anisotropy [8]. In addition, the materials with lower damping constant value have been studied for its application in spin-transfer switching devices [9]. Various deposition parameters and fabrication methodologies are being used to tune the value of damping constant. In magnetic bilayers, the interface roughness has a strong role in tuning the magnetic properties. We have fabricated Co (soft)/ $Co_{40}Fe_{40}B_{20}$ (hard) magnetic bilayers in UHV deposition system with oblique angle of deposition which induces uniaxial magnetic anisotropy. We have chosen the position of the targets in our deposition system in such a way that the plane of projection of the sputtered atoms of the individual layers on the substrate is perpendicular to each other. This geometry is termed as perpendicular configuration. Again, we rotated the substrate by 90° after depositing the first magnetic layer such that the direction of deposition of both magnetic layers becomes parallel to each other. This geometry is termed as parallel configuration. With these deposition methodologies, we tuned the value of magnetic anisotropy and damping constant. Table 1 shows the sample structure of all the magnetic layers with the deposition configuration and coercive field (H_C). The domain imaging and damping constant have been probed with magneto-optic Kerr effect (MOKE) based microscopy and ferromagnetic resonance (FMR) method. Due to direct exchange interaction between the individual layers, the magnetic domains found in the magnetic bilayers have the cumulative effect of the individual layers. Fig. 1 shows the magnetic domains of all the magnetic layers. The modification of line width and resonance magnetic field value in the magnetic bilayers indicates the existence of coupling between the individual layers. By fitting the experimental data shown in fig. 2 (a), we can get the value of damping constant. By fitting Kittel equation with experimental shown in fig. 2 (b), the magnetic properties like effective magnetization $4\pi M_{\mathrm{eff}}$ and anisotropy field value H_k are extracted. We found magnetic bilayer deposited in parallel configuration has lower damping constant value than the bilayer deposited in perpendicular configuration. The study of controlling the anisotropy, damping and reversal of the magnetic bilayers by varying the deposition geometry may have significant implications in future spintronics applications.

EW-01. Hall effect spintronics for gas detection.

A. Gerber[1] and G. Kopnov[1]
1. School of Physics, Tel Aviv University, Tel Aviv, Israel

Reliable detection of hazardous gases has become a major issue due to the more stringent environmental and safety regulations worldwide. Solid state conductometric gas sensors present a high potential for the applications where use of conventional analytical systems such as gas chromatography or optical detection is prohibitively expensive or impossible. Operation of such sensors is based on a change of electric conductivity when exposed to an atmosphere containing specific reagents, due to charge transfer between the sensor material and the adsorbed species. An important disadvantage of such sensors is the lack of chemical selectivity and sensitivity to humidity. Sensing materials are typically sensitive to more than one chemical species and show cross-sensitivity when different reactive gases are present simultaneously in the atmosphere. When the only parameter measured by the sensor is the change of resistance one cannot discriminate between different gases and their concentrations that can generate the measured signal. We present a new concept of magnetic gas sensors that will be able to solve the problem of cross-sensitivity by monitoring two independent parameters sensitive to the target gases: resistance and magnetization. The detection is based on the spintronics phenomenon of the Extraordinary Hall effect (EHE). Feasibility of the approach was demonstrated by detecting low concentration hydrogen using thin CoPd films as the sensor material. The Hall effect sensitivity of the optimized samples exceeds 240% per 10^4 ppm at hydrogen concentrations below 0.5% in the hydrogen/nitrogen atmosphere, which is more than two orders of magnitude higher than the sensitivity of the conductance detection.

Eco-friendly vehicles consist of a motor, an inverter, and a battery, and high current flows through all of the components. In order to ensure the efficiency and safety of a vehicle, there is a need for a high-performance current sensor capable of monitoring the status of instantaneous current in real time. In general, a Hall-effect sensor, a shunt resistor, and a current transformer are widely used as a current sensor. A shunt resistor causes several critical problems such as insulation breakdown and significant power dissipation, and in case of a current transformer as an indirect measurement, a non-sinusoidal waveform is distorted. A Hall-effect sensor overcomes the disadvantages of a shunt resistor and a current transformer, but big ferromagnetic core in a Hall-effect sensor is needed to avoid magnetic saturation in measuring high current. Recently, a Hall-effect current sensor with an integrated magnetic concentrator (IMC) has been developed for solving the disadvantages of the three conventional sensors by inserting a thin soft magnetic material into an integrated circuit chip instead of ferromagnetic core. The remove of ferromagnetic core makes an IMC sensor more compact at high current. However, because an IMC Hall-effect current sensor is sensitive to external magnetic field, a ferromagnetic shield outside the current sensor is employed to ensure the linearity and accuracy of current measurement, and the design of a shield plays an important role in determining the size of an IMC Hall-effect current sensor [1-4]. In this paper, how to minimize a magnetic shield is proposed in an IMC current sensor suitable for eco-friendly vehicles. In Fig. 1(a), a commercial IMC Hall-effect sensor having a U-shaped shield is given, and the sensor is designed under the condition of 600 amperes in current. Because a concentrator starts to be magnetically saturated at 25 milli Tesla in an integrated circuit chip, flux density around the chip must be maintained under 25 milli Tesla in designing a shield. As shown in Fig. 1(a), an IMC current sensor has the width of 30 millimeters in its U-shaped shield targeted at 600 amperes in current, but the shield of a proposed IMC sensor in Fig. 1(b) is significantly reduced due to the enclosure of the shield to have better prevention of external magnetic field. The optimization of magnetic reluctance in the enclosed shield plays a critical role in volume reduction, and a step-by-step design procedure will be detailed in the final paper. In designing the shield, it is important to consider four key performances such as shield magnetic saturation, flux density around a sensing chip, shielding factor, and error rate caused by skin effect in a bus bar. An experimental design method is employed to meet the four performances in optimizing the enclosed shield. Fig. 2 shows the simulation result of the proposed IMC Hall-effect current sensor having an enclosed shield, and it is verified that all the given specifications are satisfied at current level of 600 amperes. As a result, compared to a commercial IMC sensor with a U-shaped shield, approximately 84% of size is reduced in the proposed structure under the same current condition.

1. BCMaterials, Leioa, Spain; 2. Electricity and electronics, University of the Basque Country (UPV/EHU), Leioa, Spain; 3. SGIKER Magnetic Measurements, University of the Basque Country (UPV/EHU)), Leioa, Spain

I- Introduction The magneto-impedance (MI) effect accounts for the large change of the electrical impedance experienced by soft magnetic materials when a magnetic field modifies its magnetic permeability by external agents, such as magnetic field, stress or temperature. Due to the skin effect, there is a limited penetration of the electromagnetic field associated with an alternating current flowing through the material. The skin effect reduces the effective cross section available for the ac current to flow and consequently the impedance depends on the external agents. In previous studies, we have systematically optimized the preparation conditions, structure and combination of shape and induced anisotropies to enhance the MI ratios and sensitivities on $Ni_{80}Fe_{20}$ multilayers [1-3]. In this work, we explore the route of using MI as strain gage sensors depositing them onto flexible substrates. This option has already been marginally explored [4-6], but not in materials with relative large magnetostrictive coefficient as $Fe_{60}Ni_{40}$ [7] and reasonable MI ratios. II- Structure and preparation of multilayered samples Sputtered Iron-Nickel based thin films lose their magnetic softness when the thickness is increased above the critical one (typically about 200 nm) [1,7]. Iron-Nickel films below that limit display excellent magnetic properties with slight differences below 100 nm films [2]. If nanometric non-magnetic spacers are inserted between two consecutive magnetic layers, thicker magnetically soft multilayer structures can be obtained [3]. We have therefore selected the $[Fe_{100-x}Ni_x(100\ nm)/Ti(6\ nm)]_2/Cu(200\ nm)/[Ti(6\ nm)/Fe_{100-x}Ni_x(100\ nm)]_2$ multilayered structure for fabrication of two series of the samples, with x=80 and 40. The two sets of samples were prepared using metallic masks during the sputtering to obtain elongated stripe shaped samples of 10 mm long and 0.5 mm wide. Square Cu pads were deposited at the stripe's ends for electrical contacts. For comparison, the samples were deposited simultaneously on Silicon, Cyclic olefin copolymer (COC) and Kapton® polyimide film. The samples were prepared by DC sputtering under a magnetic field oriented in a transverse direction to the stripe length inducing a transverse magnetic anisotropy. Being this field 250 Oe for $Fe_{20}Ni_{80}$ and 500 Oe for $Fe_{60}Ni_{40}$. III- Measurements and results Samples were magnetically characterized by measuring the hysteresis loops with a Vibrating Sample Magnetometer (VSM). Figure 1 shows the typical hysteresis loops, displaying a well define transverse magnetic anisotropy of 5 Oe, but with larger coercivity in the samples deposited onto flexible substrates. The impedance was extracted from the reflection coefficient measured using a network analyzer. To determine the stress-impedance characteristics of the MI material deposited onto the flexible substrates, a custom sample holder was designed as described in [4,5]. The samples are glued to a miscrsotrip line together with a commercial resistive strain gage, closely situated to the sample and experiencing the same deformation. At the same time that the stress is applied, the hysteresis loops is measured using the magneto-optical Kerr effect (MOKE) while measuring the impedance as function of the applied magnetic field. As shown in figure 2, the sample deposited onto Silicon shows a maximum MI ratio, calculated for the absolute value of the impedance Z as MI(%) = 100x $(Z-Z_{min})/Z_{min}$, of 80% at 70 MHz and a sensitivity, defined as the derivative of the MI ratio, of 25 %/Oe.

Abstract All materials interact with an external magnetic field to some extent quantified by the magnetic susceptibility c. There is a correlation between local c value and local anomalies of material composition, deformation and stress, which makes it interesting to explore related sensor principles with a potential for NDT application. This contribution however concerns a modification over the magnetic force based sensor for laterally resolved susceptibility measurement and demonstrates the possible range of NDT applications on different non-ferromagnetic material samples. This sensor however eliminates the use of cantilever to avoid possible vibrations in the industrial environment. Keywords: non-destructive testing, magnetic force, magnetic susceptibility, paramagnetism, diamagnetism 1. Introduction Micromagnetic materials characterization is a well-known field of non-destructive evaluation and testing (NDE/NDT). It is based on the interaction of magnetic domain walls (Bloch walls) with microstructure, which is similar to the interaction of dislocations with microstructure [1 – 3]. Every material interacts with a magnetic field to some extent, depending on its internal composition and structure. The interactions which define the material's behavior in a magnetic field take place on the micro- and nanometer scale and are partially quantum mechanical in nature. The magnetic susceptibility c describes how a material interacts with an external magnetic field. It has been verified before that a correlation exists between micro- or electromagnetic and mechanical properties in para- and diamagnetic materials as well [4]. Previously, a magnetic force sensor developed [4][5] has shown promising potential in characterizing the materials like composites, plastics and many other non-ferromagnetic materials. Since, luxury car makers and aerospace industry are using more and more composites in manufacturing, it becomes very important to have a method to control the quality check, e.g., adhesion between two composites. However, one major drawback of this approach [4] was the use of cantilever which is not very useful when it comes to industrial test conditions which are more prone to vibrations. Hence, a new modification is proposed in this contribution in which the experimental set-up is changed entirely and a diaphragm is used instead of a cantilever. This system shows more stability and is less prone to vibrations. As an added advantage, the cost of the entire set-up is also reduced. 2. Experimental set-up and results Previously, a capacitive distance sensor was used in order to determine the deflection of a cantilever carrying a sensing magnet [4]. In the new proposed method, the authors use a plastic film thick enough to hold the sensing magnet with one layer of reflector on top for the laser sensor to sense the displacement (Figure 1). The sheet used to hold the sensing magnet is polyvinylidene fluoride (PVDF) in order to be strong enough to hold the magnet and at the same time thin enough to sense some stretching due to the force on the magnet when exposed to the material under test. The thickness of the diaphragm used in this set-up is 500 microns. The laser sensor used in this method is an MTI instruments device whose resolution is 0.5 μm/mV. The output voltage change of the laser sensor electronics when the sensing magnet is approaching a material is proportional to the displacement of the magnet. When investigating practical materials such as plastics or aluminium, the deflections are so small that the distance between sample and magnet changes to very small extent. In this case, the deflection (or voltage change) is almost proportional to the susceptibility of the material. The output of the laser sensor is calibrated in terms of force. Figure 2 depicts the initial results with aluminium and graphite sample over varied distances. Many other non-ferromagnetic materials characterization will be presented in the extended version of this article to verify the efficiency of the sensor. Figure 1: Experimental set-up schematic Figure 2: Initial results 3. Conclusions In this study a new experimental set-up is proposed for the characterization of the non-ferromagnetic materials non-destructively. A diaphragm is used to avoid any vibrations which are a major possibility in the industrial testing conditions. Additionally, the cost of the sensor is also reduced to make it easily available for the industry. In the extended version of the article, many different non-ferromagnetic materials will be characterized and imaged as per their magnetic susceptibility.

EW-05. Low noise fundamental mode orthogonal fluxgate (FM-OFG) magnetometer built with an amorphous ribbon core.

I. Sasada[1]
1. Sasada Magnetics & Sensors Laboratory, Fukuoka, Japan

Room temperature operating magnetometers able to detect a few pT magnetic field would play a crucial role in such areas as bio-magnetic field detection and very tiny ferromagnetic contaminats detection in battery production lines. We have already reported fundamental mode orthogonal fluxgate having a noise density ~3 pT/√Hz at 1 Hz using a Co-based amorphous wire (made by Unitika) core sensor head [1]. However, the supply of the amorphous wire is limited. In this paper, we present that the narrow amorphous ribbon core is an alternative to the wire core if the dc bias current for the fundamental mode operation [2] is properly adjusted. In a particular case of as-cast Metglas 2714A ribbon of 1 mm width, the dc bias current elevated to 200 mA, which is to be 40 mA for the wire core sensor head, reduces the noise down to a few pT/√Hz. In the experiment, we made several sensor heads listed in Table I using the above mentioned ribbon. A 1 mm width ribbon which is made by slitting a wider sample is bent in a U-shape or more likely in a hair-pin shape and inserted into a cylindrical pickup coil of length 30 mm, bore diameter of 2 mm and having 500 turn copper winding. The driving and signal processing electronics used is the one developed for the wire core sensor head. The only difference is that an adopter circuit is inserted between the ribbon core sensor head and the driving electronics to supply a large dc bias current from the battery and to moderately (≈2x) amplify the ac excitation current; the ac excitation current for ribbon core sensor heads is 24 mArms while that for wire core one is 12 mArms. The driving frequency is 100 kHz and the magnetometer is configured to operate in a closed loop (feedback) using a 10 kΩ feedback resistor. The sensitivity increases slightly with increase in length of the core, because the demagnetization effect becomes smaller for longer cores. The sensitivity of the magnetometer with the wire core sensor head is about one half of that of the magnetometer with the ribbon core sensor head because the number of turns of the pickup coil used for the wire core is 1000. It should be noted that the sensitivity of the closed loop system is R/n [V/A/m] where R is the feedback resistance and n is the winding density per meter of the pickup coil. The noise spectral density of the magnetometer was measured by placing the sensor head in a five shell cylindrical shield and by using an FFT analyzer (Stanford Research Systems SR780). Results are listed in Table I from which we can conclude that the noise level obtained with a ribbon core sensor head is comparable to that obtained with a wire core sensor head. Fig. 1 shows the noise spectral density of the ribbon core sensor head R19 for three different dc bias currents. It is interesting to see that the noise level is dramatically reduced by increasing the dc bias current. This is probably related to the nature of the as-cast Metglas 2714A ribbon such that weak magnetic anisotropies are distributed randomly in the ribbon plane. It is also interesting to compare the magnetic field produced by the dc bias current at surfaces of the ribbon core and of the wire core. For the wire core, the radius is about 60 μm and the bias current is 40 mA, hence the magnetic field is about 106 A/m. For the ribbon core, because the thickness (<20 μm) is negligible compared to the width (1 mm), the magnetic field at the surface of the ribbon is quite uniform along the width direction, hence the magnetic field can be calculated by dividing the current (220 mA) by the peripheral length which is twice the width, yielding 110 A/m which is similar to the one for the wire. One may expect that necessary dc bias current can be reduced by making the width of the ribbon narrower. A very weak magnetic field of rectangular waveform of 15 pT in peak-to-peak is well detected with a short averaging. Details on the adapter circuit will be explained.

EW-06. Accuracy Analysis of Sensing Coils in 2D Magnetic Properties Measurement.

X. Ding[1] and S. Ren[1]
1. Beihang University, Beijing, China

It has long been recognized that the rotating magnetic flux appears in electrical machine cores and leads to considerable power loss [1]. Beisides, the magnetic properties of electrical steel sheet are affected by stress because of produce process and external environment. The alternating and rotating magnetic properties have been invesgated widely [2-6]. However, there is a lack of research on two-dimensional magnetic properties of electrical steel sheet under laminated direction stress, and few mature measurement apparatus has been proposed. In the two-dimensional magnetic properties measurement considering laminated direction stress, the traditional micro-holes method[7], novel needle probe method[8] and H-coils could not be employed, since the B- and H- sensing part is restricted to destruction due to mechanical stress. While a novel sensing structure with cubic specimen is designed for three-dimensional magnetic properties measurement [9], which could be expanded to two-dimensional properties measurement considering laminated direction stress. Whereas the accuracy of the novel sensing structure has not been emphasized. Therefore, the sensing structure with cubic specimen is designed for two-dimensional properties measurement considering laminated direction stress, and the accuracy of the sensing is analyzed in detail. The two-dimensional magnetic properties measuring apparatus considering laminated direction mechanical stress is illustrated in Fig.1(a). The overall apparatus is composed of stress loading part, closed magnetic circuits, support and pedestal. As the amplitude, frequency and phase of X- and Y-direction currents controlled, the vector *B* along arbitrary direction in magnetization plane XOY could be induced in specimen. And the stress along Z-direction which is parallel to laminated direction of electrical steel sheets specimen, is exerted by rotating the handle wheel. The sensing coils for *B* and *H* are attached to the surfaces of cubic specimen, as shown in Fig.1(b). In order to enhance the magnetic field in cubic specimen, the gap in which the *B* and *H* sensing coils are placed needs to be reduced. Hence, the *B* coils made of four layers PCB (Printed circuit board) is employed, and the *H* coils are wound around the PCB, as shown in Fig 1(c). However, in the measurement of two-dimensional magnetic properties, the normal component H_n of magnetic field strength in sensing coils regions is considerable, which could lead to measuring error of *H*, as shown in Fig.1 (d). Therefore, a modified *H* coil made of four layers PCB is proposed in this paper. Fig.1(e) and (f) illustrate the PCB diagram as well as the product of modified *H* coil respectively. Since the projection of the conductors of each coil are coincided perfectly, the equivalent closed loop whose area is perpendicular to Hn is eliminated. Consequently, the modified *H* coils just examine the tangential component H_t of *H* on the boundary which between the specimen and gap. The thickness of *H* sensing coil is 1mm, and the thickness of the overall sensing structure for *B* and *H* is less than 2mm. The accuracy of the sensing coils in the apparatus is validated by both FEM and experiment. In the FEM analysis of closed magnetic circuits, the currents which present 5A amplitude, 50Hz frequency and 90 degree phase difference are set to the exciting coils. The distribution of B_x and B_y components both in specimen and *B* sensing coils regions are shown in Fig.2(a). Each component of the vector *B* is homogeneous in specimen, and equal to the counterpart in *B* sensing coils regions. In the same way, the H_x and H_y components in specimen and *H* sensing coils regions are also examined. Fig.2(b) shows the H_x and H_y components in specimen and *H* sensing coils regions. It indicates that each component of *H* in specimen is homogeneous, and the same as the counterpart in *H* sensing coils regions. The modified *H* sensing coils are also validated by the experiment. As the exciting current shows the same phase of magnetic field in the gap, the phase of Hx-coils induced voltage presents 90 degree ahead of the X-direction exciting current. However, the phase difference of original Hx coils induced voltage and X-direction current is 21.3 degree, as shown in Fig.2(c). The obtained voltage of original H_x coils contains considerable induced voltage which influenced by Y-direction current. Fig.2 (c) also shows the induced voltage of modified H_x coils. The phase difference between X- direction current and induced voltage is 90 degree. Thus, the modified H_x coils could not affected by Y-direction magnetic field. For further validation of *B* and *H* sensing structure in this paper, plenty of measuring experiments of different types of steel sheet would be conducted, applying both Epstein frame measuring system, which acts as the standard measuring method of one-dimensional magnetic properties of magnetic meterial, and the measuring apparatus in the full paper.

EW-07. Magnetic Properties and Detection Methods of the Metal Wear Particles under Harmonic Magnetic Field.

R. Jia[1], B. Ma[1], C. Zheng[1], L. Wang[2] and Q. Du[1]
1. Beijing Institute of Technology, Beijing, China; 2. Beijing Information Science and Technology University, Beijing, China

1.Introduction The wear particles, as the production of abrasion, not only involve rich information of device-wearing but also will lead to further failure of equipment. According to the statistics, more than 75% failures of mechanical equipment were caused by the abrasion or wear particles[1]. Consequently that analyzing particles mixed in lubricating oil in real time appears particularly importance,and the inductive wear particles detection sensor has been widely studied and concerned due to its advantages of simple structure, good temperature stability and anti-interference ability. In order to guarantee the wear particle detection sensor both can detect ferromagnetic and non-ferromagnetic particles, this type of sensor often adopt alternating magnetic field. The field frequency covers an extremely wide range. S.P.Wang established a kind of particle detection sensor based on the static magnetic field, which only effective for ferromagnetic particles. The MetalScan system adopted 107Khz, Du Li et[2-4] fabricated a microfluidic device for metal particle detection in lubrication oil, which fluidic channel with dimension of 250μm×500μm and the excitation frequency was range of 1 and 3MHz. It is known that the magnetic field disturbances caused by metal particles, when debris through the sensor, is closely related to the field frequency. Researchers often adopt the static magnetization model to approximately analyze the effect of the ferromagnetic particles on the magnetic field and ignore the Eddy current effect in the particle, but with the increase of the field frequency the eddy current effect will show more significance. 2.Magnetic properties of wear particles The excitation signal of three-coil abrasive detection sensor is generally sinusoidal AC power supply, so the internal magnetic field of the sensor is alternating. The metal wear debris in alternating magnetic fields will produce eddy currents effect and affect the external magnetic field. The influence of metal sphere particle on the magnetic field in the sensor should satisfy the equation:$\sigma(\partial A/\partial t)+\nabla\times(1/\mu\nabla\times A)=0$, Where: A is the vector magnetic potential,μis the permeability of material,σis conductivity. Under harmonic magnetic field, the vector magnetic potential A can be described as $A=Ae^{-j\omega t}$which makes $\partial A/\partial t=j\omega A$, so the governing equation can be expressed as$\sigma j\omega A+\nabla\times(1/\mu\nabla\times A)=0$. In the cartesian coordinate, the magnetic orientation of the sensor oscillates along the X axis, so the vector magnetic potential outside of the particle is:$A=[A_x,A_y,A_z]=[0,0,B.y]\cos(\omega t)$, Where B is peak value of the local magnetic induction intensity at the position of particle; When calculate the distribution of magnetic field inside and around the particle, some boundary conditions should also be satisfied as follows. The equations (2) (3) describe the continuity of magnetic potential at the inside and outside surfaces of the sphere wear particles, and the equations (4) is the infinite boundary condition. 3.Validation of the model To verify the validation of the model, the magnetic property of iron particles in static magnetic field is calculated by both of the analytical solution and the numerical solution. We calculated the magnetic field distribution around the particle by the numerical method under the circumstance of $B_0=0.035T$,the magnetic induction intensity along the X and Z axes are presented in Fig.3. It shows that the distribution of magnetic field in the particle is equally distributed, and the magnetic induction intensity in the particle is B_{inner}=0.1047T, which agrees perfect with the analytical solution and validates the solution of the harmonic magnetic field model. 4.Magnetic properties of iron particles under harmonic field For the wear particle detection sensor, the frequency of the magnetic field generally ranges from 80 kHz to 3 MHz, so the magnetic properties of iron particle under the magnetic field of different frequencies were simulated. In this case, the radius of the particle was set to 0.125mm, and the frequency of magnetic field was set 0Hz, 100 Hz,1kHz,10kHz and 100 kHz respectively. The magnetic flux intensity distribution inside and around of the particle at different circumstance is shown at the Fig.4. It illustrates that when the exciting frequency is lower than 1 kHz, the eddy current in the particle can be ignored, the magnetic field distribution can be approximately estimated by static model, and with the increase of the exciting frequency, the magnetic field in the particle gradually weaken to 0, and the magnetic flux intensity at the surface of the particle along the direction of the initial magnetic field shows a maximum(0.5129T when f_0=100kHz) which is much larger than background magnetic field(0.035T). 5.The influence on sensor coil of particles The change of the local induced electromotive force caused by wear particles lead to the variation of magnetic flux of the through the sensor coil. In the studies[5, 6], the variation of magnetic flux of the through the sensor coil is estimated by the equation$\Delta\phi=N\iint\Delta B ds$, where N is the turns of coil. However the change of the induced electromotive force caused by wear particles only occurs at local position, so this calculation method over-estimated the inductance change of the coil resulted from the wear particle; especially on the occasion of the length of coil *l* is greatly larger than the diameter of particle. To precisely estimate the influence on sensor coil of wear particle, The total change of magnetic flux of the sensor coil caused by wear particle $\Delta\phi=\int\gamma\iint\Delta B ds dl$.

EW-08. Graphene-Co Nanoparticle Composites: Sensor Applications.

c.g. ünlü[1], A. Tekgül[3,4], M. Acet[2], M. Ak[1] and M. Farle[2]
1. Department of Chemistry, Pamukkale University, Denizli, Turkey; 2. Department of Physics, Duisburg-Essen University, Duisburg, Germany; 3. Department of Physics, Akdeniz University, Antalya, Turkey; 4. Department of Physics, Uludag University, Bursa, Turkey

Graphene based two dimensional carbon nanostructures that is characterized by exceptional biological, electrical, electrochemical, mechanical, optical and structural properties. To detect a wide variety of targets including biomolecule, chemical, electronical, and even living cells, graphene has a particularly great potential for use in sensors. Despite its recent discovery, graphene has already demonstrated its superiority to the well-established carbon nanotube in terms of electrocatalytic activity and conductivity. For electrochemical sensor applications, graphene is a promising material due to its large electrochemical window. Similarly, for electronic sensor such as field-effect transistor, graphene offers high carrier mobility and has low noise for better detection [1]. The properties of graphene based sensors could be tuned by incorporating magnetic nanoparticle to be formed as graphene-nanoparticle hybrid structure. Functionalized with different nanoparticle in order to enhance their individual properties to bring additionally advantages for the sensing application. Bio-compatibility property of graphene based sensors provides the promising candidate in the bio-sensor application. Their flexibility, easy integration and high precision gain new advantage than the other sensor systems in the biological systems. In this perspective, we present the sensing application of graphene-Co nanoparticle hybrid structure. In these systems, graphene sheets were prepared by chemical vapour deposition (CVD). Graphene is growth to be 0.1 mm thick, 2×2 cm^2 Cu-foils of 99.8 % purity were used as metallic catalyser. Copper foils were pre-cleaned by acetone, isopropanol and deionized water for 10 min in an ultrasonic cleaner. Then, it was placed into a furnace. The furnace was evacuated to 10^{-6} Torr and pre-heated to 1000°C with flowing H_2 at 100sccm for 30 min. This pre-heating and annealing process for Cu is targeted to create graphene seeds for growth. After annealing, CH_4 gas is let into the chamber at 30 sccm flow for 30 min. The chamber pressure was kept at 9×10^2 Torr while holding the Cu-substrate at 1000°C during the growth of the graphene. Finally, the Cu-foil covered with graphene was quickly cooled to room temperature. The large-area graphene ($2\times2cm^2$) prepared on the Cu foils was transferred onto FTO substrates. To be able to carry out the transfer, graphene on Cu foil was covered homogeneously with PMMA (Poly methyl methacrylate) solution with a spin-coater rotating at 4000 rpm for 40 s. Then, the sample was floated onto $Fe(NO_3)_3 9H_2O$ for a day in order substrate etched. The remaining graphene with PMMA was transferred onto the FTO substrate. After the PMMA solution was removed by acetone, we were able to complete transferring the pure single layer graphene onto the FTO substrate. Primary and sintered Co nanoparticles were prepared by the inert-gas condensation method based on DC-magnetron sputtering in a gas-flow of Ar and He [2, 3]. The primary nanoparticles are produced without in-flight annealing whereas the sintered particles are subjected to in flight heat treatment. The liquid nitrogen cooled nucleation chamber hosts the Co targets. The total gas pressure was maintained at 0.5 mbar. After nucleation and growth, the particles undergo in-flight annealing in a sintering furnace at 1000 K. The particles were deposited on standard carbon coated copper TEM grids held at liquid nitrogen temperature and Graphene/FTO substrate. The morphological and structural properties and the composition of the deposited particles and graphene were investigated ex-situ by using Raman Spectroscopy, High Resolution Electron Microscopy (HRTEM) and Energy Dispersive X-ray Spectroscopy (EDX). Furthermore, the magnetic properties of the samples were investigated by Magnetic Properties Measurement System (MPMS). Analytical and electrochemical performance of the samples were investigated with Iviumstat potentiostat-galvanostat.

EW-09. Force sensors based on magnetic amorphous wires.

C. Hlenschi[1,2], S. Corodeanu[1], *H. Chiriac*[1] and N. Lupu[1]
1. National Institute of Research and Development for Technical Physics, Iasi, Romania; 2. Alexandru Ioan Cuza University, Iasi, Romania

The very convenient soft magnetic properties of the amorphous magnetic wires, that originate in the combination of the magnetic structure and cylindrical symmetry [1-3], and the high sensitivity to stress of their magnetic properties recommends them for a large number of applications, mainly as sensors and actuators [3-5]. A new type of sensor with high capability to measure applied forces is proposed by this paper. The sensing element consists of a $Co_{68.18}Fe_{4.32}Si_{12.5}B_{15}$ amorphous micro wire with100 μm in diameter and 12 mm in length, around which was wound a two layer coil with 200 turns using enameled 0.04 mm copper wire. The sensitive element is mounted circumferentially between two elastic tubes having around 7 mm in diameter and 5 mm in length (Figure 1). This attaching mode assure a pretension of the sensitive element, by bending it around the tube, and possibility to tailor the sensitivity and force measuring range by using tubes with different diameter and elasticity. For the presented results we used a latex tube with 7 mm external diameter and 2 mm wall thickness as inner tube and a heat shrinking tube around, to fix the sensitive element (Figure 1). The operating principle of the sensor is based on the variation of the coil impedance due to magnetic core permeability modification when the stress induced by bending is changing. The sensor coil is connected in series with a 470 Ω resistor, to limit the current trough the sensor coil at peak values smallest than 1 mA, and powered, using a sinusoidal signal. The drop voltage at the coil terminals is processed by a specific electronic device and correlated with the applied force by calibration. The coil excitation frequency was chosen at 160 kHz in order to obtain a good balance between the amplitude of the coil drop voltage and force sensitivity. At low frequencies the output signal is low due to small coil impedance (3.7 Ω in DC) and requires strong amplification while at to higher frequencies the coil signal is higher but the sensing element response to stress is less sensitive due to wire permeability decrease. At a frequency of 160 kHz the impedance of the sensor is approximately 75 ohm. The change of the applied force modifies the wire curvature, stress and permeability and consequently the drop voltage amplitude at the coil terminals. An analogical device was built to extract the amplitude of the coil signal, to filter and amplify the signals and to provide offset correction. In the first stage, the pick-up signal is amplified using a low noise operational amplifier to obtain a signal with higher amplitude. Then the signal is applied to a precision rectifier and the positive components of the signal are selected. To extract the force related signal, the signal from the previous step is passed through a low pass filter to remove the AC component which is coming from the excitation. In the last stage of analogue processing the offset is removed and the signal is filtered and amplified to get rid of hi frequency noise and to obtain a reasonable voltage value for output. To trace the compressive force versus output voltage characteristic we build a test device consisting of a non-magnetic metal frame and a vertical piston witch have at top end a tray and at the bottom the force sensor which is pressed under the action of weights placed on tray. The applied force was calculated as product between loaded weight and gravitational acceleration (9.81 m/s^2). The sensor voltage was measured using a voltmeter and the measured voltage values where plotted for each applied force. When the compressive force is applied (referred as positive values) the elastic tube is compressing and become elliptic with the center of the sensing element perpendicular to the major axis. In this case the stress induced in the sensing element is increasing, permeability of the wire is decreasing and consequently the output voltage is decreasing (Figure 2). If a tensile force is applied the elastic tube is also deforming and become elliptic with the center of the sensing element perpendicular to the minor axis. In this case stress on which the sensing element is subjected decrease, permeability of the wire is increasing and consequently the output voltage is increasing. The applying of tensile force is similar wit the case of compressive force on the sensor rotated with 90 degree. The dependence of output voltage versus compressive force shows a linear dependence for a wide range of applied force values (Figure 2). The sensitivity of the force sensor for the given configuration was 1.24 V/N and the force range up to 1N. The new developed force sensor can be easily adapted for specific applications such as medical devices and instrumentation (robotic surgery, tweezers for manipulating fragile objects) or other devices which requires force feedback. The magnetoelectric sensor has the advantages of high sensitivity, low noise and simple preparation process. It has great application prospects in weak magnetic field detection such as geomagnetic field, biomagnetic field and so on. What's more, the resolution of detection for low-frequency AC magnetic field can reach pT magnitude[1]. Because the piezoelectric material will produce a continuous output only when it is in a periodic vibration. so it needs to use modulation technology when measuring the statics magnetic field. The modulation techniques commonly used today are AC modulation and electric field modulation[2~3].But now, a new modulation method will be introduced in this paper, that is what referred to as rotation modulation. As shown in Fig.1(a), the component of the measured direct current projection on the shaft is a sinusoidal signal whose frequency is equal to the frequency of rotation, thus, we can measure constant magnetic field directly. More exciting, we may apply the rotation to MEMS structure to achieve miniaturization and integration. The test platform shown in Fig.1(b) is consist of rotation system and measurement system. Rotation system inclueds a ultrasonic motor and a fixture used for installing the magnetoelectric sensor and induction coil providing DC bias. The measurement system is composed of Signal Generator, Regulated DC Power Supply, Spectrum Analyzer, Magnetic Shield Tube. The magnetoelectric sensor used in the experiment was composed of Metglas/PZT/Metglas, which top layer and bottom layer are composed of two-layers of magnetostrictive Metglas. In order to obtain the best bias magnetic field, we firstly design a series of experiments with linearly increasing bias DC field at 2Hz(because the maximum rotation frequency of ultrasonic motor is 2Hz). Fig.2(a) shows that the optimal DC bias is about 8Oe. Then our group has tested the ME output voltage of magnetoelectric sensor with 10Oe measured DC field providing by coil, and the four groups experiments had been processed under condition of statics or rotation at three different speeds shown in Fig.2(b). There are three spikes whose value far greater than other's, and their position is just corresponding to the frequency of rotation. Fig.2(c) has shown almost linear change between ME voltage and the measured DC field. Thus, it can be conclued that the proposed modulation method is really effective. In these experiments, our team have used coils to ensure the DC bias can be controlled accurately. The next step we will use ferromagnet for bias. Using the proposed modulation method can realize high-precision DC magnetic field measurement like AC modulation and electric field modulation after enchancing ME out voltage through the selection of magnetic composite materials, the optimization of the rotating structure and the using of charge amplifier.

EW-11. Development of the Technique for Measuring the Magnetic Flux in the Motor Core under Operating Conditions.

Y. Maeda[1], S. Urata[1] and H. Nakai[1]
1. Toyota Central R&D Labs., Inc., Nagakute, Japan

The increasing need for EV, PHV and HV has led to an intense research and development in the field of high efficiency motors. In order to develop the high efficiency motors, we have to evaluate magnetic properties of the core materials that consider the influences of manufacturing processes and actual motor operating conditions accurately. It is useful to develop designing techniques that can consider those evaluated properties accurately. The evaluations are carried out with a single sheet specimen by simulating stress [1], rotating magnetic field [2], direct flux superimposition [3] and so on, because emphasis is placed on their simplicity and versatility of the measurement. However, evaluations with a single sheet specimen have problems because they can't evaluate actual magnetic phenomena occurred in the motor core under operating conditions completely. In order to solve these problems, we have examined some techniques to visualize magnetic phenomena occurred in the motor core. In this paper, we introduce the newly developed technique to measure the magnetic flux flow in the motor core. In order to measure the magnetic flux in the motor core, the magnetic flux sensor that does not disturb the magnetic flux flow and has electric noise tolerance in operating motor is required. Newly developed three directional (radial, circumferential, and axial direction of the motor core) thin magnetic flux sensor to locate in the motor core is shown in Fig.1. This sensor consists of two-layered flexible printed board. Thickness of the sensor is about 170μm, thinner than an electrical steel sheet. Therefore, the sensor is able to set easily between the steel sheets without additional modification of the motor core. The magnetic flux in the radial direction and circumferential direction are measured by the needle probe method [4], which does not require any hole-drillings for measuring. The flux in the radial direction can be calculated by measuring the induced voltage between r_1 and r_2, the one in the circumferential direction can be calculated by the induced voltage between θ_1 and θ_2. The magnetic flux in the axial direction is calculated by measuring the induced voltage of the square search coil located on the flexible printed board. In order to make the higher tolerance for electric noise depending on the leakage flux, we constructed twisted pair line by using through holes in the two-layered circuit board, as a lead line connected to the sensor and the terminal point. Then, measurement results with developed sensors and magnetic field analyses results under the motor operating condition are compared. The magnetic flux density loci comparisons at the local area on the tooth in the stator core are shown in Fig.2. The solid line means measured results. The dotted line means analyses results. According to Fig.2, the measured magnetic flux density at the tip part of the teeth has elliptical locus. And the calculated result at the same position has alternating locus. Occurrence factors of the difference between measurement and analyses are considered as follows: (1) influence depending on an anisotropic of the magnetic material, (2)influence depending on manufacturing process such as form shaping, sheet lamination, coil winding. Analyses results ignore the influence (1) and (2), on the other hand, measurement results reflect them all. In other words, the proposed measurement technique can grasp the behavior of the magnetic flux flow, which is not able to grasp by analyses results. In conclusion, the newly developed measurement technique can measure the magnetic flux flow in motor core under operating condition, and visualize the behavior of the magnetic flux flow which cannot be considered by calculation. In the future, we will evaluate the magnetic properties of the motor core in detail by using developed technique.

EW-12. The perceptually-inspired model of tactile texture sensor based on the inverse magnetostrictive effect.

L. Wan[1] and B. Wang[1]
1. Hebei University of Technology, Tianjin, China

With the development of online shopping and intelligent industry, tactile perception has become the focus of attention and research. This sensitive texture detection of human is realized by characteristics of skin structure and several kinds of highly sensitive tactile capacitors in skin. The surface texture characteristic is regarded to be important information to evaluate and recognize the object. Tactile sensors are necessary to mimic the human touch sensing ability in many areas, such as virtual environment, e-commerce, robotic telemanipulation, and so on. Most of tactile sensors are based on piezoresistive or capacitive principles. They can provide some tactile or touch information, which includes weight, stiffness, elasticity and friction. At present, the cost-effective measurement of fine geometric texture is still a challenging task because the nonvisual texture sensors are relatively difficult to be design. The magnetostrictive material has the characteristics of small saturated magnetic field, good ductility and high tensile strength, so that it can withstand a variety of mechanical loads, such as pressure, tension and impact. The inverse-magnetostriction effect indicates that the permeability of a magnetostrictive material can be changed by an external impact. Therefore, the tactile sensor can be designed, based on the inverse-magnetostrictive effect. However, the relationship between the output voltage and the external impact is still unclear on the tactile sensor, based on the inverse-magnetostrictive effect, and the theoretical model of the output voltage for the tactile sensor has not been founded. Therefore it is necessary to investigate the perceptually-inspired model of the tactile sensor based on the inverse-magnetostrictive effect. At the same time, the perceptually-inspired model can also predict surface texture and classification by mimicking the active texture perception process of a human finger. In this paper, the model of the output voltage for tactile texture sensor has been founded and the relationship between the output voltage and the contacted object texture has been determined, according to the inverse magnetostrictive effect, the flexure mode, the Jiles-Atherton model, and the signal processing theory. The output voltage is relative with the bias magnetic field, the positive force and the information of the object texture, which is dependent on the height, the width and the total number (the period) of the surface ridge in the fixed length in addition to the Galfenol material parameters and the detecting coil. The output voltage of the tactile texture sensor is caused by the change of magnetic induction in Galfenol material. When the tactile texture sensor contacts the moving object, the deflection of Galfenol sheet moves up and down with the characteristics of the surface texture, then the magnetic domains will rotate. The rotation of magnetic domains will lead to the change of magnetic induction. The magnetic induction is mainly determined by the effective magnetic field and the magnetization of Galfenol material. Based on the trajectory by probe, the deflection signal of tactile texture sensor can be represented by the step sequence in the digital signal system. The sequence function is mainly determined by the height, the number of the texture ridge. The relationship between the output voltage and the texture parameters of the object is founded. The model of the output voltage of the tactile texture sensor can be used for the classification and imperfect testing of the object. From the experimental results in Fig.1, the tactile sensor move up and down as the height of ridge and spatial period of fabric when the tactile sensor contacts with the fabric surface with the speed of 3cm/s. The output voltage in Fig.1 (a) and (e) are mostly between 5mv and 10mv, but the period of the voltage wave is relatively longer in Fig.1 (a). The peak of the output voltage in Fig.1 (b) is obviously the largest, which is more than 10mv. Both voltage amplitude in Fig.1 (c) and (d) are mostly below 5mv, but their average voltage and period are different. Therefore, we speculate that the output voltage can represent the surface texture of the object. According to the results above, two conditions can be obtained on the tactile texture sensor: the surface texture has a large effect on the output voltage of the tactile texture sensor. The tactile texture sensor can complete the classification of fabrics. This work was supported by the Natural Science Foundation of Hebei Province No. E2017202035, and national natural Science foundation of China No. 51777053.

Magnetic sensors based on the magnetoresistance effects (MR sensors for short, e.g. GMR sensors and TMR sensors) have a promising application prospect due to their excellent sensitivity[1] and advantages in terms of the integration. The traditional MR sensors detect the magnetic field based on the deviation of the magnetization direction from the easy axis in the free layer (FL). However, competition between higher sensitivity and larger measuring range remains a problem. For the MR sensor with an in-plane anisotropy in the FL, the strength of anisotropy, which determines the measuring range and the sensitivity, can be tuned via manipulating the geometry of the device[2]. However, for MR sensor with perpendicular anisotropy, the measuring range is determined by the property of the multi-layer stack[3] and cannot be tuned via the geometry of devices. Here, we propose a novel mechanism for the design of MR sensors: probing the perpendicular field by detecting the expansion of the elastic magnetic Domain Wall (DW) in the FL of a spin valve or a magnetic tunnel junction. Fig. 1 shows the structure of the structure of the proposed device. The FL of two or more MTJs are connected via wire bridges while the pinned layer of MTJs are isolated. Free layers have a PMA and magnetizations of pinned layers are perpendicularly initialized on the same direction. The response of the magnetization in the FL of the device versus external fields was simulated, as shown in Fig. 2. Before working, opposite current pulses should be applied so that the magnetization of the free layer of two adjacent MTJs are initialized to opposite directions via the spin transfer torque. A DW will be created in the bridge. When the device is put in an external field H_{ext}, the DW will be moved in either of the two directions, depending on the direction of the external field. When the DW arrives at the connection between the bridge and one of the FL, it will be pinned, since the further expansion means a larger DW surface and thus a raised DW surface energy γ, as demonstrated in our previous experiments. In equilibrium, the DW will be of a circular arc shape and the radius can be given as follows[4], $R=\gamma/[\mu_0 M_S(H_d+H_{ext})]$ Here, M_S is the saturation magnetization. The demagnetizing field H_d is determined by the magnetic state and the structure of the device, varying with H_{ext}. Other parameters are all intrinsic. Therefore, the radius of the DW arc is solely dependent on H_{ext}. The expansion of the DW leads to a change of the magnetoresistance. In this way, the external field is quantified through the resistance of the MTJ. After the external field is removed, DW can come back to the bridge owing to its elasticity. Further simulations show that the device proposed shows a good performance on the measurement of the direct or alternating field. The advantage of the proposed sensor is: the device with larger size has a better sensitivity but the measuring range is relatively small; vice versa. Various devices with different size and geometry, thus with different performance (e.g. measuring range, sensitivity etc.) can be fabricated in the same chip. No modulation of the intrinsic properties of the film, such as the PMA, is required. Therefore, magnetic sensors based on the elasticity of DWs promise a higher integration level and a better performance[5].

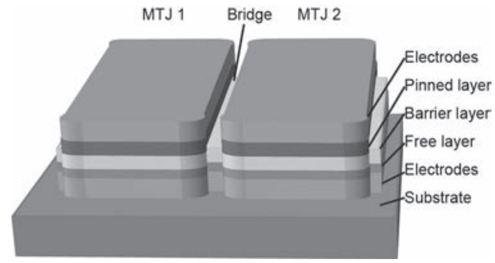

Fig. 1. Structure of a sensor device proposed based on the elasticity of the DW. Two MTJs are connected via a bridge while the pinned layer and the upper electrodes are isolated.

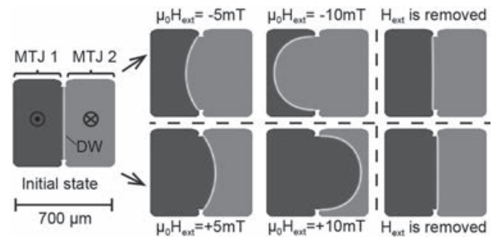

Fig. 2. DW states in the free layer of two coupled MTJs: First, DW was set in the middle of the bridge of the device. Then an external perpendicular field of -5 mT (+5 mT), -10 mT (+10 mT) was applied and the stable state of the DW was snapshotted, respectively. At last, the external field was removed and the DW returned to the bridge due to its elasticity.

EW-14. Determination of the strain-impedance gauge factor of Si-cantilever-based giant magnetoimpedance sensors.

G. Büttel[1], J. Joppich[1] and U. Hartmann[1]
1. Institute of Experimental Physics, Saarland University, Saarbrücken, Germany

Magnetoresistive sensors are currently widely investigated for flexible electronics and strain-sensing applications by employing magnetostrictive materials in GMR, TMR and giant magnetoimpedance (GMI) devices [1-3]. A true comparison of the three underlying effects for strain detection was so far not possible, because GMI strain sensors have so far been reported only on low-quality polymer substrates or Si wafers. Deposition on strongly bendable Si-cantilevers has only been reported very recently [4]. In this report a fabrication process and its effect on the magnetic and transport properties of GMI sensors integrated onto Si cantilevers are discussed. A strong change of permeability and therefore an impedance change is induced by the dry etching plasma processes needed to release the cantilevers from a 20 µm thick Si membrane. It softens the sensors magnetically. The downsizing of the GMI strain sensor required to deposit it on a cantilever allows accurate finite element simulations of induced stress/strain in the magnetostrictive layers ($Ni_{82}Fe_{18}$). As a result the strain-impedance gauge factor could be determined to be almost 200 at an ac current frequency of 2 GHz (Fig. 1). In consideration of the small dimensions, the consequently small magnetic field sensitivity and the low maximum GMI ratio of this device and due to the low-magnetostrictive NiFe employed in multilayer system, much higher strain gauge factors are assumed to be possible for GMI sensors. They could even surpass TMR strain-gauge factors. In addition, the highest strain gauge factor of the present device was measured in the ferromagnetic resonance regime. GMI ratios beyond 500% have already been reported for bigger NiFe multilayer GMI field sensors in the skin-effect regime and when magnetization rotation is the dominating reversal mechanism in the low-field regime. In the present case, complex domain-wall annihilations and creations dominate the reversal in the low-field regime and even lead to domain-wall resonances (DWR) in a distinct frequency regime. This could be proven by magneto-optical widefield microscopy and corresponding micromagnetic simulations of the magnetization dynamics. By optimizing the NiFe ratio of the sputtering target and the deposition parameters a nearly zero magnetostriction ($Ni_{80}Fe_{20}$) was realized for the sensor material. In contrast to low-magnetostrictive $Ni_{82}Fe_{18}$ (Fig. 2) the effective anisotropy field is not changing when applying compressive and tensile strain. This proves that even for thin film NiFe, which has been microstructured by means of lithography and which contains thin Ti spacer layers to bypass the critical thickness of emerging stripe domains, nearly zero magnetostriction can be reached. Therefore, ultraflexible GMI magnetic field sensors can be fabricated without the need of employing materials with high spin polarization and a high magnetostriction such as Co and Fe alloys, which are often deposited in TMR and GMR sensors. Additionally, no high-quality MgO or Al_2O_3 interfaces are necessary. In conclusion we show that thin-film GMI sensors have a very promising but not completely known potential on flexible substrates. Further optimization of the geometry is necessary and especially highly permeable materials with higher magnetostriction coefficient than that of NiFe ought to be investigated to analyze their full potential for strain or hybrid magnetic field and strain detection.

Since the discovery of the giant magnetoresistance (GMR), many spintronic devices have been developed and used in various applications such as information storage and automotive industry. Nowadays, increasing research in the field of spintronics and its application in the development of magnetoresistive (MR) biomolecular and biomedical platforms is giving rise to a new family of biomedical sensors [1-3]. Magnetic tunnel junctions (MTJ), based on MgO barriers, are promising magnetic field sensor solutions in the framework of electronic components integration and miniaturization. MgO-based MTJs show superior sensitivity for the detection of small magnetic fields needed in many industrial and biomedical applications. MgO-based MR sensors have been integrated for biological applications, such as biochips. The concept, explained in [4] and [5], relies on the capability of the sensor for detection of the fringe field generated by magnetized nano/microparticles attached to biomolecules. In this work, we aim to implement MgO-based MR biosensors for measurement of the flux of magnetically labeled cells. As a representative schematic, the biochip in figure 1.a shows different components of the MR biosensor. Figure 1.b illustrates the concept with superparamagnetic beads. As shown, a magnetic bead above the sensor will be magnetized by the magnetic field generated by the current in the gold strip. The stray field of the bead can be sensed by the magnetic field sensor, if the magnetic bead is within its sensing space. When a larger number of magnetic beads labeling the cells are mobilized inside the micro-tube, a larger signal will be observed. We should mention that the manipulation of these particles and biomolecules requires handling fluidic samples. Moreover, the labeling particles should be handled under minimum aggregation, preferably in a paramagnetic state. We designed and fabricated MgO-based MR sensors presented in figure 2.a. Each sensor consists of 1200 elliptic 16*8 mm^2 pillars in series. MTJ multilayer films were deposited using a magnetron sputtering system (Singulus Rotaris) on thermally oxidized Si wafers. The MTJ stack used in this study had the following layer structure: (thicknesses in nanometers) Si/SiO2/ (3) Ru / (8) Ta / (3) Ru / (8) Ta / (3) Ru / (8) $MnIr_{20}$ / (2.3) $Co_{70}Fe_{30}$ / (0.85) Ru / (2.4) $Co_{60}Fe_{20}B_{20}$ (ferromagnetic pinned layer)/ (1.53) MgO / (1.45) $Co_{60}Fe_{20}B_{20}$ (magnetic free layer)/ (3) Ru / (8) Ta. MTJ stack was patterned into micron-sized elliptical devices using standard optical lithography and ion milling. A 150-nm-thick gold layer was deposited over the junction area and patterned into low-resistance electrical contacts for each MTJ. After patterning, the samples were annealed at 360 °C for 2 h at 1.10^{-6} Torr in an applied field of 8 kOe. The magnetoresistance properties of the MR sensors were measured at room temperature in air by a conventional DC four-probe method and current driven Helmholtz coils controlled with LabView. Figure 2.d shows the transfer curve of one of MR sensor. The results prove that the proposed MR sensor has great sensitivity and has linear response in the range of [-5 Oe -5 Oe]. In this work we propose a new design for MgO-based MTJ magnetoresistive biosensor and demonstrate its functionality for detection of magnetically labelled cells. More experiments are in progress to fully optimize and characterize the proposed device.

Biosensor technology to detect specific biomolecules such as protein and DNA has the potential to provide fast and accurate diagnosis of cancer and diabetes. Bio-functionalized magnetic nanoparticles are known to be sensitive and cost-efficient for labeling specific biomolecules, and the use of magnetic nanoparticles are also attractive for drug delivery by magnetic field gradient and heating therapy by alternating magnetic field. We consider spin wave biosensor to detect magnetic nanoparticles with high sensitivity, and in this paper we report the detection of Fe_3O_4 nanoparticles by the variation of magnetization dynamics of Co/Ni multilayers. Co/Ni multilayer is known to exhibit large perpendicular anisotropy [1] which is useful to create large field gradient at the surface by forming the maze domain structure, and the large field gradient was used to capture the Fe_3O_4 nanoparticles dispersed in liquid. Moreover, low Gilbert damping is reported in Co/Ni multilayers [2] which will be effective to detect the variation of magnetization dynamics by the adsorption of Fe_3O_4. In this experiments, we used water-based liquid containing 0.003 mol/L Fe_3O_4 nanoparticles with average diameter of 10 nm. The magnetization dynamics of Co/Ni multilayers were measured by vector network analyzer - ferromagnetic resonance (VNA-FMR) technique under static field of H_{dc} = 2 – 10 kOe along the film normal direction. Figure 1 shows (a) atomic force microscope (AFM) and (b) magnetic force microscope (MFM) images of Ta (2) / [Co (0.29) / Ni (0.71)]$_{10}$ / Ta (30) / SiO_2 substrate (thickness in nm) after adsorbing of Fe_3O_4 nanoparticles. Before adsorbing nanoparticles, the multilayer was demagnetized to form the maze domain structure as shown in Fig. 1 (b). In Fig. 1 (a), the adsorbed Fe_3O_4 nanoparticles were clearly seen as bright contrast, and the shape of the bright region is well consistent with the maze domain structure seen in Fig. 1 (b). This means that the large field gradient produced on the surface of Co/Ni multilayer effectively capture the nanoparticles dispersed in the liquid. Figure 2 (a) shows the applied field dependence of resonance frequency f_r of Ta buffered [Co (0.29 nm) / Ni (0.71 nm)]$_{10}$ multilayers with and without magnetic nanoparticles. The anisotropy field H_k of the Co/Ni multilayer estimated from Fig. 2 (a) was 2.6 kOe, and it increased to 3.7 kOe by adsorbing magnetic nanoparticles. Figure 2 (b) shows the dependence of full-width-half-maximum (FWHM) Δf_{50} of the resonance curve on the resonance frequency f_r. Anisotropy field dispersion ΔH_k and damping α were estimated from y-intercept and slope of the linear fits, respectively, and both were found to increase by adsorbing the nanoparticles. Similar results were also confirmed for Pt buffered Co/Ni multilayers. These results suggest the adsorption of Fe_3O_4 nanoparticles significantly modifies the magnetization dynamics of Co/Ni multilayer, and the Co/Ni is considered as a candidate material for spin wave sensors to capture and detect biomolecules.

FA-01. Topology of magnonic bands: From chiral edge modes to spin superfluidity.

Y. Tserkovnyak[1]
1. Physics and Astronomy, UCLA, Los Angeles, CA, United States

Topological contrast in magnetic materials can lead to robust gapless modes, as dictated by an appropriate bulk-edge correspondence. I will discuss our recent proposal for engineering such an (chiral) edge mode in the coupled dynamics of magnetic solitons in a honeycomb lattice [1]. The existence of the chiral magnonic edge can be understood by mapping the system to the Haldane model for an electronic system. Extending the topological magnon-band arguments, we propose an emergent spin superfluidity in classes of rather mundane easy-axis magnets (both ferro- and antiferromagnetic), at their domain boundaries. We thereby suggest to utilize such domain walls for the establishment and manipulation of robust spin transport in magnetic insulators. The spin superfluidity at a topological boundary, furthermore, turns out to have several emergent topological properties that are absent in conventional superfluids. In particular, the phase-unwinding slips create and destroy skyrmions to obey the conservation of the total skyrmion number, which allows to use a domain wall as a generator and detector thereof.

FA-02. Topological Magnon Materials.

I. Mertig[1,2], A. Mook[1] and J. Henk[1]
1. Physics, Martin-Luther-Universität Halle-Wittenberg, Halle, Germany;
2. Max Planck Institute for Microstructure Physics, Halle, Germany

Topology has conquered the field of condensed matter physics with the discovery of the quantum Hall effect. Since then the zoo of topological materials is steadily increasing. In this talk, I demonstrate how to realize different topological phases with magnons: the magnon pendants to topological insulators [1] as well as Weyl [2] and nodal-line semimetals are presented [3]. Magnon bulk spectra are characterized by topological invariants, dictating special surface properties. For instance, the bulk bands of topological magnon insulators (TMIs) carry nonzero Chern numbers, causing topological magnon edge states that revolve unidirectionally the sample [1]. Magnon Weyl semimetals possess zero-dimensional band degeneracies acting as source and sink of Berry curvature; at their surface they feature "magnon arcs" connecting the surface projections of Weyl points [2]. Magnon nodal-line semimetals exhibit one-dimensional band degeneracies, i. e., closed loops in reciprocal space. Surface projections of these nodal lines host "drumhead" surface states whose details depend strongly on the surface termination [3]. Similar to the electronic case, nonzero Berry curvature causes transverse transport, that is, magnon Hall effects [1]. I show how these effects can be quantified by classical spin dynamics simulations of the TMI Cu(1,3-benzenedicarboxylate) [4] and a skyrmionic TMI [5].

FA-03. Quantum anomalous Hall effect and topological Hall effect in magnetic topological insulators.

Y. Wang[1]
1. Tsinghua University, Beijing, China

The interplay between the nontrivial topology and broken time reversal symmetry in topological insulator (TI) can lead to exotic quantum phenomenon such as the quantum anomalous Hall effect. However, there are still many open questions regarding the mechanism of magnetic order and magneto transport in TI. In this talk, we present transport studies on magnetically doped TI thin films grown by molecular beam epitaxy. We found a variety of interesting transport phenomena by varying the magnetic dopants, film thickness, applied electric field, and device geometries. In Cr doped Bi2(Se,Te)3 near a topological quantum critical point, we found a gate-tuned ferromagnetic to paramagnetic phase transition. We propose that the most likely mechanism is the Stark effect induced electronic energy level shift, which causes a topological quantum phase transition followed by magnetic phase transition. In Mn doped Bi2Te3, we observe pronounced topological Hall effect only at a specific film thickness at the dimensional crossover regime. We propose that this is due to the coupling between the top and bottom surface states, which stabilizes the magnetic skyrmion structure. More recently, we construct a bilayer structure consisting of two magnetic topological insulator films with different coercivity. By using a moderate magnetic field, we can drive the system from a quantum anomalous Hall phase with chiral edge states to a synthetic quantum spin Hall phase with helical edge states.

FA-04. Mixed semimetals for magnetization and momentum space topology control.

J. Hanke[1], C. Niu[1], F. Freimuth[1], G. Bihlmayer[1], S. Bluegel[1] and *Y. Mokrousov*[1]
1. IAS-1, Forschungszentrum Julich, Juelich, Germany

The topological properties of magnets, encoded in the reciprocal space distribution of the Berry phase, have caused a revolution in our understanding of their transport and response properties. By focusing on two-dimensional spin-orbit-gapped ferromagnetic materials, we uncover the richness of their topological phase diagrams as a function of the magnetization direction and its magnitude. We further uncover that the phase transitions between various topological states, which manifests in an emergence of topological metallic features in the electronic structure, can be best understood by referring to the topology of the "mixed" space of k-vectors and magnetization direction. We show that non-trivial topological features such as mixed Weyl points and mixed nodal lines not only give rise to complex topological phases in the k-space of two-dimensional magnetic materials, but also manifest in "singular" magnetic properties. Namely, we predict that in 2D magnetic systems with non-trivial mixed topologies the strength of orbital magnetism and magneto-electric response, as manifested e.g. in the magnitude of the current-induced spin-orbit torques and Dzyaloshinskii-Moriya interaction, can exceed significantly that of conventional metallic magnets. Given that the direction of the magnetization in complex spin-orbit ferromagnets can be efficiently controlled by spin-orbit torques, our findings open new perspectives in low-dissipation control of magnetization and topological phases in low-dimensional magnetic materials. This work was supported by the DFG under Grant No. MO 1731/5-1 and SPP 1666, by the EU Horizon 2020 research and innovation programme under grant agreement number 665095 (FET-Open project MAGicSky), and by the DFG through the Collaborative Research Center SFB 1238.

FA-05. Topological bands and topological phase transitions in electronic and magnonic systems.

S. Murakami[1,2]
1. Department of Physics, Tokyo Institute of Technology, Tokyo, Japan;
2. TIES, Tokyo Institute of Technology, Tokyo, Japan

In electronic systems, various interesting phenomena such as spin Hall effect and topological insulators originate from Berry curvature of Bloch wave-functions. We theoretically study analogous phenomena for magnons (spin waves). We propose that the dipolar interaction gives rise to nonzero Berry curvature [1-3]. In a thin-film ferromagnet in a long-wavelength regime, we can calculate the Berry curvature for each magnonic band, and only when the magnetic field is out-of-plane, the Berry curvature is nonzero. When the exchange coupling is included, the magnonic bands are modified, and there appear a number of band anticrossing points. Around such an anti-crossing point, the Berry curvature is enhanced. This Berry curvature gives rise to thermal Hall effect of magnons [1,2], and it also gives rise to a shift of wavepackets in reflection or refraction [3]. Furthermore, in analogy to the quantum Hall effect for electrons, we can design topological magnon band structure. By introducing artificial spatial periodicity into the magnet, for example by fabricating nanostructures with two different magnets in a periodic structure or by making a periodic array of nanomagnets, we theoretically propose emergence of topological edge modes, analogous to those in electronic quantum Hall effect. The edge modes are chiral, and propagate along the edge of the magnet in one way. We call this a topological magnonic crystal [4,5]. As a related subject, we also have been studying topological phase transitions. It leads to the notion of topological semimetals in the context of electronic band structures. In particular, in the Weyl semimetal [6,7], which is an example of topological semimetals, the band structure has nondegenerate 3D Dirac cones in the bulk. We show that in a transition between topological and ordinary insulators, the Weyl semimetal phase necessarily appears, for any inversion-asymmetric crystals [6,8]. This transition from an insulator to the Weyl semimetal is realized for example in tellurium (Te). At high pressure the band gap of Te decreases and it runs into a Weyl semimetal phase, as shown by our ab initio calculation [9]. As various examples show, transitions between different topological phases with a gap are universal, and they depend only on dimensionality and symmetry. For example in three dimensions with broken inversion or time-reversal symmetry, such topological phase transitions usually accompany a topological semimetallic phase between them. This topological evolution of band structure applies to magnon band structures as well.

Topological matters have attracted enormous attention in recent years because of their interesting and exotic properties. One such property is the existence of unidirectional and topologically protected surface/edge states that are robust against internal and external perturbations. The study was initially exclusive for electron systems and was believed to be a quantum phenomenon. It is now known that the topological states can exist in classical mechanics and photonics. Topological states can also exist in magnetic materials govern both by quantum mechanics at the zero temperature and by classical magnetization dynamics at finite temperatures. In fact, topological states do not depend on the detail of their underlying dynamics, whether it is Newtonian mechanics for vibrations or Maxwellian equations for lights, or Schrodinger/Dirac equations for electrons. So far, the important ingredients are the collective modes form inverted bands with gap in the bulk. Magnetic materials are highly correlated spin systems that do not respect the time-reversal symmetry. The low-energy excitations of magnetic materials are spin waves whose quanta are magnons. In the ambient temperature that is far below the Curie temperature, the magnetization dynamics of real magnetic material shall be govern by the Landau- Landau-Lifshitz-Gilbert (LLG) equation. Like electronic materials that can be topologically nontrivial, magnetic materials govern by the LLG equation can also be topologically nontrivial with topologically protected edge spin waves. Unlike the normal spin waves that are very sensitive to the system changes and geometry, these edge spin waves are robust against internal and external perturbations such as geometry changes and spin wave frequency change. Therefore, the magnetic topological matter is of fundamental interest and technologically useful in magnonics. We will see several examples of magnonic topological materials, including pyrochlore [1] and stacked honeycomb [2] ferromagnets as Weyl magnons, as well as perpendicularly magnetized two-dimensional films with Dzyaloshinskii-Moriya and/or pseudodipolar interactions as generic magnonic insulators [3,4]. The edge spin waves in these magnonic materials are robust against perturbations. Interesting functional magnonic devices called beamsplitter and interferometer can be made out of a domain wall in a strip. It is shown that an in-coming spin wave beam along one edge splits into two spin wave beams propagating along two opposite directions on the other edge after passing through a domain wall. This work was supported by National Natural Science Foundation of China (Grant No. 11374249) and Hong Kong RGC (Grant No. 16301115 and 16301816).

The discovery of the interstitial rare earth nitride $Sm_2Fe_{17}N_3$ came about seven years after the discovery of the rare earth iron boride $Nd_2Fe_{14}B$ [1,2], and the nitride initially seemed to offer intrinsic magnetic properties that were superior (Curie temperature T_C, magnetocrystalline anisotropy K_1) or comparable (spontaneous magnetization M_s) to those of its illustrious predecessor. However, the promise of the new material to seriously challenge $Nd_2Fe_{14}B$ was not realized. The 2:17 nitride powder, prepared by a low-temperature gas-phase interstitial modification process proved difficult to orient and worse still, it lost its nitrogen at the temperatures needed to process dense sintered magnets [3]. Attempts at explosive compaction [4] or spark sintering [5] failed to yield material with good enough coercivity. Nevertheless, work continued in Japan and China to develop a coercive powder that could be used for bonded magnets. An early realization was zinc-bonded $Sm_2Fe_{17}N_3$ [6] with an energy product of 84 kJm^3 but a rather low coercivity of 480 kAm^{-1}, less than 5 % of the anisotropy field ($H_a = 2K_1/M_s \approx 11$ MAm^{-1}). The anisotropy field of $Nd_2Fe_{14}B$ is significantly less (6 MAm^{-1}) yet several decades of intensive development have led to higher values and continuous improvements of the coercivity, even in unsubstituted material. Historical experience with permanent magnets shows that a long period of materials development is needed to arrive at the best composition and processing conditions tfor a microstructure that allows the hard magnetism to be optimized. Coercivities of about 25% of the anisotropy field are utimately achieved. Here we compare the magnetic properties of melt-spun material. Our *Nitroquench* powder, produced by Daido Steel, was in the form of flakes 10 μm thick and up to 100 μm in diameter. A crystallite size of approximately 15 nm deduced from Scherrer broadening of the X-ray reflections. Composition was checked by EDX microprobe analysis. Hysteresis loops have been measured in applied fields of up to 14 T, at room temperature and at 4 K.The material exhibits a room-temperature coercivity of 690 kAm^{-1}after saturation in 14 T, with a remanence of 700 kAm^{-1} in zero applied field and an extrapolated saturation magnetization of 1230 kAm^{-1}. The remanence ratio M_r/M_s of 63% when the remanence is corrected to zero internal field, is reflected in a preferred orientation seen in the X-ray powder diffraction patterns and in ^{57}Fe Mössbauer spectra of magnetized powder. Spectra obtained after saturation of an immobilized powder absorber either in-plane or perpendicular to the sample plane exhibit distinctly different relative intensities of the $\Delta M = 0$ absorption lines. The maximum energy product for the powder, assuming full density, is 162 kJm^{-3}. The remanence enhancement is attributed to fact that the nanocrystallite size is not much greater than the exchange length. Melt-spun Sm-Fe-N powder has superior corrosion resistance and thermal stability compared to melt-spun Nd-Fe-B. The *Nitroquench* powder may be used to produce polymer-bonded magnets with an energy product in excess of 100 kJm^{-3}.

I. INTRODUCTION Bonded Nd-Fe-B magnets are widely used in the fields of electrical appliances, automation equipment and automobile due to their stable magnetic properties, and easy processing into smaller [1-3]. However, the use of epoxy (EP) bonded magnets is limited because of poor mechanical properties and low heat resistance of epoxy. In this work, phenol formaldehyde resin (PF) was considered as a binder for NdFeB magnets because PF has high temperature resistance properties and excellent bonding properties. The magnetic properties, mechanical properties and fracture morphology were investigated. The results show that PF can endow high temperature resistance and excellent mechanical properties to the material. II. EXPERIMENTS PF/NdFeB bonded magnets were prepared by compression molding. First, NdFeB powders and PF were pre-mixed to get uniform mixture. Then, the mixture was transferred into a mold to moulded and densified with isostatic pressing. Finally, the magnets were obtained by curing in the oven. The magnetic properties of PF/NdFeB bonded magnets at 20^{o}C and 200^{o}C were tested by B-H hysteresis loop tracer. The compressive strength was measured by electronic tensile testing machine. The fracture surface observation and composition analysis for crushed magnets was performed on the Scanning Electron Microscope (SEM) with the Energy Dispersive X-ray (EDX). III. RESULTS AND DISCUSSIONS In Fig.1(a), Br, Hcj and (BH)max of 2.5 wt.% PF/NdFeB magnets can reach 6.659kG, 9.569kOe and 9.573MGOe respectively at room temperature. The results are close to 2.5 wt.%EP/NdFeB magnets data of the same process, and this means that PF binder has no effect on magnetic properties during the preparation of Nd-Fe-B bonded magnets. The magnetic properties of NdFeB will decrease with the increased of temperature. From our previous work, EP/NdFeB magnetic data were not obtained because epoxy can't keep the original shape of magnet at 200^{o}C. While PF/NdFeB magnets the magnets still has usable magnetic properties at 200^{o}C in this work. The reason is that the main chain of PF binder molecule containing rigid structure, which can form the strong cross-linking network structure with high temperature resistance during the curing process. Therefore, the bonded magnets can keep the shape and usable magnetic properties at 200^{o}C. While the magnetic properties are satisfied, the mechanical properties are important factors for the application. Fig.1(b) shows that with the increasing of binder content, the compressive strength of PF/NdFeB magnets were increased effectively. The compressive strength of 4 wt.% PF/NdFeB increased to 253.6MPa, which was 15 times higher than EP/NdFeB magnets. In order to further disclose the mechanism of compressive strength enhancement, SEM photos and EDX analysis of fracture surface morphology were obtained from 4 wt.% PF/NdFeB, and it was illustrated in Fig.2(a-g). Fig.2(a) shows that the morphology of facture surface is very smooth, this suggests that the magnet has higher compactness. To further explore PF how to work with magnetic powders, the facture surface was investigated by EDX analysis. We have carried out line and point scanning for randomly selected gaps in Fig.2(b), according to the elements distribution, the results shows that PF binder can be enriched in the gaps of magnetic powders from Fig.2(c-d). In sum, the mechanism of compressive strength enhancement can be inferred according to the discussed results. On the one hand, liquid PF binder can endow magnetic powder better liquidity to obtain higher compact magnets in the process of molding. More importantly, the main chain of PF binder molecule containing rigid structure (benzene ring), it can form the hard cross-linking network structure in the gaps of magnetic powders to combine tightly during the high temperature curing process. Two mechanisms of action can effectively increase the mechanical properties. IV. CONCLUSIONS The binder PF was applied in NdFeB bonded magnets. The magnetic properties, mechanical properties and fracture morphology have been investigated. We also researched the reason of the high temperature resistance and the mechanism of compressive strength enhancement by SEM-EDX analysis. PF as a kind of excellent binder can increase the working temperature and the compressive strength of NdFeB bonded magnets obviously. Therefore, it would have a wide application prospect. FB-03. Effects of initial alloy on microstructure and magnetic properties during hot-deformation of Nd-Fe-B HDDR powder.

J. Lee[1], J. Yoo[1,2], Y. Baek[1], D. Lee[2] and H. Kwon[3]
1. Korea Institute of Materials Science, Changwon, The Republic of Korea; 2. Pusan National University, Pusan, The Republic of Korea; 3. Pukyong National University, Pusan, The Republic of Korea

High coercive Nd-Fe-B magnets are indispensable materials to traction motors in hybrid and electric vehicles. However, substitution of heavy rare earth element (HRE) such as Dy or Tb for Nd has been necessary for high coercive Nd-Fe-B magnets despite the critical problem of supply and demand with HRE. Therefore, HRE-lean and/or HRE-free high coercive Nd-Fe-B magnets have drawn a great attention to solve HRE resource problem in the automotive industry [1]. To achieve high coercivity with reducing HRE, the control of microstructures, such as grain size and grain boundary, is of significant importance. Melt-spinning and hydrogenation–disproportionation–desorption–recombination (HDDR) are known as quite suitable method to decrease grain size down to the single domain size (~250nm). It addition, hot-deformation is known as a useful method to obtain anisotropic magnets with magnetic powders produced by these methods. On the other hand, the coercivity of hot-deformed Nd-Fe-B magnets was too low to be used for motors of hybrid and electric vehicles even though they had submicron grain size. It is because of the presence of crystallographic defects, low anisotropic energy at the grain surface, and exchange coupling between neighboring grains, which could be improved by grain boundary diffusion process (GBDP) with HRE compounds or non-magnetic materials. However, the GBDP of ultrafine grained materials produced with melt-spun powders should be done at a temperature, lower than about 700 °C. The GBDP above 700 °C could induce remarkable grain growth and low coercivity. On the other hands, HDDR powder has relatively large grains about 250~400 nm compared to melt-spun powders, so the grain growth does not occur at temperature up to about 850 °C. Therefore, it can be expected that hot-deformed magnets produced with HDDR powder have an advantage for subsequent GBDP compared to that of the melt-spun powder. However, there were only a few studies examining the hot-deformation behavior of HDDR powders and the reported magnetic properties were relatively poor. On the other hand, numbers of research reveal that rare earth-rich phase is critical factor to the texture formation during the hot-deformation process. So, it is expected that the microstructure of initial alloy could effect on the deformation behavior during hot-deformation process. Therefore, in this study, effect of initial alloy on microstructure and magnetic properties during hot-deformation of Nd-Fe-B HDDR powder was investigated. Alloy with composition of $Nd_{12.5}Fe_{bal}Ga_{0.3}Nb_{0.2}B_{6.4}$ prepared by strip-casting process was used as a starting material. The alloy was subjected to HDDR process after pre-annealing (SC-HT) at 1100 °C for 12 hours or without pre-annealing (SC). Produced HDDR powders were then hot-pressed at 700 °Cunder 400 MPa in a vacuum. The cylindrical compact with 7 mm in diameter and 6 mm in height were then die-upsetted at 800 °C with deformation degree of ε= 1.5 and deformation rate of ε'=~0.01 s^{-1}. Figure 1 shows magnetic properties and microstructure of each initial HDDR powder. The remanence of the powders is similar. However, their coercivity is diffenent about 1 kOe. This could be attributed to that the SC_HT HDDR powder have non-uniform and discontinuous Nd-rich phase distribution in grain boundary which can decrease coercivity by magnetic coupling between neighbor grains although it is not clear from SEM image as shown in Fig. 1 (b) and (c). Figure 2 shows demagnetization curve ((Fig. 2 (a)) and microstructure of hot-deformed magnets which is deformed using SC_HDDR powder (Fig. 2 (b)) and SC_HT (Fig.2 (c)), respectively. The remanence of hot-deformed magnet with SC_HT HDDR powder is lower than that with SC_HDDR powder. The difference in the remenance could be attributed to the fact that the distribution of the Nd-rich phase of the grain boundary may be affected by the hot deformation behavior which could be confirmed from Fig. 2 (b) and (c). This non-uniformed Nd-rich phase of grain boundary can make it difficult to grain boundary sliding during the hot-deformation process, which induce poor grain alignment and low remanence. Based upon these results, effect of initial alloy on microstructure and magnetic properties during hot-deformation of Nd-Fe-B HDDR powder will be discussed. Fig. 1. Demagnetization curve (a) of obtained HDDR powders and FESEM images of SC_ HDDR powder (b) and SC_HT HDDR powder. Fig. 2. Demagnetization curve (a) of hot-deformed magnet and FESEM images of hot-deformed magnet with SC_HDDR powder (b) and hot-deformed magnet with SC-HT HDDR powder (c).

FB-04. Comparison of two Magnetizing Fixture Designs to Achieve Radial Magnetization Profile for Isotropic Bonded Neo Magnets.

R.C. Angara[1], K.W. Hsu[1], P.J. Villar[1] and N.K. Sheth[1]
1. R&D Magnequench, Magnequench Neo Powders Pte Ltd, Singapore, Singapore

The requirement of stringent environment and fuel efficiency target on automotive demand the use of lighter, smaller and efficient motors. The advantages like higher magnetic properties than ferrite, near net shape magnet production, and no use of heavy rare earth elements makes the use of bonded neo magnet in an automotive accessory motors very attractive. The isotropic nature of bonded neo magnets offers a feasibility to obtain wide range of magnetization profiles. The magnetization of the magnet influences the air-gap flux distribution and hence the motor performance[1]. The performance of permanent magnet motors using isotropic bonded neo magnet can be improved by optimizing the air-gap flux profile using magnetization. Based on the magnet circumference touching the motor air-gap and the desired magnetization profile, an appropriate magnetization fixture needs to be designed. In an external rotor permanent magnet brushless (PMBL) DC motor and brushed DC motors, the inner circumference of the magnet touches the airgap and hence the magnet is magnetized using an inner-only fixture which has magnetization coils next to the inner circumference of the magnet. When the radial magnetization is desired, a double sided magnetization can also be used to magnetize bonded neo ring magnets[2]. The use of double sided magnetization helps in enhancing the motor performance[3]. To ensure that the bonded neo magnet is fully saturated a minimum magnetizing field of around 3T is to be generated throughout the magnet thickness[4]. Considering this required magnetizing field, a fixture each offering inner-only and inner-outer magnetization (double sided magnetization) is designed using Finite element analysis (FEA) to achieve the radial magnetization. The simulation based results on the performance comparison of two fixtures is summarized. Figure 1 shows the simulated mid airgap flux density when magnet is magnetized with inner-only and inner-outer magnetizing fixtures. From this figure it is observed that, compared to inner-only fixture, the inner-outer fixture results in flat topped radial wave shape of flux density. Both designed fixtures are fabricated and the measured performance is used to validate the simulation results. It is observed that the peak magnetizing current and the energy required to achieve the magnet saturation in an inner-outer fixture is 19.8% and 26.5% less respectively compared to inner only fixture. The reduction in peak magnetizing current and magnetization energy requirement will lead to reduced thermal stress and improved fixture reliability. It will also help in reducing the magnetization cycle time due to better heat dissipation in inner-outer fixture. During magnetization of the magnet, the effectiveness of the inner-outer fixture depends highly on the alignment of the inner and outer magnetization coils. The alignment and hence the performance of the fixture is influenced by the fabrication tolerances[5]. Even a small misalignment between the coils on either side of the magnet will result in flux waveform distortion and reduction in magnetic flux. Considering the manufacturing tolerances, the effect of the various misalignment angles between the inner and outer magnetization coils on the magnet flux is arrived at using the FEA based simulation. The magnetization result is also measured by creating various misalignments between the inner and outer magnetization coils in the fabricated inner-outer magnetization fixture. Table I gives the measured magnet flux integral for various misalignment angles. It is observed from Table I that the ±2° mechanical misalignment between the coils will not result in significant change in magnet flux and higher misalignment angles will result in considerable reduction of flux per pole. It is also observed that the misalignment effect is symmetric about the aligned position and higher degree of misalignment causes drooping wave shape on one side and a hump on the other side in any given pole depending on the direction of misalignment.

FB-05. Desirable Measurement on Accurate Hysteresis Curve for Large Nd-Fe-B Sintered Magnets at Elevated Temperatures.

H. Nishio[1,2] and K. Machida[1]
1. Division of Applied Chemistry, Osaka University, Suita, Japan;
2. Research Institute for Measurement of Magnetic Materials, Yokohama, Japan

1. Introduction Nd–Fe–B sintered magnets have excellent intrinsic coercivity (H_{cJ}). They are widely used in motor generators and electric power steering and compressor motors for electric vehicles. Hence, it is very important to determine with accuracy the magnetic properties of magnets at elevated temperatures. To provide an accurate hysteresis curve in large Nd-Fe-B sintered magnets with high H_{cJ} at elevated temperatures, we compared the magnetization curves obtained from the following methods: superconducting magnet-based vibrating sample magnetometer (SCM-VSM) and the hysteresis graph (HG) which is widely used [1]. Attention was paid to the values of the differential susceptibility (dJ/dH) near H_{cJ} related to the squareness ratio (H_k/H_{cJ}) and the distribution of nucleation fields, where H and H_k are the magnetic and knee fields, respectively [1], [2]. 2. Experiment The samples with different shapes were machined from the same Nd-Fe-B sintered magnet block. To prevent the effects of machining on the magnetic properties, we used $S/V \leq 1.0$ mm^{-1}, where S and V are the surface area and volume, respectively [3]. The cylindrical samples used for the HG method had a diameter (D) of 10 mm and lengths (L) of 7, 14, and 21 mm ($S/V = 0.5 – 0.69$ mm^{-1}). We prepared a cube of $L = 7.1$ mm, then, a spherical sample with a D of 7 mm ($S/V = 0.86$ mm^{-1}) was prepared using the two-pipe method for the SCM-VSM measurement [4]. To remove the deteriorated surface layer of approximately 8 μm, all processed samples were chemically etched in 3% HNO_3 solution for 1 min. H_{cJ} of the Nd-Fe-B sintered magnet samples A and B were 1.2 and 2.7 MA/m, respectively. The samples were magnetized with a maximum magnetic field (H_m) of 8.0 MA/m in the case of SCM-VSM. Hybrid twisted superfine wires composed of NbTi and Nb_3Sn were used for the cryogen-free solenoid coil superconducting magnet (SCM). This is very suitable for the control of H precisely because of very small screening-current-induced field related to unstable central field of the SCM [5]. The HG measurements were performed according to the IEC 60404-5 and JISC 2501 standards [1], [6], [7]. The technique in the fixture of heated sub-pole pieces has been generally applied for the HG method at elevated temperatures over the past years [8]. In this study, a large electromagnet (H_m of 2.7 MA/m) was employed with a fixture of 80-mm diameter heated Fe-Co main pole pieces. This represents an improvement relative to the former techniques as follows. This has the advantage that the condition of the air-gap between the face of the test specimen and the pole piece can be considered independent of the sample temperatures. 3. Results and Discussion In the measured curves obtained from the HG method, the magnetization distortion in H values up to 1.0–1.3, 1.1–1.5, and 1.4–1.8 MA/m was shown clearly for samples with L = 7, 14, and 21 mm, respectively. The magnetization distortion was closely related to the values of H_m, L, and saturation magnetization (J_s) as has been previously found in our study [2]. On the contrary, the magnetization distortion did not appear at all in the SCM-VSM method. The value of dJ/dH near H_{cJ} increased linearly as the temperature increased for the magnet A with a lower H_{cJ} regardless of measuring method. On the other hand, these obtained from the HG method (in all cases of L/D) increased rapidly as the temperature increased for the magnet B with a higher H_{cJ} at temperatures below 373 K (Fig. 1). The measured values almost agreed well at temperatures above 423 K in all cases of measurements, where H_{cJ} and J_s above 423 K were considerably decreased relative to the values below 323 K. The value of H_k/H_{cJ} for the magnet B with a higher H_{cJ} obtained from the SCM-VSM method gradually decreased and these obtained from the HG method at temperatures below 373 K increased rapidly as the temperature increased (Fig. 2). However, these agreed well at temperatures above 423 K in both methods. The effect of the distortion of magnetic flux distribution was decreased at temperatures above 423 K in the HG method. This is caused by the deterioration of H_{cJ} and J_s as the case of dJ/dH near H_{cJ} mentioned above. For the magnet A with a lower H_{cJ}, H_k/H_{cJ} decreased as temperature increased in all cases of measurements. The value obtained from the HG method deteriorated in the order of decreases in L/D above 373 K. It is caused by the distortion of magnetic flux distribution in the HG method. In the HG method, greater L/D led to easier uniform magnetization of cylindrical magnets, causing larger L/D to improve dJ/dH near H_{cJ} and H_k/H_{cJ}. However, the magnetization distortion did not appear at all in the SCM-VSM method at elevated temperatures and thus we could measure the values of dJ/dH near H_{cJ} and H_k/H_{cJ} as well as the magnetization curve exactly.

FB-06. High performance magnetic properties of CoFe2O4 nanoparticles for rare earth free permanent magnet applications.

Y. Kumar[1] and P.M. Shirage[1,2]
1. Metallurgy Engineering and Materials Science, Indian institute of Technology Indore, Indore, India; 2. Discipline of Physics, Indian Institute of Technology Indore, Indore, India

High performance magnetic properties of $CoFe_2O_4$ nanoparticles for rare earth free permanent magnet applications Yogendra Kumar[1], and Parasharam M. Shirage[1, 2] 1. *Discipline of Metallurgy Engineering and Materials Science, Indian Institute of Technology Indore, Simrol, Indore-453552, India* 2. *Discipline of Physics, Indian Institute of Technology Indore, Simrol, Indore-453552, India* pmshirage@iiti.ac.in, yogendra.iitp@gmail.com In the recent decades, rare earth (RE) materials based permanent magnets have great scientific and technological attention because of their large number of applications in modern technologies such as high-density magnetic-recording media, electronic devices, and hybrid electric vehicles [1]. On the other hand, nowadays risk of supply of RE materials have increased because of natural exhaustion, social, and environmental serious concerns about their mining process [2]. Furthermore, extraction of rare-earth materials produce the large volume of toxic reagents and contaminate the water sources. Based on the USGS reports, demand of rare earth based permanent magnets increasing per year in global market [3]. The rapidly growing demands of permanent magnets in the global market and a limited supply of raw materials, diverting the attention of the researcher towards a viable alternative to these rare earth based permanent magnets. Nevertheless, it is a consensus among the scientific community that complete substitution of RE based magnets in all existing technological applications is not a long term plausible option due to high-performance magnetic properties of $SmCo_5$ and $Nd_2Fe_{12}B$ phase [2]. Therefore, there is a high demand of suitable materials for permanent magnets which led to wide demands of a low-grade rare earth based magnets in some industry application [4]. Cobalt ferrites nanostructured have been point out as a promising alternative to rare earth based permanent magnets due to its higher saturation magnetization and coercivity [5]. To achieve this goal, we studied the magnetic properties such as the saturation magnetization (M_s) remanent magnetization (M_r) and coercivity (H_c) of a series of cube shaped cobalt ferrite NPs with different size. Figure 1 (a) shows the X-ray diffraction patterns of the series of as-prepared cobalt ferrite nanoparticles, which are in well agreement with the inverse spinel cubic crystal structure of ferrites. Fig 1 (b) exhibits the TEM images of cubic shaped NPs with 34 nm particle size. M (H) loops of CF NPs at room temperature shown in Fig. 2 (a), which exhibit that M_s increases consistently as a function of particle size up to saturation point. We observed the M_s of 62.40 emu/g for CF-1 NPs, whereas 93.45 emu/g for CF-6 NPs. H_c exhibits the non-monotonous behaviour with the particle size as shown in Fig 2 (a). H_c at 10 K and at room temperature observe 16921Oe and 3229 Oe CF-4 NPs. Decrease of H_c at larger particle size may be due to expected crossover from single domain to multi-domain behaviour with increases particle size. H_c increases with size up to single domain limit, where the magnetization reverses its orientation through a uniform coherent rotation of all spins. From analysis of M_s, M_r and H_c, we extract the energy product (BH_{max}) at low and room temperature. A higher value of $(BH)_{max}$ of 2.53 MGOe obtained for CF-4 NPs at room temperature shown in Fig 2 (b), which is the highest reported to date in literature for cobalt ferrite NPs. The highest $(BH)_{max}$ product exhibits the potentiality of cobalt ferrite NPs in permanent magnet applications.

FB-07. 3-D Magnetic Field Analysis of a Permanent Magnet Spherical Actuator Using Spherical Harmonics.

X. Li[1,2], J. Liu[1] and W. Chen[1]
1. School of Automation Science and Electrical Engineering, Beihang University, Beijing, China; 2. Department of Materials and Production, Aalborg University, Aalborg, Denmark

I. INTRODUCTION With the rapid development of multi-DOF precision devices applied for complex movement, integration of multi-DOF motors has attached more and more attention. Conventionally, the implementation of multi-axis motion is realized by connecting several single-axis actuators in parallel or in series. However, this leads to a significant increase in complexity of the mechanical structure, bulkiness of the volume, and deterioration of the dynamic performance. Permanent magnet spherical actuator (PMSA) is a type of electromagnetic device similar to human joints which can realize multi-DOF rotations in a single joint. Due to its advantages of compact structure, high energy density, low inertia moment and rapid response, PMSAs show extensive application prospect in areas like satellite attitude control [1][2], medical apparatus, robotic applications [3]. To design efficient PMSMs for applications, a high torque density is a beneficial factor that should be taken into account. According to the Lorentz force law, the torque density generated by the PMSA is related to the magnetic field distribution of the rotor permanent magnets (PMs) in the air gap. Among various numerical methods, finite element analysis (FEA) is a widely used modeling tool to analyze the 3D magnetic field and to optimize the actuator design. However, FEA is very time-consuming, and analytical models are needed. Spherical harmonic (SH) analysis [4] is an analytical solution which has been put forward in various spherical motors. The spherical harmonic model can be expressed as a closed-form function by a finite space harmonics, and then the specific distribution of permanent magnetic field can be obtained based on suitable boundary conditions [5]. In this paper, an analytical model of the 3-D magnetic flux density is solved by the magnetic scalar potential equation in the spherical coordinate system using spherical harmonics. Verification of the magnetic field distribution surrounding the rotor is also carried out by a finite element software Maxwell. Afterwards, the design of the proposed PM array is analyzed using the analytical model. II. DESIGN AND WORKING PRINCIPLE A CAD model of the proposed PMSA is shown in Fig. 1. Figure 1 (a) and (b) show that the rotor with eight PMs surrounded in a ring is housed in a spherically shaped stator with three-layer individually activated coils. The rotor can generate continuous spinning motion about its output shaft, and incline about its equatorial plane to a position that the axis of a PM pole and the coil are aligned. The maximum tilting angle is ±15°. The structure of the rotor PM array is described in Fig. 1 (c). The eight PMs are uniformly distributed around the rotor equator with the alternative variation of the N pole and S pole. Conventionally, the magnets are shaped as cylinder or dihedral cone. Herein, the shell-shape PM is adopted. Compared with the cylindrical PM, the shell-shape PM decreases the interspace between the adjacent poles considerably, and has smaller moment of inertia than the dihedral cone PM. III. OPERATING PRINCIPLE OF THE PROPOSED SPHERICAL ACTUATOR According to the magnetic field distribution, space can be divided into four zones, PM, rotor core, air region outside the rotor and inside the rotor core. For each region, the magnetic field distribution is established, which is used to solve the general solution to Laplace equations. Using the method of separation of variables, the expression of the scale magnetic potential is solved by the boundary conditions and the spherical harmonic functions. The torque generated by the interaction between the PMs and the stator coils mainly depends on the radial component of magnetic field in the air gap, so only the spatial distribution of radial magnetic flux density in the air gap is calculated. (The detailed model will be introduced in the final paper.) IV. VERIFICATION OF THE ANALYTICAL MODEL In Fig. 2 (a), the fundamental component of B_r varies in the form of a cosine-like wave along θ and ϕ. There are four positive peak points and four negative peak points around the equator, which are in accordance with the four pairs of poles array. In order to validate the results of the analytical model, a numerical method is used. A finite element model built in the environment of Ansoft Maxwell is introduced to verify the analytical results. The analytical results are compared with FE results, which show the variation of radial magnetic flux density along the ϕ-direction at r=55.5mm, θ=90° (Fig.2 (b)) and r=55.5mm, θ=80° (Fig.2 (c)), respectively. It can be seen that the analytical model and FEM are in good agreement, thus, the analytical model can be used for further structural optimization design of PMSA. In addition, to obtain the optimal design of the rotor efficiently, several related configuration parameters used in the analytical model, such as spherical angle, radial thickness, and material of rotor core, are analyzed in this paper. V. CONCLUSION In this paper, an analytical model using spherical harmonics has been developed for analyzing the proposed rotor PM array of spherical motor and the 3-D solution of the spatial magnetic flux density is obtained. By comparing with the numerical FEA, the spherical harmonics is validated as an effective method with advantages of with reasonable accuracy and rapid computation, which has already been used to optimize the PM array design of the spherical actuator.

FB-08. Influence of Soft Magnetic Material type in Fixture Components on the Magnetization of Bonded Neo Magnet and Motor Performance.

R.C. Angara[1], K.W. Hsu[1], P.J. Villar[1] and N.K. Sheth[1]
1. R&D Magnequench, Magnequench Neo Powders Pte Ltd, Singapore, Singapore

The advantages like higher magnetic properties than ferrite, near net shape magnet production, and no use of heavy rare earth elements makes the bonded neo magnet very attractive in motors used for automotive accessory, home appliance and office automation. The isotropic nature of bonded neo magnets offers a feasibility to obtain wide range of magnetization profiles. The magnetization of the magnet influences the air-gap flux distribution and hence the motor performance[1]. Magnetizing fixture comprising of copper coils embedded in soft magnetic material is used to magnetize the magnet. When radial magnetization profile is desired, a back iron made up of soft magnetic material is also used to reduce the amount of magnetizing energy needed to saturate the magnet. Laminated steel is the preferred material for the magnetizing fixture as well as back iron. We have observed that at times solid steel is used in place of laminated steel. This paper presents the effects of using solid steel in place of laminated steel on the magnetization and motor performance. A magnetizing fixture is designed using the 2-D finite element analysis (FEA). The designed fixture is fabricated with fixture core and back iron made of laminated steel (LCLB). The magnetization performance of the designed fixture is evaluated using 2-D FEA and validated by performing magnetization of the magnets. To evaluate the influence of solid steel as a soft magnetic material two more combinations; (i) fixture core is of laminated steel but the back iron is of solid steel (LCSB) and (iii) both fixture core and back iron made of solid steel (SCSB) are simulated and evaluated. To ensure the full saturation in a bonded neo magnet a magnetizing field of 3T is desired through the thickness of the magnet[2]. From the simulation it is observed that to achieve 3T magnetizing field for LCLB combination the magnetizing energy required is 5.44 kJ. The required energy increases to 34.02 kJ and 68.28 kJ for LCSB and SCSB combinations respectively. The increase in energy is due to the generation of eddy currents in solid steel components which counteract the applied field, reducing the available field for magnetization. The energy needed to achieve full magnet saturation in LCSB and SCSB combination exceeds the capability of most of the commercially available magnetizers also the increase in magnetization energy requirement will lead to higher thermal stress and reduced fixture reliability. Based on the capability of the available magnetizer we applied up to 6 kJ for LCSB and SCSB combinations. We have also measured the corresponding applied field at the back of the magnet as 1.6 T and 1.4 T respectively. The less than desired applied field led to the partial saturation of the magnet. Figure 1 shows the measured mid airgap closed circuit flux density waveforms for magnets magnetized using various combinations. From this figure it is observed that the use of solid steel component makes the airgap flux density waveform less radial. The flux integral is reduced by 11% and 6.6% for LCSB and SCSB combinations compared to LCLB combination. The magnets magnetized using various combinations are assembled in a motor for performance measurement, the results of which are summarized in Table I. The presence of solid steel component during magnetization leads to partial magnetization of the magnet, resulting in higher no-load speed and lower stall torque. It is also observed that the motor with the magnets magnetized using LCSB and SCSB combinations has 64% and 60% lower cogging torque compared to LCLB combination. This is due to partial magnetization and hence lower flux offered by the magnets from these combinations.

FB-09. A hybrid coercivity mechanism for exchange-coupled nanocomposite permanent magnets.

G. Zhao[1]
1. Physics, Sichuan Normal University, Chengdu, China

Hard/soft permanent magnets have been a subject of continuous interests in the past two decades due mainly to their potential in achieving giant energy products as well as their rich variety of magnetic behaviors, *e.g.*, exchange-spring in the response of the applied field[1-4]. Recently the applications have been extended to the area of data storage as exchange-coupled composite (ECC) media has been found to own various advantages over the traditional longitudinal and perpendicular recoding media[5]. Although there are some limitations, micormagnetics is still the most important theoretical tool to elucidate the reversal mechanism, to predict the magnetic behaviors and to provide clues on how to improve the magnetic properties of nanocomposite permanent magnets[6-8]. In this work, we propose a hybrid coercivity mechanism for exchane coupled hard-soft permanent magnets, which incorporates elemnts of both the traditional nucleation and pinning mechanisms based on our micromagnetic calculation. Our proposed coercivity mechanism and calculated results agree very well with available experimental results, especially the recent reported high energy products achieved in NdFeB[9] and SmCo[10] based hard/soft multilayers. Careful comparison and contrast with other numerical and analytical micromagnetic methods have been done, where the virtues and weakness are classified and discussed, with salient deviations between experiment and theory listed and analyzed. A critical assessment on how to reach a satisfactory micromagnetic theory will be made. The focus of the comparison and contrast is on the thin film system, where the thickness of the layers can be controlled precisely so that the calculated results can be compared directly with available experimental data. Spin distributions and microscopic hysteresis loops are important references on whether a calculation is reliable, along with the well-known macroscopic hysteresis loops. Based on the calculations, magnetic phase diagrams, nucleation modes and coercivity diagrams as well as their size effects are summarized. The influences of various microstructure structures, such as defects, easy axis distributions and interface qualities on the hysteresis loops are evaluated. These issues help to digest the outstanding deviations between the observed and calculated energy products in composite magnets. This paradox is closely linked to the more famous and widely existed coercivity paradox proposed by Brown in 1940s. The proposed coercivity mechanism and modeling techniques are ready to be extended to single-phased permanent magnets and ECC system. Further, they shed light on the micromagnetic calculations of the antiferromagnet-ferromagnet bilayers, where exchange bias and exchange springs have some common underlying physics. This work is supported by Natural Science Foundation of China (51771127, 51571126, 51772004)

FB-10. The corrosion behavior with sintered (Ce,Nd)-Fe-B in the presence of pressurised vapour.

X. Shi[1], M. Zhu[1], D. Zhou[1], *L. Song*[1], Y. Fang[1] and W. Li[1]
1. Division of Functional Materials, Central Iron & Steel Research Institute, Beijing, China

Introduction Sintered neodymium-iron-boron (Nd-Fe-B) magnets have become the most widely used as the high energy product [1]. Recently, Cerium, is used to substitute Nd in $Nd_2Fe_{14}B$ for reducing the cost. The double main phase (DMP) methods, sintering the mixture of Ce-free and Ce-containing Re-Fe-B powders, is taken to synthesize the (Ce, Nd)-Fe-B magnets. The method can realize the adjustment of the composition and combination of main phases, and reach the fine magnetic properties [2-3]. The corrosion of the magnets, which is an important material selection criterion in practical application, is affected by the microstructures and composition [4]. In this paper, the microstructures and corrosion of $(Ce_xNd_{1-x})_{30}Fe_{bal}B$ (x=0.15, 0.3, 0.5, wt.%) named as Ce15, Ce30, Ce50 were studied. The commercial Ce-free magnet with energy product 45MGOe named as N45 is used as the reference magnet. The corrosion was tested in pressurised vapour atmosphere, which enables the electrochemical reaction and facilitates the transfer of the water molecules through the magnet. Key words : Ce, sintered Nd-Fe-B, microstructure, galvanic corrosion Experimental Procedure The DMP magnets $(Ce_xNd_{1-x})_{30}Fe_{bal}B$ were prepared with mixture of $Nd_{30}Fe_{bal}B_1$ (wt.%) and $Ce_{15}Nd_{15}Fe_{bal}B_1$ (wt.%) powders. The magnets $(Ce_xNd_{1-x})_{30}Fe_{bal}B$ were sintered and annealed at temperatures between 400°C and 600°C without the traditional high temperature annealing around 900°C. The reference magnets have the same energy product with Ce15. The samples were put in an autoclave at 120°C, 1.2Mpa, 100% RH with the size of 15mm×15mm×4mm for the corrosion testing. The inductively coupled plasma (ICP) mass spectrometry is used for measuring element composition of the magnets by PerkinElmer optima 2100 DV. The back scattered electron (BSE) images and element distribution (EDS) maps of the polished sample surfaces and the corrosion surfaces were carried out by Phenom ProX. Results and discussion Fig. 1 presented the microstructures of magnets. The dark contrast with highest volume fraction corresponds to the magnetic $Re_2Fe_{14}B$ grains and the bright one refers to the Re-rich phase around magnetic phase. The single area of Re-rich phase in N45 (Fig.1a) is largest, and the magnetic particle is not isolated by the Re-rich phase. The distribution of the Re-rich phase in Ce15 (Fig.1b) is relatively scattered. The network structure of Re-rich phase is formed in Ce30 and Ce50 (Fig.1c and Fig.1d), and the structure is efficient to improve coercivity by blocking interaction of the magnetic phase. The EDS maps show the distribution of elements with the same area in the magnets. In Ce15 and Ce30, some of magnetic phase is Ce-free while some magnetic particles contain high content Ce. Ce exists in all the Re-rich phase of Ce15. Some of Re-rich phases contain high Ce while some of Re-rich phases contain low Ce in Ce30 and Ce50. Besides, it is clearly that the concentration of Nd and O elements is high while Fe and Ce is low in Re-rich phase, which means that O prefers to combine with Nd in Ce30 and Ce50. The uneven distribution of Ce is caused by solidification process in the Re-rich phase of the Ce30 and Ce50. Ce performs better infiltration than Nd to the magnetic phase, so Ce is easier to solidity on the surface of the magnetic particle than Nd. That may be also the reason that Nd prefer to combine with O. The corrosion morphology of samples is observed (Fig.2). The corrosion morphology of N45 (Fig.2a) represents pitting. The pitting occurs when the potential difference is small between the magnetic phase and Re-rich phase, the existence of Co and Al decreases the potential difference which makes pitting easier. The appearance of Ce15 (Fig.2b) performs discontinuous pits. The grain boundary phase is small and scattered, the grain boundary phase dissolves as the anode, so the corrosion channel is difficult to form further corrosion depth. The corrosion morphology of Ce30 and Ce50 is different from N45 and Ce15, the corrosion form is that the magnetic phase is corroded while the Re-rich phase keeps intact. Larger magnification image of corrosion morphology and element distribution of special area were taken of Ce30 and Ce50. Re-rich phase located in grain boundary is corroded, lager area of the Re-rich phase is clear and distinguishable in Ce30. In the Ce50, the magnetic phases present corrosion, the Re-rich phases almost have no missing. So untraditional galvanic corrosion that Re-rich phases refer to cathode and the Re-Fe-B main phases refer to anode appear in Ce30 and Ce50. Conclusion The effects of Ce on the microstructure and corrosion of sintered (Ce,Nd)-Fe-B permanent magnets were investigated. Taken together, we found that: 1. Some of the magnetic phases contain Ce while some of the magnetic phase doesn't contain Ce in the dual-main-phase magnet. 2. All the Re-rich phase contains Ce in the Ce15 magnets. However, the distribution Nd and Ce is uneven in different Re-rich phase of Ce30 and Ce50. The uneven distribution is caused by the fine wettability of Ce. 3. The magnetic phase is corroded as the anode and the grain boundary phase keep intact as cathode in the samples of Ce30 and Ce50. The shift of anode and cathode between the magnetic phase and Re-rich phase is due to the compact microstructure.

FB-11. Element-specific characterization of Co:FePt nanocomposite magnet films.

F. Wilhelm[1], V. Dupuis[2], D. Le Roy[2], N. Dempsey[3] and A. Rogalev[1]
1. ESRF, Grenoble, France; 2. Institut Lumière Matière, Villeurbanne, France; 3. Institut Néel, Grenoble, France

Nanocomposite magnets consisting of a mixture of a hard magnetic material and a high saturation magnetization ferromagnet are promising systems to overpass performances of the best permanent magnets. Theoretical descriptions of nanocomposite magnets [1] revealed the necessity of confining a soft magnetic material in clusters of typically less than 10 nm. Yet standard fabrication processes do not permit to produce such microstructures in a controllable manner. In this context a cluster-dedicated synthesis could permit to realize model films to experimentally explore underlying mechanisms that govern magnet performances in such nanocomposite magnets [2]. We have been able to synthesize Co:FePt nanocomposite films by combining low energy cluster beam deposition (LECBD) technique and e-beam evaporation. To separately adjust size, composition and concentration, Co:FePt nanocomposite were prepared from low energy cluster beam deposition technique (LECBD) of mass-selected Co clusters preformed in gas phase, in-situ embedded in hard L10-FePt matrix independently produced by alternative electron gun evaporation on substrate. Doing so, the soft phase is restricted to clusters of nanometer size, selected from 2 to 8 nm while the volume fraction of nanoclusters in L10-FePt matrix was varied up to 30%. Here we report on results of standard structural (e.g. XRD, SEM, TEM) and magnetic characterizations (SQUID magnetometry, MFM) performed on these nanocomposite samples. A typical XRD pattern of nanocomposite on Si substrate is reproduced on a left panel of Fig. 1. An anomalously intense (001) reflection with respect to (110) peak is a signature of a certain texture of the L10-FePt film. A strong magnetic coupling is between FePt and Co clusters could be inferred from SQUID magnetization curves on nanocomposite when compared with the results obtained from superparamagnetic Co clusters in an inert carbon matrix and from a pure FePt film (see right panel on Fig.1). Macroscopic characterization was complemented with more sophisticated element selective approaches, i.e. X-ray natural linear dichroism (XLD) and X-ray magnetic circular dichoism (XMCD) spectroscopies at the K-edges of Fe and Co. We have concentrated on Co:FePt nanocomposite with Co nanoclusters of 6 nm size embedded in L10-FePt matrix. Firstly, a high degree of texture in composite films is confirmed on microscopic level. Secondly, XLD signals at both Co and Fe sites are found to be nearly identical in amplitude and spectral shape. The latter is nearly identical to those measured on a pure L10-ordered FePt film. This observation is a very indication that the Co clusters do not keep fcc structure as expected but rather adopt a tetragonal L10 structure. Microscopic magnetic characterization with XMCD has revealed that Co magnetic moments are aligned ferromagnetically with Fe moments in the L10-FePt matrix. Moreover, both are exhibiting the same magnetization curves that demonstrates that the Co:FePt nanocomposite behaves like a single magnetic phase material. Funding by the ANR-SHAMAN (ANR-16-CE09-0019) is acknowledged.

Hydrogen decrepitation (HD) has been widely used in Nd-Fe-B magnets preparation[1]. Traditional 2:17 type Sm-Co alloys have very harsh hydrogen absorption conditions. Recently, our group reports that 2:17 type Sm-Co alloys with high iron content shows excellent ability to absorb hydrogen and the HD has been applied in the magnets preparation[2]. HD utilizes two steps (absorption and release)[3] and if the hydrogen does not need to release, it could be much shorter time for HD process. However, the effect of residue hydrogen to the microstructure and magnetic properties remains unknown in iron-rich 2:17-type Sm-Co magnets. Therefore, it is meaningful to systematically investigate the effect of residue hydrogen in iron-rich 2:17-type Sm-Co magnets. The nominally $Sm(Co_{bal}Fe_{0.28}Cu_{0.053}Zr_{0.02})_{7.84}$ magnets were prepared by traditional metallurgy route. The as-cast alloys were pre-crushed by HD technology. The HD powders with different hydrogen content (25 ppm, 715 ppm, 1512 ppm) were prepared through changing dehydrogenation time (240 min, 20 min, 0 min). The green bodies were sintered at 1200°C for 30min, and then homogenized at 1175°C for 3h, followed by a rapid cooling step to room temperature. The subsequent isothermal aging was at 830°C for 16h, followed by slow cooling to 400°C and finally rapid cooling to room temperature. Fig. 1 shows demagnetization curves of the magnets A (25 ppm), B (715 ppm) and C (1512 ppm) at the room temperature. The remanence doesn't change with the residue hydrogen content. However, the intrinsic coercivity is improved from 24.03 kOe to 26.37 kOe as the residual hydrogen content increases from 25ppm to 1512ppm. Interestingly, the squareness also increases from 0.56 to 0.63. Fig. 2(a-c) show the BSE images of aged magnets. Obviously, the average grain size of magnet A is smaller than B and C. The average grain sizes of magnet A, B and C are 49μm, 53μm and 59μm, respectively, which means the residual hydrogen content can promote the average grain size. Fig. 2(d-f) show the TEM-BF image with c-axis within image plane and corresponding Fresnel Lorentz images for magnet A at the grain boundaries. The regions near grain boundary shows indistinct cell boundaries and less lamellar phase (Fig. 2d). The lamellar phases provide diffusion paths for rapid segregation of Cu atoms to cell boundaries[4]. Therefore, less lamellar phase may lead to indistinct cell boundary phase and less Cu content in cell boundary. In addition, minor grain boundary phase with many stripes can be also observed, as is shown in Fig. 2e (over focus) and Fig. 2f (under focus). Because domain walls (white arrows) pass through the grain boundary phase, it should be magnetic phase. These two regions act as easy points for the occurrence of reversal magnetic domains. Therefore, a reduced amount of grain boundary phase results in less weak pinning points, and as a result, the intrinsic coercivity and the squareness are improved. Furthermore, cell structures and lamellar phase are comprehensively investigated.

FC-01. Voltage-driven precessional switching at zero bias magnetic field in a conically magnetized free layer.

R. Matsumoto[1], T. Nozaki[1], S. Yuasa[1] and H. Imamura[1]
1. Spintronics Research Center, National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan

Voltage-driven magnetization switching [1] at zero bias magnetic field has become one of the key requirements in developing voltage-controlled magnetoresistive random access memory (MRAM). In a conventional magnetic tunnel junction (MTJ) with a perpendicular magnetization, however, voltage-driven magnetization switching has been demonstrated under a bias magnetic field having in-plane (IP) component [2-4]. Instead of bias magnetic field, the IP component of the shape anisotropy field, H_k, is being often used for controlling the magnetization. Finite H_k is commonly obtained in a ferromagnet having an elliptic-cylinder shape. In the case of a perpendicularly magnetized free layer, on the other hand, the shape anisotropy field cannot move the magnetization from an equilibrium state because H_k is zero at $(m_x, m_y, m_z) = (0, 0, \pm 1)$ where m_x and m_y (m_z) are IP (perpendicular) components of the unit magnetization vector (m) of the free layer (see Fig. 1(a)). Tilting the magnetization from the perpendicular direction is also necessary for the switching of the free layer magnetization. To tilt the magnetization, we propose the use of a cone state. Cone state is the magnetization state (see Fig. 1(b)) where the tilted magnetization is stabilized by the competition between the first- and the second-order magnetic anisotropy energies, $K_{1,\mathrm{eff}}$ and K_{u2} [5, 6]. Here $K_{1,\mathrm{eff}}$ is the effective anisotropy constant, where demagnetization energy is subtracted from the first-order anisotropy constant (K_{u1}). In this study [7], the voltage-driven precessional switching in a conically magnetized free layer having an elliptic cylinder shape is theoretically analyzed in order to derive analytical expressions of the conditions for the precessional switching at zero bias magnetic field. The MTJ we assume is illustrated in Fig. 1(a). The axis x is parallel to the major axis of the ellipse. The conditions for the precessional switching is analyzed using the following dimensionless energy density, $\varepsilon = (1/2)(N_x m_x^2 + N_y m_y^2 + N_z m_z^2) + \kappa_1(1 - m_z^2) + \kappa_2(1 - m_z^2)^2$. Here $\kappa_1 = K_{u1}/(\mu_0 M_s^2)$ and $\kappa_2 = K_{u2}/(\mu_0 M_s^2)$. μ_0 is the vacuum permeability, and M_s is the saturation magnetization of the free layer. The demagnetization coefficients, N_x, N_y, and N_z are assumed to satisfy $N_z \gg N_y > N_x$. Although our analysis can be applied to a general situation, it is easier to understand the benefit by showing specific examples. Accordingly, following parameters are assumed: M_s = 1400 kA/m, the volume of the free layer is $50 \times 20 \times \pi \times 1$ nm^3, $K_{u1}^{(0)}$ = 1067 kJ/m^3, $K_{1,\mathrm{eff}}^{(0)} = K_{u1}^{(0)} - (1/2)\mu_0 M_s^2(N_z - N_x)$ = -80 kJ/m^3, $K_{u2}^{(0)}$ =150 kJ/m^3, $m_z^{(0)}$ = 0.856, and the thermal stability factor at 300 K is 61.2. Hereafter the superscript "(0)" indicates the quantities at zero bias voltage. The direction of $m^{(0)}$ is indicated by an open circle in Fig. 2(a). Voltage-driven dynamics in the free layer is analyzed with the contour curve of ε including $m^{(0)}$ on the Bloch sphere shown in Fig. 2(a). When $(\kappa_{1,\mathrm{eff}}(=K_{1,\mathrm{eff}}/(\mu_0 M_s^2)), \kappa_2) = (-0.040, 0.025)$ at a finite voltage, for example, the contour curve extends from the upper hemisphere to the lower hemisphere as shown in Fig. 2(a). It enables the voltage-driven precessional switching. The switching in the free layer is confirmed by the calculations using the Landau-Lifshitz-Gilbert equation, $\mathrm{d}m/\mathrm{d}t = -\gamma_0\, m \times H_{\mathrm{eff}} + \alpha\, m \times \mathrm{d}m/\mathrm{d}t$, as shown in Fig. 2(a). Here t is time, γ_0 is the gyromagnetic ratio, α is the Gilbert damping constant being $\alpha = 0.005$, and H_{eff} is the effective magnetic field defined as $H_{\mathrm{eff}} = -M_s \nabla\varepsilon$. Starting from $m_z^{(0)} > 0$, m switches to the lower hemisphere moving along the contour curve of ε including $m^{(0)}$. It indicates that voltage-driven precessional switching at zero bias magnetic field is possible in a conically magnetized free layer with the elliptic-cylinder shape and that the trajectory can be analyzed by the contour curve of ε. The analyzed conditions for the precessional switching at zero bias magnetic field are shown as a $\kappa_{1,\mathrm{eff}}$ - κ_2 phase diagram in Fig. 2(b). The shade region indicates the switching region. The switching region is analytically expressed as follows. At $\kappa_{1,\mathrm{eff}} < \kappa_{1,\mathrm{eff}}^{(i)}$, $\{-\kappa_{1,\mathrm{eff}} - [-\kappa_{1,\mathrm{eff}}(N_y - N_x) - (1/4)(N_y - N_x)^2]^{1/2}\}/[2(1 - Z^{(0)})] < \kappa_2 < -\xi\,\kappa_{1,\mathrm{eff}}$. At $\kappa_{1,\mathrm{eff}}^{(i)} \le \kappa_{1,\mathrm{eff}} < 0$, $-\xi\,\kappa_{1,\mathrm{eff}} - \eta < \kappa_2 < -\xi\,\kappa_{1,\mathrm{eff}}$. At $\kappa_{1,\mathrm{eff}} \ge 0$, $-\xi\,\kappa_{1,\mathrm{eff}} - \eta < \kappa_2 < -(\kappa_2^{(0)}/\kappa_{1,\mathrm{eff}}^{(0)})\,\kappa_{1,\mathrm{eff}}$. Here, $\kappa_{1,\mathrm{eff}}^{(i)}$ is $\kappa_{1,\mathrm{eff}}$ of the point (i) in Fig. 2(b) being $\kappa_{1,\mathrm{eff}}^{(i)} = -(N_y - N_x)[2 - 2Z^{(0)} + (Z^{(0)})^2]/[2(Z^{(0)})^2]$, $Z^{(0)} = (m_z^{(0)})^2$, $\xi = 1/(2 - Z^{(0)})$, and $\eta = \xi(N_y - N_x)/(2Z^{(0)})$. The results provide a practical guide to design the bias-field-free voltage-controlled MRAM, which simplifies the device structure and reduces the fabrication cost. This work was partly supported by the ImPACT Program of the Council for Science, Technology and Innovation and JSPS KAKENHI Grant Number 16K17509.

Magnetic random access memory (MRAM) is becoming a mainstream memory due to its non-volatility, unlimited endurance, and low power consumption.[1,2] One of the key challenges for MRAMs is to efficiently manipulate the magnetization of the free layer. Recent studies demonstrate that data writing can be achieved by spin Hall effect (SHE), in which an in-plane charge current flowing in a nonmagnetic layer generates a vertical spin current, leading to the magnetization reversal of the adjacent magnetic layer.[3] Voltage-controlled magnetic anisotropy (VCMA) is another promising method for low-power write operations.[4] It enables reducing the interfacial perpendicular magnetic anisotropy (PMA) by applying a voltage, thus lowering or even eliminating the energy barrier during switching. With a combination of the SHE and VCMA effect, it is feasible to decrease the critical SHE switching current by applying a gate voltage.[5-7] However, an external magnetic field is commonly needed for switching of perpendicularly magnetized tunnel junctions (pMTJs) with SHE.[8] Recently, field-free switching of perpendicular magnetization was reported in the IrMn/CoFeB/MgO structure, where the antiferromagnetic material IrMn provides an exchange bias and the SHE at the same time.[9-10] Nevertheless, the VCMA effect in the IrMn/CoFeB/MgO structure has never been reported. Consequently, it is essential to investigate the VCMA in the IrMn/CoFeB/MgO-based pMTJs and to study the voltage-gated SHE switching in this structure. In this paper, we first studied the VCMA effect in the IrMn/CoFeB/MgO structure. The films consisting of IrMn(5nm)/$Co_{40}Fe_{40}B_{20}$(1.05nm)/MgO(2.5nm)/Al_2O_3(5nm) were deposited on thermally oxidized Si substrate using magnetron sputtering, followed by annealing at 150°C for 30 minutes in vacuum (<10^{-7} Torr). Subsequently, the films were patterned into Hall bar devices with dimension of 20 μm × 130 μm. Figure 1(a) presents the anomalous Hall resistance under an in-plane magnetic field. When a gate voltage is applied, the interfacial PMA is changed due to the VCMA effect, leading to variations of the anomalous Hall resistance, as clearly shown in the right inset of the Fig. 1(a). Using the method reported in Ref. 11, we acquire the electric field dependence of the interfacial anisotropy constant, as shown in Fig. 1(b). From the slope of the linearly fitting, we obtain a VCMA coefficient of 39 fJ/Vm for the IrMn/CoFeB/MgO structure, which is comparable with that of Ta/CoFeB/MgO structure.[12] Figure 2(a) illustrates the voltage-gated SHE switching of the IrMn/CoFeB/MgO-based pMTJ device. With the aid of an exchange bias generated by the IrMn layer, field-free magnetization switching can be achieved by flowing an in-plane charge current in the IrMn layer. In addition, when a gate voltage is applied, the energy barrier for magnetization reversal can be reduced due to the VCMA effect, as shown in Fig. 2(b). Consequently, the critical SHE switching current can be controlled by the gate voltage. Micromagnetic studies are performed to study the voltage-gated SHE switching. Figure 2(cd) present the results. When no gate voltage is applied, field-free switching is observed, but a large SHE current of 45 MA/cm^2 is required. When a gate voltage of 1.5 V is applied, the critical switching current drops to 4.5 MA/cm^2, which is 10-folds decreasing. These results verify that a gate voltage can be used to effectively modulate the SHE-driven switching. A spintronics memory array with multiple MTJs located on a single IrMn strip is proposed and evaluated with hybrid pMTJ/CMOS circuit simulations. During switching, a bidirectional current is applied in the IrMn strip, combined with a voltage above the MTJs for addressing. It is worth noticing that all MTJs on a single IrMn strip share two driving transistors and can be switched simultaneously, leading to high density and fast speed. Moreover, the energy dissipation is much lower than that of conventional SHE-driven switching. In summary, we experimentally investigated the VCMA effect in the IrMn/CoFeB/MgO structure and obtained a VCMA coefficient of 39 fJ/Vm, which is comparable with that of Ta/CoFeB/MgO structure. Field-free switching of perpendicular magnetization is demonstrated with the aid of an exchange bias generated by the antiferromagnetic IrMn layer. Moreover, when a gate voltage of 1.5 V is applied, the critical switching current can be reduced by 10 times due to the VCMA effect. A spintronics memory array based on this pMTJ was proposed and evaluated by hybrid pMTJ/CMOS circuit simulations. The results demonstrated that reliable and fast-speed write operations can be achieved by the voltage-gated SHE. We believe our work may promote the development of high-density and low-power spintronics memories with pMTJs.

Perpendicular magnetic anisotropy (PMA) and its voltage control in magnetic heterostructures [1] are expected to be the key to achieve low-power consumption spintronic devices such as voltage-torque magnetoresistive random access memories (MRAMs). For actual high-density memory applications, large interface PMA energy density (K_i) and voltage-controlled magnetic anisotropy (VCMA) coefficient (β), e.g., K_i > 2-3 mJ/m^2 and β > 1000 fJ/Vm, are needed. In order to achieve such a large VCMA effect, exploring the origin of the VCMA effect using ideal PMA heterostructures without any interfacial defects is indispensable. Recently, large PMA energies were reported in lattice-matched Fe/$MgAl_2O_4$ [2] and Co_2FeAl/$MgAl_2O_4$ heterostructures [3]. Also, the Cr/Fe/Oxide layered structure is well-known to form quantum well (QW) states of majority spin electrons in the Fe layer, since there is no Δ_1 states near the Fermi level in metallic Cr. Note that Cr can be regarded as a "potential barrier" for Δ_1 electrons. The formed QWs can modulate the coherent tunneling behavior referred as spin dependent resonant tunneling (SDRT) effect, where the tunneling conductance enhances at specific resonant bias voltages due to different QW width, namely effective Fe thickness [4]. Associated with QW-SDRT effect, the VCMA is likely to be anomalously modulated. Hence, in this study, we focused on the Cr/ultrathin-Fe/$MgAl_2O_4$ epitaxial interfaces to achieve high K_i and β and investigate the possible influnence of QW-SDRT effect on VCMA. We report that only a monolayer thickness difference has a significant impact on the PMA energy and VCMA effect. Magnetic tunnel junction (MTJ) stacks of Cr buffer (30)/Fe (t_{Fe})/$MgAl_2O_4$ (2)/$Co_{20}Fe_{60}B_{20}$ (5)/Ru (10) (unit in nm) were epitaxially grown on an MgO(001) substrate by electron-beam evaporation, where t_{Fe} = 0.70, 0.84, 0.98 nm and correspond to 5, 6, 7 atomic layers, respectively. The top 5-nm CoFeB is the reference layer with in-plane magnetization for evaluating the VCMA effect of the bottom Fe layer. The Cr, Fe, $MgAl_2O_4$, and CoFeB layers were post-annealed to improve their crystallinity and flatness. Magnetic properties were investigated using a vibrating sample magnetometer incorporated with superconducting quantum interference device (SQUID). After microfabrication (5×10 mm scale), magnetotransport properties of the MTJs were characterized by a Physical Property Measurement System (PPMS) at room temperature. The positive bias was defined with respect to CoFeB (electron tunneling from the bottom to top electrode). Figure 1 shows the typical in-plane magnetization curves for the MTJ stacks with different Fe thicknesses. It was found that the 5- and 6-ML Fe layers had perpendicular magnetization. Areal PMA energy density $K_{eff} \times t_{Fe}$ for the 5-ML (6-ML) Fe sample was determined to be 0.85 mJ/m^2 (0.77 mJ/m^2). We investigated the bias voltage dependence of $K_{eff} \times t_{Fe}$ for the 5- and 6-ML Fe samples using normalized tunnel magnetoresistance ratios as functions of both bias voltage and in-plane magnetic field. As clearly seen in Fig. 2, a strong SDRT effect is confirmed as significant enhancement of conductance at resonant voltages around ± 0.5V for the 5-ML sample (around 0 V for 6-ML sample). The resonant voltages agree well with those of the theoretical calculation [4]. Importantly, the areal PMA energy, $K_{eff} \times t_{Fe}$ values for the both samples behave similar with bias dependence of conductance, demonstrating strong Fe atomic layer number dependence. The underneath mechanism of the QW-SDRT modulation on VCMA is unclear, nevertheless, the modulated density of states of ultrathin Fe and the interface resonant states may play important roles. This work was partly supported by the ImPACT Program of Council for Science, Technology and Innovation, Japan.

FC-04. The lower bound of the write error rate of a voltage-torque MRAM.

H. Imamura[1] and R. Matsumoto[1]
1. Spintronics RC, AIST, Tsukuba, Japan

Spin manipulation by voltage controlled magnetic anisotropy (VCMA) in a thin ferromagnetic film has attracted much attention as a key phenomenon for low power spintronics memory called "voltage-torque magnetoresistive random access memory (VT-MRAM)" [1-7]. In the VT-MRAM the information is stored by the direction of magnetic moments in a perpendiculary magnetized recording layer, and an in-plane magnetic field is applied to the memory cells. Application of the voltage pulse eliminates the MA and induces the precessional motion of the magnetic moments around the external magnetic field. If the voltage is turned off at one-half period of the precession the magnetization switching completes. It was shown that an MgO-based magnetic tunnel junction is a powerful candidate for a memory cell of the VT-MRAM because of the fast (less than 1 ns) switching time as well as of the low (order of 10^{-5}) write error rate (WER) [7]. For practical application, however, the WER of less than 10^{-9} is necessary. The thermal distribution of the equailibrium state and switching trajectory are the main origins of the WER. The dependence of the WER on the material parameters such as the anisotropy constant (K) and the Gilbert damping constant (α) has been studied by solving the Langevin equations [6,7]. It was predicted that the WER decreases with decrease of α and/or with increase of K. Although the Langevin equation based numerical studies are useful to calculate the statistical properties, it is very difficult to estimate the practical value of the WER because of the huge computational cost. For example, in order to evaluate the WER less than 10^{-9} enormous amount of trials more than 10^{10} are required. In this paper we performed the Fokker-Planck (FP) equation based analysis [8] of the WER. The FP equation is a differential equation for the probability distribution function and can be solved analytically under appropriate assumptions. The macro-spin model is employed to represent the dynamics of the magnetization in the recording layer. The direction of the magnetization is expressed by the unit vector m=($\sin\theta\cos\phi$, $\sin\theta\sin\phi$, $\cos\theta$), where θ and ϕ are the polar and azimuthal angles, respectively. We assume that the easy axis of the MA is the z-axis, and the MA vanishes during the voltage pulse. The magnetic field (H) is applied to the positive x-direction during the voltage pulse. The initial state is assumed to distribute around $\theta=0$ because of the thermal agitation field. Since the thermal stability factor (Δ) of VT-MRAM should be larger than 60 the distribution function of the initial state can be well approximated by the Gaussian distribution on the upper hemisphere. During the voltage pulse the magnetization precesses around the x-axis with the frequency of $f=\gamma H/[2\pi(1+\alpha^2)]$. Introducing $\mu=\cos(\theta-2\pi f t)$ the FP equation during the voltage pulse is given by $\partial F(\mu,\tau)/\partial\tau=\partial/\partial\mu[(1-\mu^2)\partial F(\mu,\tau)/\partial\mu]$, where $\tau=[\alpha/(1+\alpha^2)][(\gamma k_B T)/(\mu_0 M_s V)]t$ is the dimensionless time. Here γ is the gyromagnetic ratio, k_B is the Boltzmann constant, T is temperature, μ_0 is the vacuum permeability, M_s is the saturation magnetization, and V is the volume of the recording layer. This FP equation can be solved by using the Legendre polynomial expansion. The WER is estimated by setting pulse width (τ_p) to the half period of the precession and integrating $F(\mu, \tau_p)$ on the uppre hemisphere. Figure 1 shows the Δ-dependence of WER for various values of τ_p. For all values of Δ the WER decreases with decease of τ_p, which means the WER decreases with increase of H. From the definition of τ one can see that WER decreases with decreasing (increasing) α and/or T (M_s and/or V). Assuming that $M_s = 10^6$ A/m, T = 300 K, V = $\pi\times15^2\times2$ nm^3, the value of τ_p = 0.02 corresponds to the pulse width of 0.78 ns. For all values of τ_p the WER is a decreasing function of Δ. It should be noted that the decreasing rate of WER decreases with increase of Δ, which implies that the WER remains finite in the limit of $\Delta\to\infty$. The analytical expression of the lower bound of the WER, $\lim_{\Delta\to\infty}$ WER, can be calculated by setting the initial distribution to be a delta function. After some algebra we obtain $\lim_{\Delta\to\infty} \mathrm{WER} = 1/2 - \Sigma_{n=1}^{\infty} \{(2n+1)/[2(n+1)]\, P_{n-1}(0) \exp[-n(n+1)\tau_p]\}$, where $P_{n-1}(0)$ is the (n-1)-th Legendre function. Figure 2 shows the lower bound of the WER as a function of τ_p. The circles indices WER at τ_p = 0.02, 0.04, 0.06, 0.08, and 0.1. The results show that in order to achieve the WER less than 10^{-9} τ_p should be less than 0.03. The authors would like to thank T. Nozaki and S. Yuasa for valuable discussions. This work was partly supported by the ImPACT Program of the Council for Science, Technology and Innovation and JSPS KAKENHI Grant Number 16K17509.

FC-05. Study of voltage-controlled perpendicular magnetic anisotropy in Ta/FeB/MgO and W/FeB/MgO nanowires by the Hall effect measurements.

V. Zayets[1], T. Nozaki[1], A. Fukushima[1] and S. Yuasa[1]
1. Spintronics Center, National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan

Voltage-controlled perpendicular magnetic anisotropy (PMA) is a recently-found effect, which may be used in MRAM and all-metal transistor[1] applications as a magnetization-switching mechanism. Conventionally the strength of the voltage-controlled PMA effect is measured in a MTJ, which electrodes are magnetized perpendicularly each other[2]. The angle between magnetization of electrodes is evaluated from the magneto-resistance at different applied voltages. From this data the strength of the voltage-controlled PMA is estimated. The second method is the measurement of the dependence of the coercive field on a gate voltage[3-5]. The second method is the direct measurement the voltage-controlled PMA effect and it can reveal different interesting features of the effect. However, the magnetization switching is thermo-activated process and the required high-precission measurement of the coercive field is difficult. Therefore, the measurements of the voltage-dependence of the coercive field have been reported only for the cases when the change of the coercive field is substantial. It is the case when the sample temperature is near the Curie temperature[3] or the change of the coercive field is larger than 100 Oe[4] or when the easy axes of the sample is near the transition from in-plane to out-plane direction[5]. We have developed a method of a precise measurement of the coercive field. Main merit of this method is that it is able to detect even very small changes of the coercive field. Therefore, the magnitude of the voltage-controlled PMA effect can be measured in a variety of different samples of different structure and of different magnitude of the voltage-controlled PMA. The coercive field is measured by measuring Hall angle in a pulsed magnetic field. The precise value of the coercive field was evaluated from two sets of the measurements. In the first measurement, the magnetic pulse of a gradually-increased amplitude was applied and the switching field was measured. In the second measurement, the magnetic pulse of constant amplitude was applied and the switching probability was measured. A sufficient number of those two combined measurements and a statistical analysis were used to evaluate the coercive field. Details of the proposed method will be described at conference site. The precession of measured coercive field was better than 1 Oe. We have studied the voltage-controlled PMA effect in Ta(2)/FeB(1.1)/MgO, W(3)/FeB(1.1)/MgO, Ta(2)/FeB(0.5)/W(0.8)/FeB(0.5)/MgO and W(3)/ $(FeB/W)_n$ /FeB(0.2)/MgO multilayers. The width of fabricated nanowires was 100, 200, 400 and 1000 nm. A pair of 80-nm-wide Hall nanoprobes was connected to the middle of nanowire. A thick 6-nm MgO gate oxide and Ta(1)/Ru(5) gate electrode were used (Fig. 1(a)). All studied samples show the increase of the coercive field under a negative gate voltage and the decrease of the coercive field under a positive gate voltage (See Fig.1(b)). The polarity of the voltage-controlled PMA effect is the same as when it was measured by another method[2]. Additionally to change of the coercive field, there is a small change of the Hall angle. The Hall angle increases at a negative gate voltage and decreases at a positive gate voltage. Figure 2(a) shows coercive field of Ta(2)/FeB(0.5)/W(0.8)/FeB(0.5)/MgO 400-nm-wide nanowire as a function of the gate voltage. In the measurement range, the dependence is linear. The magnitude of the voltage-controlled PMA is 11 Oe per 1 V or 1.8 Oe/(V/nm). All fabricated samples shows the magnitude of the voltage-controlled PMA effect in the range between 5 and 11 Oe / V. Figure 2(b) shows the Hall angle as a function of the gate voltage for the same nanowire. The change is about 5 mdeg per 1 V of gate voltage or 2.5% per 1 V. Additionally, there is a hysteresis loop. The CV-measurements indicate that the hysteresis loop might be due to the deep defects in the thick MgO gate oxide. The defects in the MgO gate oxide might be due to a low annealing temperature of our samples (~200^0 C). Figure 2(c) shows the magnetization switching probability as a function of an external magnetic field. The switching probability is clearly distinguished at different gate voltages. A feature, which is substantially different for all our studied samples, is the value of the Hall angle. The Hall angle in the Ta(2)/FeB(1.1)/MgO was the largest (1200 mdeg). The Hall angle decreases to 30-50 mdeg, when the number of the W/FeB interfaces increases. It is known[6] that the polarity of the Anomalous Hall effect is opposite for electrons and holes. The measurements of the ordinary Hall effect and anomalous Hall effect is a standard method[6] to determine the type of conductivity in a metal and to estimate the position of the Fermi level. The study the dependence of the magnitude of the voltage-controlled PMA effect on the conductivity type (the Hall angle) will be reported at the conference site.

Exchange stiffness plays a crucial role in determining the performance of various magnetic and spintronic devices. For nanoscale magnetic tunnel junctions, which are the heart of nonvolatile spintronics memory devices, exchange stiffness governs the magnetization reversal mode and determines the thermal stability factor with an incoherent reversal.[1,2)] For other devices utilizing domain wall or skyrmion,[3,4)] size and stability of such magnetic solitons also depend on the exchange stiffness.[5)] To access the physics of magnetic parameters like the exchange stiffness in terms of electronic structures, application of electric field often provides a useful insight.[6)] Recently, electric-field effect on the exchange stiffness constant A_S was observed in a magnetic domain structure[7,8)] and spin-wave resonance.[9)] In addition, first-principles calculation predicts that the electric field could modulate the exchange stiffness.[10,11)] In this study, we investigate the electric-field effect on A_S of CoFeB/MgO stacks, a key building block of nonvolatile spintronics devices. A_S is evaluated from an observation of domain structure and an analytical model[12)] describing the relation between the domain period D_P and A_S. The stacks, Ta/ CoFeB (t_{CoFeB} = 1.18 - 1.25 nm)/ MgO (2 nm)/ Al_2O_3 (5 nm), are deposited by dc/rf magnetron sputtering on thermally oxidized Si substrate, and are annealed at 350°C for 1 h. Subsequently, they are processed into a capacitor structure to apply electric fields. Indium tin oxide (30 nm) is deposited and patterned into a transparent top electrode. Positive gate voltage V_G is defined in a direction where electrons are accumulated at CoFeB/MgO interface. The applied V_G of +10V corresponds to an electric field of approximately 0.2 V/nm. Magnetic anisotropy with electric field is first determined from ferromagnetic resonance. Electric-field dependence of effective anisotropy field H_K^{eff} for each t_{CoFeB} is shown in Fig. 1. Sign of H_K^{eff} is positive for all samples, indicating a perpendicular easy axis. H_K^{eff} varies almost linearly with the applied electric field for all the thicknesses. Closer look at the slope reveals that the electric-field effect slightly increases with decreasing t_{CoFeB} as observed in a previous work,[13)] which is accounted for by a screening effect where the electric field penetrates only into sub-nanometer region near the interface. Domain structure under electric field for the same samples is then observed by magneto-optical polar-Kerr-effect microscope. The details of measurement and analysis procedure are described in Ref. 8. Kerr microscope images of the domain structure are taken after ac-demagnetization (Fig. 2(a)). To analyze the structure, we conduct image processing by two-dimensional fast Fourier transform (2D-FFT). This process yields a circular-shape pattern as shown in Fig. 2(b), indicating in-plane isotropic domain structure. The inverse of distance from center in the 2D-FFT pattern represents the distance in real space and D_P is defined as the distance for the peak. Figures 2(c) – (f) show electric-field dependence of D_P for the samples with different t_{CoFeB}. Interestingly, the electric-field modulation of D_P shows non-linear behavior for all t_{CoFeB} unlike the case for H_K^{eff} that varied almost linearly with the electric field (Fig. 1). Note that the variation in D_P in a small electric field region ($|E| <\sim \pm 0.1$ V/nm) is consistent with our previous work,[8)] whereas non-linear response of D_P to the electric field observed in larger region ($|E| >\sim \pm 0.2$ V/nm) has not been reported so far. We finally quantify the electric field effect on A_S using an analytical model that describes the relation between A_S, H_K^{eff}, M_S, and D_P in thin films whose thickness is much smaller than D_P.[12)] Here, spontaneous magnetization M_S is assumed to be unchanged with the electric field because the expected number of electrons accumulated/depleted under $E = \pm 0.3$ V/nm is estimated to be only about 0.008 per a Fe(Co) atom, which is too small to observe sizable change in M_S according to the Slater-Pauling curve.[8)] The analysis with the obtained electric-field dependence of H_K^{eff} (Fig. 1) and D_P (Fig. 2) reveals that A_S shows non-linear response to the electric field and the direction of response depends on the magnitude of the applied electric field. Such a non-monotonic variation in A_S implies that the A_S of CoFeB/MgO is governed by more than two factors, such as p-d hybridization[10,11)] and itinerant 3d band,[14)] which is expected to have an opposite response to the electric field. These results offer significant insight into the understanding of the exchange stiffness in ultrathin magnetic systems and engineering of spintronics devices operated under electric fields. We thank M. Tsujikawa and M. Shirai for fruitful discussion. This work was supported in part by JST-OPERA, JSPS KAKENHI 16J05455, and GP-Spin of Tohoku Univ.

Data transport between the processor and the memory in conventional von-Neumann architecture results in huge power consumption (power wall) and performance degradation (memory wall), known as the von-Neumann bottleneck, which becomes increasingly challenging in current big-data era [1]. Previous studies have shown that moving data is even much more expensive than computing itself [2]. Memory-centric processing-in-memory (PIM) paradigm has been considered as an effective way to address such a data transport bottleneck and maintain the data locality by embedding computation capability into the memory. On the road towards implementing such a promising architecture, finding a novel memory that is able to support dense data storage and logic processing capability is the key step. Unfortunately, until now, such promising studies cannot render practical prototype designs owing to the incompatibility of the state-of-the-art logic and memory technologies within the same die. Recently, the emergence of nonvolatile memories, such as resistive random access memory, phase change memory, and magnetic RAM (MRAM), provide great potential as candidates for PIM implementation. The earliest attempt is based on the material implication with resistive devices [3], which can form a complete Boolean logic set, however, relies on lengthy iteration processes for some certain logic functions. On the other hand, PIM studies based on spintronic devices, e.g., magnetic tunnel junctions (MTJs), have also been widely reported in literature [4]. In comparison with resistive devices, spintronic devices generally can allow for higher endurance, higher speed, and lower power consumption for PIM implementation. In this abstract, we report a voltage-controlled MTJ device, which is a potential candidate for efficient PIM implementation. We fabricated 60/80 nm MTJ devices and characterized at room temperature. The utilization of a voltage (via voltage-controlled magnetic anisotropy, VCMA) instead of a current for MTJ switching is promising to achieve ultralow-power memory and PIM by significantly reducing Joule heating. As shown in Fig. 1(b), the magnetic field for magnetization switching of the MTJ device can be tuned by V_b, which can be exploited for stateful logic operations. The key idea is to program the magnetization or resistance state (denoted as logic value, R) of the MTJ based on the configuration of V_b and H_{ex} (denoted as two logic inputs, p and q). In our experimental demonstration, we set R_{ap} and R_p denote logical value "1" and "0", respectively. Further, we set two V_b, i.e., V_H = +1.0 V and V_L = - 1.0V, denote the logical values "1" and "0" of input p, respectively. Accordingly, we can obtain four critical H_{ex}, denoted as H_1, H_2, H_3, and H_4, respectively, under V_H and V_L for MTJ magnetization switching operations, as shown in Fig. 1(c). In this configuration, we choose H_H and H_L to denote the logical values "0" and "1" for input q, respectively. In practice, the magnetic field can be generated via a current line similar to that in the field-driven toggle-MRAM. In a practical memory chip, the translation between the logical signals and the physical signals can be automatically performed via a peripheral circuity, just like the operations for a regular memory. In the following, we present the experimental demonstration of the Boolean logic functions with our fabricated VCMA-MTJ device. Furthermore, typical stateful Boolean logic functions, e.g., "OR", "AND" and "NXOR", were experimentally demonstrated with the MTJ device, as shown in Fig.2. Based on the above configuration, the final logic state of the MTJ can be transited as diagram in Fig. 1(d). Arbitrary combination logic functions can be realized in two steps: initializing and programming. An additional read step is required to readout the logic output that is in-situ stored in the MTJ (or memory cell). Our work opens up a new way for PIM implementation in spintronic memories.

FC-08. Ultrafast random number generator based on voltage-controlled switching.

A. Fukushima[1], T. Yamamoto[1], T. Nozaki[1], K. Yakushiji[1], H. Kubota[1] and S. Yuasa[1]
1. Spintronics Research Center, National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan

Random number generator is one of the key elements of security devices. We have developed a new type of random number generator (RNG) based on spin torque switching in small magnetic tunnel junctions (MTJs), named spin dice [1]. Setting the pulse current to switch an MTJ with the switching probability of 50%, the switching results are unpredictable and can therefore be used as an ideal entropy source of random number generator. In our previous study [1], we generated random numbers from an MTJ by the verbose procedure using a pair of the initial pulse and the excite pulse to obtain the same initial state and the same switching probability. Consequently, the speed of random number generation was limited to about several hundred Mbit/sec. Later, a modified version of spin dice with enhanced generation speed was proposed, where two different current pulses are applied depending on the parallel or antiparallel magnetic state, and both current pulses switch the MTJ by 50% [2]. Spin dice using a random telegraph noise type switching in a super-paramagnetic tunnel junction was also proposed as RNG with lower power consumption [3]. Recently, the voltage-controlled switching in perpendicular magnetic tunnel junctions (p-MTJ) has been attracting considerable attentions due to its high switching speed and ultra-low power consumption. We have studied the mechanism of the voltage-controlled switching events [4], where the switching probability oscillatory varies as the function of the voltage pulse width in nanosecond regime. With an appropriate pulse width, the voltage-controlled switching can yield the switching probability of 50% and therefore be used as a new type of entropy source for spin dice. Furthermore, the circuit concept of RNG based on voltage-controlled switching in an MTJ has already proposed [5]. Here, we experimentally demonstrate random number generation using voltage-controlled switching in p-MTJ. The p-MTJ has the bottom-free and top-pinned structure. The p-MTJ film was deposited on a thermally oxidized Si substrate with a thick bottom Cu lead electrode at room temperature. The film stack was [substrate/ bottom electrode/ Ta(5)/ $Co_{24}Fe_{56}B_{20}$(1.1)/ MgO(1.4)/ $Co_8Fe_{72}B_{20}$(1.4)/ W(0.3)/ Co(0.5)/ synthetic antiferromagnetic layer (CoPt/ Ru/CoPt)/ capping layer], where numbers in parentheses are the thicknesses in nm. The MgO thickness was adjusted to have the resistance-area (RA) product about 1 kΩμm^2. After the deposition, the film was annealed at 250 degrees C for 1 hour and then was fabricated into circular junctions with about 80 nm diameter (the resistance of the p-MTJ is about 200 kΩ) using a conventional microfabrication process. The switching probability (P_{sw}) of the p-MTJ was measured at room temperature using the experimental setup shown in Fig. 1. The external magnetic field (H) of 900 Oe with the polar angle θ of 80 degrees was applied to the p-MTJ to slightly tilt the free-layer magnetization from perpendicular direction. Voltage pulses with the duration time t_{pulse} were generated by a pulse generator and were fed into the p-MTJ through the rf port of a bias tee. To sense the tunneling magnetoresistance effect, the p-MTJ was biased at about 30 mV by a dc voltage source through a 1 MΩ resister. The magnetization configuration of p-MTJ, either parallel (P) or antiparallel (AP), was measured by the voltage across p-MTJ using a real-time oscilloscope. P_{sw} depends on the voltage pulse amplitude and t_{pulse}. We choose the voltage amplitude of 1.26V, which was the highest possible voltage below a breakdown voltage, to obtain the fast magnetization switching. Figure 2(a) shows the t_{pulse} dependence of P_{sw}, where P_{sw} varies oscillatory as a function of t_{pulse}. The t_{pulse} of 0.36 ns was chosen to generate random numbers from the switching results of P to AP switching, because P_{sw} was too sensitive to t_{pulse} to control at the shorter pulse range (t_{pulse} < 0.2 ns). Output voltage of the MTJ after switching trials is shown in Fig. 2(b), and its histogram is shown in Fig. 2(c). The unbalance between P and AP peaks in Fig.2(c) is due to a slightly higher switching probability (> 0.5) from AP to P state. By setting the intervals between the voltage pulses to 10 ns t_{pulse}, the speed of random number generation speed can be up to 100 Mbit/sec, which is 2 orders of magnitude faster than the previous spin dice. Moreover, the voltage-controlled spin dice is suited for the parallel processing with a large number of MTJs because each MTJ consumes a very small power. The voltage-controlled switching in p-MTJs will be one of the promising candidates for a ultrafast physical random number generator. This work was funded by ImPACT Program of Council for Science, Technology and Innovation (Cabinet Office, Government of Japan).

The choice of proper materials for magnetic tunnel junctions (MTJs) for storage and communication applications (like MRAM or spin-transfer-torque nano-oscillators (STNOs)) is always an issue. On the one hand, the magnetic layers should exhibit as little stray field as possible and be mostly insensitive to the external magnetic field. On another hand, in order to maximize the tunneling magnetoresistance (TMR) ratio, these materials should provide high spin polarization, or even ideally possess half-metallic properties. An option which satisfies both criteria are the compensated half-metallic ferrimagnets (CHFMs) — a class of materials predicted in 1995 by van Leuken and de Groot [1]. CHFMs are materials which behave as antiferromagnets (AFMs) with respect to external magnetic fields, since the magnetic moments of the two sublattices compensate, while simultaneously exhibiting half-metal behavior from the point of view of magnetotransport. Experimentally, the first identified zero-moment half-metal was Mn_2Ru_xGa (MRG) in 2014 [2]. It was already known that Mn-based Heusler compounds possess huge uniaxial anisotropy fields (exceeding tens of teslas [3]); this, together with their vanishing magnetization, lead to resonance frequencies of several hundred GHz in such materials [4,5], making them very attractive candidates for STNOs in the sub-THz range [6]. Such devices, due to the much higher bandwidth accessible, are expected to open the way for remote hospitals, 3-D remote meetings and much more. Earlier MRG studies have already shown that these materials exhibit tunable magnetic properties. Indeed, the compensation temperature varies between 2 and 450K, depending on the Ru concentration [2]. They also yield giant spontaneous Hall angle (7.7%) [7]. MRG has also been successfully integrated into perpendicular MRG/MgO/CoFeB MTJs, with low-bias TMR reaching up to 40 % at 10 K and 7 % at 300 K [8]. As the low value of TMR was attributed to diffusion of Mn atoms inside the MgO barrier, here, we investigate the effect of different insertion layers introduced between MRG and MgO on the magnetic properties and transport of MTJs. Mn_2Ru_xGa (23)/insertion layer(t)/MgO(1.7)/CoFeB(1)/Ta(0.3)/CoFeB(0.9)MgO(0.7)/Ta(3)/Ru(4) multilayers were deposited using a "Shamrock" fully automated sputter deposition tool (thickness given in nm). Mn_2Ru_xGa was grown by co-sputtering from a Mn_2Ga and a Ru target. Different MRG compositions ($Mn_2Ru_{1.1}Ga$, $Mn_2Ru_{0.9}Ga$, $Mn_2Ru_{0.75}Ga$, and $Mn_2Ru_{0.65}Ga$) have been obtained by varying the sputtering power of Mn_2Ga while keeping the sputtering power of Ru constant. Changing Ru concentration in MRG allows adjusting the compensation temperature T_{comp} from 2 to 450 K. We fabricated MTJs without insertion layers, as well as stacks with Ta (0.3 nm, 0.6 nm, 0.9 nm) and Al (0.3 nm, 0.6 nm, 0.9 nm) insertion layers. The switching properties of MTJs were analyzed through magnetotransport measurements as a function of applied bias voltage at room temperature. Al 0.6 nm acts as the best diffusion barrier. Magnetic properties of the multi-layers were characterized by the quantum design superconducting quantum interference device (SQUID) with a maximal applied field of 7n T at the range of temperatures from 60 K to 300 T. The magnetometry data was extracted from the typical out-of-plane hysteresis loop of the investigated MTJs (Fig.1). As the magnetic field is swept from +7 T to – 7 T, the magnetic moment of CoFeB starts to rotate first and switches close to 0 T. The sharp jump observed at -0.4 T is attributed to the reversal of MRG magnetization. With conducting the same measurements at different temperatures, it is possible to detect the compensation temperature of MRG, which will lead to a decrease of its magnetic moment and a divergence of the coercive field. The temperature with zero magnetic moment and extremely high H_c corresponds to the compensation point of MRG (the grey area in the Fig.2). In Fig.2 the temperature dependence of magnetic properties of MTJs with the same MRG composition, but different diffusion barriers, is presented. For different insertion layers, T_{comp} can shift over a large range, showing that the choice of insertion layer can have a dramatic effect on the properties of MRG. For instance, in MTJs with no insertion layer 100 K < T_{comp} < 160 K; the shift to the higher temperatures is observed for Ta 0.3 nm insertion (140 K < T_{comp} < 200 K), and to the lower temperatures with Al 0.6 nm insertion (T_{comp} < 120 K). Moreover, we demonstrate that T_{comp} can also be altered by post-annealing, as a 20 K shift is observed after annealing at 325°C for 1 hour. Mn_2Ru_xGa integrated into MTJs demonstrates a low magnetic moment, high coercivity, and thereby high immunity to the applied magnetic field over a broad temperature range (60 K – 300 K). At the same time, these MTJs show TMR even at the compensation temperature [10], highlighting a fundamental difference between an AFM and a CHFM. All these make MRG extremely attractive for spintronics applications, and for the excitation of magnetic resonances in STNOs. Part of this work was carried out under the EU Project TRANSPIRE - DLV-737038.

Perpendicular magnetic tunnel junctions (p-MTJs) based on MgO/CoFeB structures are drawing attention as their excellent thermal stability, scaling potential, and power dissipation are significant for the study of spin-transfer torque magnetic random access memories (STT-MRAMs) [1]. In particular, p-MTJs with a MgO/CoFeB/heavy metal structure have been thoroughly studied for their enhanced perpendicular anisotropy that originates from both MgO/CoFeB and CoFeB/heavy metal interfaces [2], bringing a reasonable magnetoresistance ratio (TMR) and STT switching threshold current density (*Jc*). Moreover, p-MTJs with a double MgO/CoFeB interfaces free layer, have been shown to have a considerably better thermal stability factor (Δ) and *Jc* compared to that of p-MTJs with a single interface [3]. However, it is still challenging to realize both a large TMR and a low junction resistance in p-MTJ nanopillars that can perform current-induced magnetization switching. In this work, the bottom-pinned p-MTJ stack with atom-thick W layers and double MgO/CoFeB interfaces are patterned into nanopillars to demonstrate the current-induced magnetization switching, which present a large TMR of 249%, a resistance area product as low as 7.0 $\Omega\mu m^2$ and relatively low *Jc* at room temperature (Fig. 1). Furthermore, by using the first-principle calculation, we find that atom-thick W layers can induce resonant tunnelling transmission that are more efficient than Ta layer, providing a comprehensive explanation to the origin for this large TMR [4]. Besides, the robustness of W layers against high temperature diffusion can avoid TMR degradation during annealing (Fig. 2). We expect that this work can contribute to the research and development of STT-MRAMs.

FC-12. Highly (001)-textured $MgAl_2O_4$-based magnetic tunnel junctions with large magnetoresistance over 240%.

I. Tiar[1], *H. Sukegawa*[1], X. Xu[1], M. Belmoubarik[1], H. Lee[1], S. Kasai[1] and K. Hono[1]

Recently, $MgAl_2O_4$ spinel-based oxides (Mg-Al-O) have been investigated as alternatives to MgO for barrier materials in a magnetic tunnel junction (MTJ) [1]. Tunnel magnetoresistance (TMR) ratios over 300% at room temperature (RT) were observed in epitaxial Mg-Al-O based MTJs due to the coherent tunneling mechanism [1,2]. Nevertheless, polycrystalline Mg-Al-O based MTJs in combination with CoFeB electrodes failed to show a large TMR ratio due to the absence of (001) texture in Mg-Al-O grown on amorphous CoFeB [3]. Therefore, achieving highly (001) textured Mg-Al-O on CoFeB is critical in realizing industrially viable polycrystalline spinel-based MTJs. Here we report (001) textured Mg-Al-O barriers realized through the use of CoFe/MgO insertion between Mg-Al-O and CoFeB [4]. The insertion worked as an effective templating layer in order to obtain a highly textured Mg-Al-O(001) barrier. Large TMR ratios exceeding 240% at RT were obtained in the polycrystalline CoFeB/Mg-Al-O/CoFeB MTJs. Pseudo-spin-valve type MTJ stacks of Si/SiO_2 substrate/Ta (5)/Ru (10)/Ta (5)/$Co_{20}Fe_{60}B_{20}$ (CoFeB) (5)/$Co_{75}Fe_{25}$ (CoFe) (1)/MgO (t_{MgO} = 0-0.7)/Mg-Al-O (1.2)/CoFeB (3)/Ta (5)/Ru (5), (thickness in nm) were prepared using RF/DC magnetron sputtering system at RT (base pressure ~ $1x10^{-6}$ Pa). The Mg-Al-O layer was RF-sputtered [5] from two different sintered targets with the Mg-Al compositions of Mg-rich Mg_2Al-O_x and Al-rich $MgAl_2-O_x$. The stacks were patterned into elliptical pillars (200x400 nm^2) using electron-beam lithography, photolithography, and Ar-ion etching. The MTJs were then post-annealed at 500°C. Magnetotransport measurements were performed at RT by DC 4-probe method under in-plane magnetic fields. For microstructural analysis, high resolution scanning transmission electron microscopy (STEM) imaging was performed using an FEI G2 80-200 Titan transmission electron microscope equipped with an aberration probe corrector. Figures 1 shows the cross-sectional bright-field STEM image of an $MgAl_2-O_x$ MTJ stack with t_{MgO} = 0.7 nm. The grain-to-grain epitaxy of CoFe(B)/Mg-Al-O/CoFe(B) with the (001) orientation was observed. Therefore, the CoFe/MgO insertion effectively promotes the crystallization of Mg-Al-O. Additionally, the MgO/$MgAl_2-O_x$ bilayer was confirmed to transform into a single barrier layer. No misfit dislocations are observed within the Mg-Al-O grain. Therefore, the structural prerequisite for the coherent tunneling was fulfilled. The formation of the uniform Mg-Al-O barrier, i.e., a CoFeB/Mg-Al-O/CoFeB(001) structure, is very likely to reduce the lattice mismatch with CoFeB-based electrodes. Figure 2 shows the TMR ratio (upper panel) and resistance-area-product (*RA*) (lower panel) as a function of t_{MgO} for Mg-rich Mg_2Al-O_x and Al-rich $MgAl_2-O_x$ MTJs. The trend of ln(*RA*) versus t_{MgO} for the Mg_2Al-O_x MTJs is almost linear, suggesting that the MgO/Mg_2Al-O_x bilayer forms a physically single barrier for a wide t_{MgO} range. The TMR ratio increases with increasing t_{MgO}, and a large TMR ratio up to 242% is achieved (see the inset of Fig. 2). This significant TMR enhancement can be attributed to the Δ_1 symmetry filtering effect by the coherent tunneling through the barrier. For the $MgAl_2$-O MTJs, the non-linear In(*RA*) regime and much smaller TMR ratios are observed for t_{MgO} < 0.3 nm due to a loss of the (001) texture. Therefore, the MgO insertion and Mg-Al compositional optimization are important to obtain a (001) textured Mg-Al-O barrier. Further enhancement of TMR ratio can be expected through fine tuning of elemental composition and process optimization. This study demonstrates the industrially viability of polycrystalline spinel-based barriers for spintronic devices with a large TMR signal output. This work was partly supported by the ImPACT Program of Council for Science, Technology and Innovation, Japan, and JSPS KAKENHI Grant 16H03852.

FD-01. Finding the separation between first- and second-order phase transitions in $La(Fe,Ni,Si)_{13}$ magnetocaloric materials.

L.M. Moreno-Ramírez[1], J. Law[1], C. Romero-Muñiz[2], *V. Franco*[1], A. Conde[1], F. Maccari[3], I.A. Radulov[3], K. Skokov[3] and O. Gutfleisch[3]

Magnetocaloric (MC) materials have the potential to renew the basis of refrigeration technologies for the next years. To date (and since first commercial devices in 1927), refrigerators operate by expansion/compression of gases in a closed circuit where the condensation/evaporation produces wasted heating/the cooling of a load. The main disadvantages of such devices are their usage of non-environmental-friendly gases (e.g. ozone depletion) and low energy efficiency. Conversely, magnetic refrigerator using magnetocaloric materials addresses these issues by utilizing solids of non-contaminating refrigerants and their prototypes show a larger energetic efficiency. In this case, the MC material replaces those gases and the expansion/compression is replaced by the application/removal of a magnetic field. The largest reversible temperature variation of a material submitted to a variable magnetic field in adiabatic conditions (ΔT_S) occurs near the temperature of a magnetic or magnetostructural phase transition. These phase transitions can be classified as first order (FOPT) or second order ones (SOPT) according to the Ehrenfest classification. Therefore, the MC characterization is not only useful from a technological point of view but can also be used to extract information about the phase transition. It has been demonstrated that assuming a power law expression for the field dependence of the magnetic entropy change (ΔS_T), taking the form $\Delta S_T(T,H)=a(T)\Delta H^{n(T,H)}$. The values of the exponent n at the transition temperature (T_{trans}) are related with the critical exponents of a SOPT as $n=1+(1-1/\beta)/\delta$, where the exponents β and δ give the temperature dependence of M at zero field and the field dependence of M at T_{trans}, respectively. For materials with long range interactions the values of $n(T_{trans})$ in SOPT are typically close to those using the critical exponents for mean field model (0.67). On the other hand, for short range interactions, the typical values are close to Heisenberg or 3D-Ising models (0.63 and 0.57, respectively). For the $n(T_{trans})$ of SOPT there exists a lower limit that corresponds to the case where the material transits from a SOPT to a FOPT character, this point is called the critical point of the second order phase transition. The value at that point is 0.4 according to the critical exponents obtained from theoretical considerations. For FOPT, even if there is no critical region, the field dependence of ΔS_T in the high field range leads to n values lower than 0.4. Therefore, a clear criterion exits to identify the change from SOPT to FOPT according to the values of $n(T_{trans})$. One of the most promising families of magnetocaloric materials are LaFeSi alloys. These alloys show a magnetic FOPT that implies a large magnetocaloric response. Hydrogenation of the samples shifts the transition temperature from ≈200 K to temperatures close to room temperature, to facilitate their applications in devices. However, some issues have to be solved before commercialization: its cyclic stability needs to be improved and thermal hysteresis is to be minimized. Different dopants can be used to tune properties such as T_{trans}, the MC response and hysteresis. In this work, we study the magnetocaloric properties of LaFeSi alloys doped with Ni ($LaFe_{11.6-x}Ni_xSi_1$ with x=0, 0.1, 0.2, 0.3 and 0.4). Microstructural characterization (BSE and XRD) shows a high percentage of $LaFe_{13}$ phase in the alloys. EDX analysis confirms the desired nominal compositions. Magnetocaloric characterization has been performed by indirect measurements of ΔS_T (from magnetization measurements) and direct measurements of ΔT_S (dedicated device built in TU Darmstadt). Figure 1 shows how the temperature dependence of ΔT_S is modified by the addition of Ni. The criterion to distinguish the order of the phase transition from the value of the exponent of the field dependence of ΔS_T has been applied (Figure 2). This procedure allows us to estimate the composition for which the transition is in the critical point of the second-order phase transition (sample with x=0.21), also shown in Figure 2. DFT calculations have been performed in order to explain the role of Ni atoms in $LaFe_{13}$ phase, showing a good agreement with experimental data. FD-02. Magnetocaloric effect in melt-spun rare earth high entropy alloy YGdTbDyHo.

N. R[1], A. Sankar[1], A. Chelvane[2], A. Morozkin[3], A.K. Nigam[4], S. Quezado[5] and S.K. Malik[5]
1. Physics, Indian Institute of Technology Madras, Chennai, India; 2. DMRL, Hyderabad, India; 3. Lomonosov Moscow State University, Moscow, Russian Federation; 4. TIFR, Mumbai, India; 5. UFRN, Natal, Brazil

In the last decade, high entropy alloys (HEA) have emerged as novel materials for various applications with superior mechanical and corrosion resistance properties. These generally contain five or more major principal elements in nearly equimolar ratio and the formation and stability of the alloy phase is determined by Gibb's free energy of mixing. Recently, a rare earth high entropy alloy, namely, YGdTbDyHo, has been found to crystallize in single phase, in Mg-type hexagonal close packed structure [1]. This particular system is considered very special because it is formed on a hcp lattice of near zero-distortion but with a huge chemical disorder thus possessing a dual nature of a metallic glass on an ordered lattice. In addition, this alloy presents a very complex, magnetic field-temperature phase diagram and promises to be a potential material for magnetocaloric applications [2, 3]. Since melt-spinning technique is known to yield a highly crystalline giant magnetocaloric materials such as $La(Fe, Si)_{13}$ with superior magnetic and magnetocaloric properties [4], the YGdTbDyHo HEA has been prepared by this rapid solidification process and studied. Melt-spinning leads to texture effects in the sample. The room temperature X-ray diffraction data confirm the hcp structure and the formation of preferred crystal orientation in the melt-spun sample of YGdTbDyHo alloy. The intensity of Bragg reflection (0 0 2) is found to get greatly enhanced in the melt-spun ribbon of YGdTbDyHo. The sample composition has been confirmed using EDAX analysis. The arc-melted and melt-spun samples of YGdTbDyHo show an antiferromagnetic cusp around 178 K and 176 K in their magnetization vs temperature data obtained in 5 kOe field. Both samples develop ferromagnetic interactions at low temperatures. The field-cooled magnetization data shows thermal hysteresis around this first order AFM-FM transition. The thermal hysteresis is more pronounced in the field-cooled magnetization data of the melt-spun sample and that could be related to the enhanced anisotropy. Field dependent magnetization (M-H) data at 2 K and 5 K display a metamagnetic transition in both samples with a tendency to saturate in high fields. The isothermal magnetic entropy change (ΔS_m) close to T_N has been calculated from the M-H data. The maximum isothermal magnetic entropy change, ΔS_m^{max}, is ~6.3 J/kg K and ~6 J/kg K for the arc-melted and melt-spun YGdTbDyHo alloy for 50 kOe field change, near T_N [Fig. 1a-b]. The sluggish nature of the magnetic transition in this high entropy alloy system leads to a broad spread of magnetic entropy over a large range of temperatures and hence the relative cooling power values are reasonable. Small positive DS_m values are observed for small field changes signify the underlying antiferromagnetic interactions present in this system. These values gradually change to show normal magnetocaloric effect as the system undergoes metamagnetic transition into a ferromagnetic state. Thus rare earth based high entropy alloys offer a novel test bed for the study of competing RKKY interactions and also provide a possibility to build alternative magnetocaloric materials.

We present x-ray diffraction and SQUID magnetometry measurements taken under various applied pressures that demonstrate the shift in magnetic transition temperatures in the magnetocaloric high entropy alloy system FeCoNiCuMn. Bulk samples of equiatomic and near-equiatomic FeCoNiCuMn are produced via arc melting and melt spinning, a process in which molten ingots are rapidly quenched on a spinning wheel, producing powder and flakes of sample with a metastable, single phase face-centered cubic crystal structure. Our previous work identified this alloy system as a viable material for use in magnetocaloric applications due to the ease with which the Curie temperature of the alloys can be tuned with small (~1%) compositional changes, as well as the relatively large saturation magnetization of the alloys within the system with Curie temperatures at room temperature. [1] The random distribution of atoms on the crystal lattice lead to distributed exchange interactions, which broadens the change in magnetic entropy in the temperature range above and below the Curie temperature, increasing the refrigeration capacity of these alloys. We have characterized the nature of these exchange interactions using Mössbauer spectroscopy and found that the hyperfine field distributions of these alloys (fig. 1) are made up of several distinct, discrete peaks which we suggest are evidence of individual pairwise interactions between the three ferromagnetic components in these alloys (Fe, Co and Ni) [2]. The presence of discrete pairwise exchange interactions can be used to better understand the magnetic behavior of these alloys under applied pressure. M(T) curves measured after zero field cooling samples in a pressure cell show that the ferromagnetic to paramagnetic transition temperature decreases with increasing applied pressure, likely due to the smaller lattice spacing that forces atoms closer together, which favors antiferromagnetic exchange. X-ray diffraction of equiatomic FeCoNiCuMn under up to 9GPa of applied pressure show a shift in the lattice parameter of the FCC crystal structure from 3.615 Angstroms to 3.602 Angstroms over the applied pressure range of 0GPa to 9GPa, a 1% decrease in total cell volume, but no changes in phase stability or crystal structure are seen. The Bethe-Slater curve shows the empirical relationship between lattice spacing and exchange energy in magnetic elements, and the average exchange energy estimated by the lattice spacing of our alloys with applied pressure increases as well, suggesting that the Curie temperature of the alloy should get larger with pressure. However, the experimental ferromagnetic to paramagnetic transition temperature decreases with increasing applied pressure, likely due to the discrete pairwise antiferromagnetic interactions Mn-Mn and Mn-Fe, which are favored with decreased atomic spacing. We analyze the observed transitions using the Ehrenfest equations, supplemented with heat capacity data previously measured for these samples. [3] The M(T) curves measured after zero field cooling samples also reveal an antiferromagnetic to ferromagnetic phase transition at low temperatures that is not seen during field cooling due to the coupling of moments in the ferromagnetic phase (fig. 2). This transition is not observed to change with applied pressure. Additionally, we found that compositional tuning of these alloys, which has been used to shift the Curie temperatures in the range of 265K to 400K, does not influence the antiferromagnetic to ferromagnetic transition temperature, and this transition is not observed at all for FeCoNiCuAg, a high entropy alloy in which antiferromagnetic Mn is replaced with diluent noble metal Ag. This indicates that this magnetic behavior arises entirely from the presence of Mn-Mn or Mn-Fe interactions, ruling out the possibility that there are contributions from Fe-Fe antiferromagnetic interactions.

Abstract Magnetic cooling is an energy efficient and environmentally friendly thermal management technology. We report the magnetocaloric properties of low cost, high relative cooling power $Fe_{75-x}Mn_xAl_{25}$ ($12.5 \leq x \leq 20$) alloys with tunable Curie temperatures. A second order magnetic phase transition with negligible magnetic and thermal hysteresis was observed. $Fe_{60}Mn_{15}Al_{25}$ and $Fe_{57.5}M_{17.5}Al_{25}$ exhibited high values of relative cooling power i.e. 395 Jkg^{-1} and 430 Jkg^{-1} and Curie temperatures near room temperature, making such alloys technologically attractive. The low cost, easy availability and established manufacturing technology make these alloys attractive candidate materials for magnetic cooling applications. *Introduction* Global warming, climate change and the impact of ozone layer depleting chemicals necessitate alternatives to conventional gas compression based technology. Magnetic cooling offers significantly higher energy efficiency and no harmful gas emissions[1]. Recently many leading companies, like BASF, Haier and Astronautics Corporation of America have shown considerable interest in developing magnetic cooling systems and a commercial wine cooler has been developed[2]. Magnetic cooling is based on the magnetocaloric effect (MCE) which is manifested in the magnetocaloric material (MCM) by a heating or cooling effect due to the application or removal of an external magnetic field[3]. Figures-of-merit include isothermal magnetic entropy change ($-\Delta S_m$) and relative cooling power (RCP)[4]. Although rare earth (RE) metal based alloys show high $-\Delta S_m$ values the high processing cost, geographical limitations in availability and poor corrosion resistance makes these materials less suitable for commercial applications[5]. Several low cost first order transition materials exhibit "giant" MCE cost but they suffer from thermal hysteresis and narrow operating temperature range, which degrades the performance of device[6]. On the other hand, Fe based transition metal alloys are easily available, low cost, exhibit second order transitions (hence negligible hysteresis) and offer Curie temperature (Tc) tuning over a broad temperature range[7]. We explore the magnetocaloric properties in Fe-Al based alloys as they are commercially proven materials due to their low cost, excellent oxidation resistance, superior mechanical properties and established manufacturing techniques[8]. The high Tc of Fe_3Al composition was reduced to near room temperature by substitution of Fe by Mn without compromising on the magnetization values of Fe_3Al. We report for the first time the magnetocaloric properties of $Fe_{75-x}Mn_xAl_{25}$ alloys. *Experimental* Buttons with nominal compositions of $Fe_{75-x}Mn_xAl_{25}$ (x = 12.5, 15, 17.5 and 20) were prepared from high purity (~ 99%) elemental Fe, Mn and Al in an arc melter (Edmund Buhler, MAM-1) under Ar gas atmosphere and further annealed at 1000 ˚C for 48 h to achieve homogenization. The MCE properties were investigated by a Physical Property Measurement System (PPMS) unit, (EC-II, QD, USA) with a VSM head. *Results and discussion* Temperature dependent magnetization measurements at 1 kOe from 400 K to 10 K were performed to determine the Tc and magnetization values. 15 % and 17.5 % Mn addition in $Fe_{75-x}Mn_xAl_{25}$ yielded Tc values near room temperature, i.e., 305 K and 265 K respectively (Fig. 1). This reduction of Tc by addition of Mn can be explained by antiferromagnetic ordering of Mn in Fe-Al. As the Mn content increased, the effective exchange integral decreased, leading to more antiferromagnetic coupling[9]. A similar decrease in Tc upon Mn addition was observed in other iron based MCM[10]. For MCE property evaluation, field dependent isothermal magnetization curves were recorded from 10 K to 400 K at temperature intervals of 5K. The $-\Delta S_m$ was calculated using Maxwell's equation, for a range of magnetic field strengths (ΔH = 1 to 5 T). The behavior of $-\Delta S_m$ with magnetic field (Fig. 2(B)) showed a linear change in $-\Delta S_m$ values for both 15 % Mn and 17.5%Mn samples suggesting the absence of magnetic inhomogenities. The highest value of $-\Delta S_m$ was 1.07 $Jkg^{-1}K^{-1}$ at 5 T for 17.5%Mn. RCP is another important performance metric that quantifies the amount of heat that can be transferred from the hot end to the cold end during operation of a cooling cycle. It can be expressed as where is the temperature span at full width of half maximum. RCP values of 430 Jkg^{-1} and 395 Jkg^{-1} were observed for 17.5%Mn and 15 % Mn samples at 5 T (Fig. 2(A)). These value are higher than $Co_{71}Mo_9P_{14}B_6$ metallic glasses which showed $-\Delta S_m$ of 0.96 $Jkg^{-1}K^{-1}$ and RCP of 70.5 Jkg^{-1} and high entropy alloys like $NiFeCoCrPd_{0.25}$ which showed $-\Delta S_m$ of 0.9 $Jkg^{-1}K^{-1}$ and RCP of 215 Jkg^{-1} at 5 T [11, 12]. *Conclusions* The magnetocaloric properties of $Fe_{75-x}Mn_xAl_{25}$ alloys were explored for the first time. They exhibited high RCP values as well as Curie temperatures at desired values near room temperature for x = 15 and 17.5 alloys. The low cost, established manufacturing techniques, good corrosion and oxidation resistance and negligible hysteresis makes these alloys attractive for magnetic cooling. *Acknowledgement* This research is supported by grants from the National Research Foundation, Prime Minister's Office, Singapore under its Campus of Research Excellence and Technological Enterprise (CREATE) programme.

FD-05. Magnetocaloric effect in diluted magnetic ferroelectric: $Ba_{0.6}Eu_{0.4}TiO_3$.

K. Rubi[1] and *R. Mahendiran*[1]
1. Physics, National University of Singapore, Singapore

Magnetic refrigeration is an emerging technology based on magnetic solids that act as a refrigerants by magnetocaloric effect(MCE). Magnetic refrigeration makes use of the fact paramagnetic and ferromagnetic materials heat up upon increasing external magnetic field in an isothermal process and cool below the starting temperature when the external magnetic field is removed adiabatically. Many studies have devoted to Gd- based intermetallics, Heusler magnetic alloys, Mn-based oxides, MnAs based compounds and rare earth free $(LaFe)Si_{13}$, MnPSi[1,2,3,4] Although major thrust is to find cheaper and reliable materials for room temperature magnetic cooling, high performance materials are also needed for cryogenic magnetic refrigeration particularly for temperatures between 1 K and 20 K - the temperature range where hydrogen gas/fuel can be converted into liquid form. In this work, we report the occurrence of a large magnetocaloric effect in ferroelectric material doped with a magnetic element for the first time. We have measured the magnetization, heat capacity and magnetization isotherms in $Ba_{0.6}Eu_{0.4}TiO_3$. Seven unpaired 4f electrons associated with Eu^{2+} ion order antiferomagnetically below 5.6 K in $EuTiO_3$ [5]. The substitution of Ba^{2+} for Eu^{2+} dilutes magnetic interactions between 4f ions on neighboring Eu^{2+} sites. Our magnetization data indicates that $Ba_{0.6}Eu_{0.4}TiO_3$ is paramagnetic down to 2 K in zero field but the application of a 5 T magnetic field at 2 K saturates the 4f spins. Magnetic entropy change (ΔS_m) was calculated from M-H isotherms and adiabatic temperature change (ΔT_{ad}) was estimated from the zero field heat capacity and $\Delta S_{m.}$ We found ΔS_m = 25 J/Kg.K at 2K and ΔT_{ad} = 16.5 K at 5 K for a field change of 5 T. This is the highest adiabatic temperature change found in a diluted magnetic oxide for temperatures above 1 K.

Physics Department, Aveiro University - I3N, Aveiro, Portugal

Since the discovery of the Giant Magnetocaloric Effect (GMCE) near room temperature on $Gd_5Si_2Ge_2$ by Pecharsky and Gschneidner in 1997 [1], the $Gd_5(Si_{1-x}Ge_x)_4$ alloys have been intensively studied for magnetic refrigeration (MR) application. The magnetic entropy change of $Gd_5Si_2Ge_2$ is 25% higher than the observed in pure Gd – that is the reference material for MR at room temperature. The thorough $Gd_5(Si_{1-x}Ge_x)_4$ research performed so far revealed many other important properties, such as giant magnetoresistance and colossal magnetostriction (CMS) [2,3]. The interplay between magnetic and structural behavior in these system leads to an extreme sensitivity to variation of external (e.g., temperature, magnetic field and pressure) and internal (e. g. stoichiometry, dimensionality and doping) parameters. Such features makes these materials very promising for a wide range of applications such as MR at room temperature, actuator/sensors and energy harvesting. Few reports are dedicated to the study of the $Gd_5(Si_xGe_{1-x})_4$ system in a reduced dimensionality, such as thin films and nanoparticles. A recent work performed by our team have successfully obtained $Gd_5Si_{1.3}Ge_{2.7}$ granular thin film, ~790 nm thick, using the femtosecond pulsed laser ablation technique, but still with a significant amount of an unknown phase and a wide size distribution [4]. Through Synchrotron X-ray Diffraction collected in the [150,250] K range, we have shown that the obtained thin film presents a giant thermal expansion of 8000 ppm, showing its potential for sensing/actuating applications. Although femtosecond pulsed laser ablation proved to be a good technique to obtain these films without oxidation issues, it is an expensive and irreproducible method that does not guarantee a continuous surface or a homogeneous distribution. Thus, a more conventional and accessible nanosecond pulsed laser deposition was chosen to produce these metal nanoparticles (NPs). For such purposes, $Gd_5(Si_{1-x}Ge_x)_4$ with x = 0.55 and 0.6 bulk targets were chosen since they present a stable orthorhombic Gd_5Si_4-type [O(I)] structure across the magnetic transition at 301 K and 307 K, respectively [1]. The targets were produced by tri-arc melting and ablated by an Excimer KrF laser with 248 nm of wavelength, pulse duration of 20 ns with a repetition of 10 Hz and maximum energy of 550 mJ. In order to prevent oxidation issues, the chamber was pumped several times down to a base pressure of 10^{-6} Torr. For the deposition, Argon was used as the inert gas in a continuous flux in a constant pressure of 1 Torr inside the chamber and the substrates were positioned 1 cm away from the target. Two types of substrates were used to collect the nanoparticles: *i)* carbon coated grids for HR-TEM imaging and *ii)* Si (001) substrate for magnetic measurements. The TEM micrographs obtained for all samples have revealed that NPs produced by PLD present an average particle size below ~30 nm and good crystalline features. As can be seen in Fig. 1(a) for x = 0.55 composition, particles present a continuous crystalline morphology with a broad particle size distribution. An amplified image allows the observation of the interplanar distances, as shown on the inset of Fig.1(a), that correspond to the observed peaks on the X-ray diffraction patterns (not shown) and is related with the (231) plane of the O(I) phase. Magnetic results confirm that there is no changes on the Curie temperature (T_C) in relation with the bulk targets, as highlighted in Fig. 1(b) for each sample. On the inset of Fig. 1(b), it is possible to observe that the systems do not reach saturation at 5 K. By extrapolating the M vs. 1/H curve we obtain that the saturation magnetization are approximately 3.3 μ_B/Gd^{3+}, 50% less than the targets, surely associated with the particle size confinement [6]. Thereby, we can conclude that the nanosecond PLD successfully produce dispersed crystalline nanoparticles of $Gd_5(Si_{1-x}Ge_x)_4$ family compounds. This technique allows the formation of NPs with particles size under 30 nm without loss on the stoichiometry of the targets, since there is no change on the T_C [6]. Notwithstanding, there is a reduction on the saturation magnetization at low temperature as a consequence of dimensionality confinement.

FD-07. Influence of overlapping transitions on the MCE response of a series of $Ni_{0.49-x}Mn_{0.36+x}In_{0.15}$ Heusler alloys.

J. Law[1], V. Franco[1], A. Conde[1] and A. Giri[2]

2. Weapons and Materials Research Directorate, US Army Research Laboratory, Aberdeen, MD, United States

Metamagnetic NiMn-based Heusler alloys are one of the promising rare-earth-free magnetocaloric materials due to their attractive large magnetocaloric effect (MCE) arising from their first order phase transition (FOPT). Both austenitic and martensitic states of $Ni_{0.50}Mn_{0.5-y}In_y$ are ferromagnetic for composition of $0.15 \leq y \leq 0.16$ [1, 2]. For $Ni_{0.50}Mn_{0.34}In_{0.16}$, it exhibits an inverse MCE of ~12 J kg^{-1} K^{-1} at 190 K, which is far away from room temperature [2]. On the other hand, for y=0.15 in $Ni_{0.50-z}Mn_{0.5+z}In_{0.15}$, its field-induced martensitic transformation shifts to 285 K[3]. Most efforts in optimizing the performance of this alloy series have been dedicated to compositional studies and mainly reported only the temperature range of its inverse MCE due to the interest in giant MCE for practical applications. However, these ferromagnetic alloys exhibit at least three temperature-induced phase transitions: a low temperature ferromagnetic-paramagnetic (FM-PM) transition followed by a first order martensitic structural transition at higher temperatures and the FM-PM transition of high temperature austenitic phase. In this work, we aim to study, in a broad temperature range, the influence of these three overlapping transitions on the field dependence of MCE in $Ni_{0.49-x}Mn_{0.36+x}In_{0.15}$. Fig 1(a) shows the magnetization vs. temperature (*M(T))* data of $Ni_{48.1}Mn_{36.5}In_{15}$ which reveals that it exhibits three phase transitions occurring at different temperatures as observed from the $\partial M/\partial T$ slopes. The first one corresponds to the Curie transition of the martensitic phase, producing a small gradual decrease of *M* in the range of T<225 K. The steep increase of *M* observed within 225 K < T ≤ 260 K corresponds to the martensite-austenite transition, which occurs before the T_C of the martensite phase. At higher temperatures, a gradual decrease of $\partial M/\partial T$ is observed. These are in agreement with the 3D MCE (magnetic entropy change, ΔS_M) plot shown in Fig 1(b) whereby two direct MCE and an inverse MCE are observed. A small direct MCE is observed at low temperatures up to ~220 K, followed by a large inverse MCE at higher temperatures up to ~268 K due to the subsequent competing phase transitions followed by a direct MCE peak. While the martensitic-austenitic transition does not significantly overlap with the Curie transition of the austenite, the direct MCE of that FM-PM transition exhibits a magnitude of the same order of that of the inverse MCE (7.13 J kg^{-1}K^{-1} versus -2.83 J kg^{-1}K^{-1} respectively). However, the low temperature direct MCE is rather diminished due to the overlapping of its Curie transition and the martensitic transition, whereby the martensite phase disappears before its T_C. Fig 2 shows that the variant electron/atom (e/a) ratio (due to alteration of Ni/Mn ratio) shifts the different magnetic phase transitions in the $Ni_{49+x}Mn_{36-x}In_{15}$ alloys. With increasing e/a ratio, the T_{pk} of 1st direct MCE (1st transition), inverse MCE (2nd transition) and direct MCE at higher temperatures (3rd transition) regimes exhibit an increase, increase and decrease respectively. The T_{pk} of the inverse MCE agree with the temperature at which the austenite phase begins to form, as observed from DSC data. For both 2nd and 3rd transitions, it can be observed that both exhibit similar trends of increased T_{pk} for e/a ratio ≥7.86, indicating their phase competition, which also affected the visibility of their peaks as shown in the inset of Fig 2 (their peak ΔS_M remain rather small for e/a ratio ≥7.86). Hence, the peak ΔS_M values of the 2nd and 3rd transitions are comparable (i.e. same order of magnitude) when their temperatures are well separated, as observed for e/a ratio ≤7.84. Although it is previously found that the entropy change of the phase transition from DSC data correlates well with the e/a ratio[4], there is no direct correlation between the ΔS_M of the martensitic transition and the e/a ratio partly due to this overlap. The previously described behavior for $Ni_{48.1}Mn_{36.5}In_{15}$ agrees well with the observed trend of exponent *n* (as in $\Delta S_M \propto H^n$ [5]) controlling the field dependence of MCE. For its first transition, *n* gradually decreases from *n*~1 and abruptly increases as the sign of ΔS_M switches at the FOPT (2nd transition). For the 3rd transition, the typical *n* behavior for a second order phase transition is observed and the main features of the field dependence of each transition are essentially maintained.

INTRODUCTION The near room temperature magnetocaloric effect (MCE) of MnNiSi based alloys is of current interest in magnetocaloric cooling applications [1]. MnNiSi is a ferromagnetic alloy with a Curie temperature (Tc) of 620 K [2], it exhibits a structural transition from orthorhombic to hexagonal above 1200 K [3]. Single element substitution has been found to be unable to decrease T_c to near room temperature, therefore 2 element substitution is necessary to obtain magnetostructural coupling near room temperature [4] [5]. A magnetostructural transition near room temperature is observed in $(MnNiSi)_{1-x}(Fe_2Ge)_x$ (x = 0.32 to 0.36) and $Mn_{0.45}Fe_{0.55}NiSi_{1-y}Sn_y$ (y = 0.12 to 0.18) alloys. A high temperature paramagnetic hexagonal phase which is converted to a low temperature ferromagnetic orthorhombic phase. Fe_2Ge stabilizes the hexagonal phase of MnNiSi to create a Curie temperature window (CTW) near the room temperature. In $Mn_{0.45}Fe_{0.55}NiSi$, it has been observed that the T_c could only be decreased to 438K. The Sn composition was varied from 0.12 to 0.18 to further reduce T_c to near room temperature values. Sn also reduces the cost of the material. EXPERIMENTAL PROCEDURE Polycrystalline $(MnNiSi)_{1-x}(Fe_2Ge)_x$ (x = 0.32 to 0.36) and $Mn_{0.45}Fe_{0.55}NiSi_{1-y}Sn_y$ (y = 0.12 to 0.18) alloys were synthesized from the elements using arc melting. The mass of the elements was selected on the basis of the nominal composition. Arc melting was carried out several times to ensure homogeneity. For $(MnNiSi)_{1-x}(Fe_2Ge)_x$, no heat treatment was conducted. For $Mn_{0.45}Fe_{0.55}NiSi_{1-y}Sn_y$ (y = 0.12 to 0.18) alloys, heat cycling was performed by subjecting it to 2 cycles of heating above the transition temperature and cooling using liquid nitrogen to eliminate the "virgin effect" [6,7]. RESULTS AND DISCUSSIONS 1. $(MnNiSi)_{1-x}(Fe_2Ge)_x$ alloys XRD analysis was carried out of samples at room temperature, the results showed peaks corresponding to the hexagonal structure for x = 0.34, 0.35 and 0.36, indicating that the structural transition temperature (T_t) was below room temperature. The orthorhombic structure was observed for x = 0.32 and 0.33, indicating T_t higher than room temperature. The observed values of T_t from the DSC analysis were 199K, 237K, 285K, 313K and 352K during cooling and 216K, 262K, 301K, 328K and 367 K during heating for x = 0.32 to 0.36 respectively. Thermal hysteresis of ~15 K was observed between heating and cooling cycles, which is a characteristic of a first order magnetocaloric material. Magnetic measurements showed Tc values of 200K, 238K, 276K, 315K, 350K during cooling and 218K, 259K, 301K, 331K, 363K during heating for x = 0.32, 0.33, 0.34, 0.35 and 0.36 respectively. The coupling between the magnetic and the structural transformation gave rise to a giant magnetocaloric effect for all the compositions studied. The entropy, calculated using Maxwells relation, large values of 47.3, 54.1, 57.6, 55.2 and 53.5 J $kg^{-1}K^{-1}$ (ΔH = 5T) for x = 0.32, 0.33, 0.34, 0.35 and 0.36, respectively were obtained. The relative cooling power (RCP) values were 376, 332, 342, 480 and 312 J kg^{-1} for x = 0.32, 0.33, 0.34, 0.35 and 0.36 respectively. A summary of the magnetic measurements are shown in Fig 1. 2. Results for $Mn_{0.45}Fe_{0.55}NiSi_{1-y}Sn_y$ alloys Room temperature XRD Analysis of the $Mn_{0.45}Fe_{0.55}NiSi_{1-y}Sn_y$ alloys showed an increase in the intensity of hexagonal peaks and diminution of the orthorhombic peaks when y was increased from 0.12 to 0.18, suggesting a change in T_t occurring by varying the Sn content. DSC analysis showed structural transformation peaks at 382K, 355K and 325K during heating and 325K, 295K and 260K during cooling for y = 0.12, 0.14 and 0.16. However, there was no DSC peak observed for alloy with y = 0.18. This suggested that the first order transformation is limited to Sn compositions below y = 0.16. Magnetic measurements showed T_c of 352K, 330K, 290K and 255K during heating and 343K, 315K, 260K and 225K during cooling for y = 0.12, 0.14, 0.16 and 0.18 respectively. The hysteresis was 9K and 15 K for y = 0.12 and 0.14, respectively and ~30K for y = 0.16 and 0.18. The M-H measurements were performed using the loop process [8] and the entropy was calculated using Maxwells equation was 7.5, 8.6, 3.7 and 1.8 J $kg^{-1}K^{-1}$ (ΔH = 5T) and the RCP values were found to be 165, 95, 204 and 252 J kg^{-1} for y = 0.12, 0.14, 0.16 and 0.18, respectively. A summary of the magnetic measurements are shown in Fig 2. A comparison of magnetocaloric properties of the two alloys shows high entropy, easy synthesis and better magnetostructural tunability for $(MnNiSi)_{1-x}(Fe_2Ge)_x$ alloys whereas $Mn_{0.45}Fe_{0.55}NiSi_{1-y}Sn_y$, being a Ge-free alloy, can be useful for low cost applications operating near room temperature.

FD-09. Entropy Change and Hysteresis Losses in $Ni_{45}Co_5Mn_{(37-x)}In_{(13+x)}$ Alloy Family.

M. Ghahremani[1], A. Aslani[2], M. Hosseinnia[3], L.H. Bennett[2] and E. Della Torre[2]

The use of Maxwell equations to calculate the entropy change (ΔS) in materials that have a first-order phase transition (FOPT) has been questioned as they are only valid at thermal equilibrium [1,2]. Though, it has been recently shown that this artifact can be minimized after using appropriate protocol for the measurements [3]. The hysteresis losses and magnetocaloric effect of $Ni_{45}Co_5Mn_{(37-x)}In_{(13+x)}$ alloy have been studied in this work. The ingots were prepared by vacuum arc melting technique under an argon atmosphere and were annealed at 900 C for 24 h followed by water quenching. The heating and cooling isothermal magnetizations, M(H), were measured up to 1.5 T and 5 T at a temperature range of 240 K to 338 K. During the heating process the temperature was raised from 240 K to 338 K and at each discrete temperature point, the M(H) was measured. The reverse procedure was carried in the cooling process. The area between the ascending and descending loops of the field-dependent magnetization curves of the $Ni_{45}Co_5Mn_{37}In_{13}$ alloy was calculated for both heating and cooling processes at different temperatures and is shown in Fig. 1. These areas are interpreted as the magnetic hysteresis losses at different temperatures. The results reveal that under 1.5 T applied magnetic field, the heating process has significantly higher hysteresis compared to the cooling process. Both for the cooling and heating processes, the hysteresis losses are negligible up to 310 K. Though, after 314 K the hysteresis losses are considerable for the heating process, yet negligible for the cooling process. Furthermore, as shown in Fig. 1, by increasing the applied magnetic field up to 5 T, the hysteresis loss curve is shifted to the lower temperatures compared to the ones at 1.5 T. As depicted in this figure the maximum hysteresis losses at 5 T occurs at 312 K, whereas for 1.5 T the peak befalls at 318 K. By interpreting these results we can determine the temperature regions which indirect MCE measurements via Maxwell's and thermodynamic equations will produce the highest discrepancy with the direct MCE measurements. These areas are shown in Fig. 1, for the 1.5 T field (blue shaded temperature region) and the 5 T filed (red shaded temperature region). For instance, the indirect MCE measurements within 316 K to 322 K should be taken with caution for the heating process under 1.5 T. For the 5 T magnetic field this region falls within the temperature range of 307 K to 316 K. To study the magnetocaloric effect of $Ni_{45}Co_5Mn_{(37-x)}In_{(13+x)}$ alloy family (x=0, 0.4) the isofield temperature-dependent magnetization curves, M(T), were derived from isothermal magnetization loops for both ascending and descending magnetic fields, and the entropy changes (ΔS) were derived and are shown in Fig. 2. This figure reveals three distinct results as follow. Firstly, for $Ni_{45}Co_5Mn_{37}In_{13}$ sample, the peak of the entropy change curve under 5 T applied field occurs at 308 K in the descending curve and at 314 K in the ascending curve, whereas for the 1.5 T filed these peaks happen at 318 K and 320 K, respectively. This emphasizes the fact that the variation of the maximum applied magnetic field within same stoichiometry composition can very well change the critical temperature at which the peak of the entropy change curves occur. So when synthesizing the magnetocaloric materials, one should consider the maximum applied magnetic field in which the magnetic refrigeration system will be operational. Secondly, even a small change in the stoichiometry composition of a material can significantly change the material's critical temperatures. As shown in Fig. 2, the critical temperature of the $Ni_{45}Co_5Mn_{36.6}In_{13.4}$ has been shifted by about 36 K to lower temperatures compared to the $Ni_{45}Co_5Mn_{37}In_{13}$. This suggests that material with high MCE at temperatures out of room temperature can be customized by changing their stoichiometry in order to shift their high MCE toward desirable temperatures. This is promising especially in finding suitable refrigerants for room temperature magnetic refrigeration systems. Thirdly, it is observed that the entropy change curves of $Ni_{45}Co_5Mn_{36.6}In_{13.4}$ are broader than the ones for $Ni_{45}Co_5Mn_{37}In_{13}$. Relative cooling power (*RCP*) is given by $RCP=-\Delta S_M(T,H) \times \delta T_{FWHM}$, where ΔS_M is the refrigerant's isothermal magnetic entropy change and δT_{FWHM} is the full-width-at-half-maximum of the peak of magnetic entropy. Therefore, the *RCP* of the $Ni_{45}Co_5Mn_{36.6}In_{13.4}$ sample is higher than the one for $Ni_{45}Co_5Mn_{37}In_{13}$ sample. This leads to obtaining a higher refrigeration capacity in a magnetic refrigeration system. In summary, the results of this research are very promising in synthesizing high-performance magnetocaloric materials that can be used to develop practical room temperature magnetic refrigeration systems.

FD-10. Low field and large magnetocaloric effect in Ni-Mn-Sn (Fe-B) alloys.

K. Srikanti[1], R. V.V[1], G. Anusha[1] and G. Raghavan[1]
1. CAEM, International Advanced Research Centre for Powder Metallurgy, Chennai, India

Ni-Mn based ferromagnetic shape memory alloys (FSMAs) received lot of attention by virtue of their giant magnetocaloric effect and have application potential for magnetic refrigeration. They are very cheap and environmental friendly [1-5]. These alloys undergo a first-order magnetic transition from a high moment phase (austenite) to a low moment phase (martensite) with decreasing temperature, associated with the sharp changes of magnetization, leading to large magnetoresistance, giant magnetocaloric effects, and magnetic-field-induced strain. Most of these properties are attributed to their first order martensitic transition (MT), which can be tuned by changing the chemical composition, elemental doping and substitution [6-8]. In this work we investigate the structural, magnetic and magnetocaloric properties of Ni-Mn-Sn-Fe-B alloy. Fe_2B has been added with an intention to increase the magnetization. Experimental $Ni_{43}Mn_{46}Sn_{11}$ $(Fe_2B)_{0.5}$ was prepared by arc-melting the raw materials in a cold copper crucible under the argon atmosphere protection. For better homogeneity the sample was melted four times and consequently annealed in evacuated quartz tube at 1123 K for 72 hours and quenched in liquid nitrogen. The room temperature structure of the alloys was identified employing powder X-ray diffraction (XRD) using Cu Kα radiation. A Rigaku make diffractometer was used for this purpose. The austenite and martensite transition temperatures were determined by differential scanning calorimetry (DSC, Netzsch) at a heating and cooling rate of 10 K/min. The magnetization measurements were carried out using a vibration sample magnetometer (Microsense, Model EZ9) equipped with a magnetic field of 2T. Figure 1 (a) shows the room temperature XRD pattern of the $Ni_{43}Mn_{46}Sn_{11}$ $(Fe_2B)_{0.5}$ alloys. The XRD patterns of the parent alloy exhibits the cubic Heusler L_{21}-type structure at room temperature representing the austenite phase. The structural transformation temperatures of the alloy was determined from the DSC curves recorded during heating and cooling cycles (Fig. 1 (b)). A well-defined endothermic peak appears in the martensite (M) to austenite (A) phase transformation during heating while an exothermic peak observed in the austenite to martensite phase transformation during cooling. These alloys display both first-order structural transformation associated with martensitic transition and a second-order magnetic transition (small peak—change in base line) corresponding to the Curie temperature of the austenite phase ($T_{A C}$) as evident in Fig. 1 (b). Figure 1 (c) shows the temperature dependence of magnetization (*M-T* curve) for the alloy taken in the presence of 500 Oe during heating. The alloy undergo a structural transition from martensite phase to austenite phase at *As* denoted by a sudden jump in the magnetization. The structural transition occurs around 200 K, which is far below the T_{AC}. The transition temperatures *As*, *Af*, and T_{AC} determined from the thermomagnetic curves are in close agreement with the results obtained from the DSC thermograms in these alloys. The magnetic entropy (delta S_M) as a function of temperature in the magnetic field up to 2T was calculated from isothermal magnetization curves with increase in temperatures at an interval of 2 K in the vicinity of martensite transition (shown in Fig 1 (d)) using the Maxwell relation. It is observed from Fig 1 (d) that there is a sudden change in magnetization from 202 K to 204 K and around 206 K, a metamagnetic transition is observed which is attributed to the onset of magnetic field induced structural transition from martensite phase with lower magnetization to austenite phase with higher magnetization. Figure 1 (e) shows the variation of magnetic entropy with temperature. A huge positive delta S_M of 17 J/Kg-K has been observed around 203 K at a low field of 2 T. The magnetic entropy found in this work is higher than that of the values reported in the literature [9-11]. The reason for such a huge magnetocaloric effect is due to the strong magnetostructural coupling due to Fe-B addition.The variation of concentration of Fe-B and its effect on martensite transition and magnetic entropy is in progress. Conclusion We have studied the effect of Fe-B addition in Ni-Mn-Sn alloy. This alloy shows a DS_M of 17 J/Kg-K has been observed around 203 K at a low field of 2 T. The huge magnetocaloric effect found in this alloy makes it promising for fundamental studies as well as for magnetic refrigeration applications.

Abstract: The relatively high reduced glass transition temperature (T_{x1}/T_m > 0.60) and low melting point (T_m) resulted in excellent glass forming ability of $Gd_{55}Co_{35}M_{10}$ (M=Si, Zr and Nb) alloys. The Curie temperatures (T_C) for M=Si, Zr and Nb alloys were 166, 148 and 173 K, respectively. Under an applied field change of 2 T, the maximum values of magnetic entropy change $(-\Delta S_M)^{max}$ for $Gd_{55}Co_{35}Si_{10}$, $Gd_{55}Co_{35}Zr_{10}$ and $Gd_{55}Co_{35}Nb_{10}$ were 2.86, 4.28 and 4.05 $Jkg^{-1}K^{-1}$, while the values of refrigerant capacity (RC) were found to be 154, 274 and 174 Jkg^{-1}, respectively. The values of RC for $Gd_{55}Co_{35}M_{10}$ (M=Si, Zr and Nb) amorphous alloys are comparable to or larger than that of the well-known MCM crystalline alloy $LaFe_{11.6}Si_{1.4}$. With good thermal stability, large RC and a considerable magnetic entropy change, $Gd_{55}Co_{35}M_{10}$ (M=Si, Zr and Nb) amorphous alloys can be potentially used as magnetic cooling materials working in the temperature range of 150-175K, e.g., as part of a gas liquefaction process. Introduction: Magnetic refrigeration (MR) based on the magnetocaloric effect (MCE) is a promising energy efficient, green, condensed state technology, which can potentially replace conventional technology based on gas compression/expansion cycles [1-2]. Amorphous alloys have advantages such as negligible magnetic and thermal hysteresis, tailorable ordering temperature, high thermal stability, high electrical resistivity, high corrosion resistance, and good mechanical properties [3]. Among these, Gd-based alloys have recently attracted intensive interest because they are very useful for sub-room temperature magnetic refrigeration [4-7]. There are few reports on the influence of non-ferromagnetic elements Si, Zr and Nb substitution on the MCE of ternary Gd-based $Gd_{55}Co_{35}M_{10}$ (M=Si, Zr and Nb) amorphous alloys. In this work, the magnetic properties and magnetocaloric effects (MCEs) of ternary Gd-based $Gd_{55}Co_{35}M_{10}$ (M=Si, Zr and Nb) amorphous alloys are investigated. Experimental: $Gd_{55}Co_{35}M_{10}$ alloys with M=Si, Zr and Nb were firstly prepared from mixtures of high purity Gd(>99.98wt.%), Co(99.98wt.%), Si(>99.99wt.%), Zr(>99.5wt.%) and Nb(>99.5wt.%) by arc melting in argon atmosphere. Melting was performed four times to ensure composition homogeneity, weight loss was less than 0.5wt.%. Ribbons of these samples were obtained by the single roller melt spinning technique with a copper wheel velocity of 50 m/s in a purified argon atmosphere. The width and thickness of the ribbons were about 1 mm and 15 μm, respectively. X-ray diffraction (XRD) measurements were performed at room temperature using a Philips X'pert Pro MPD X diffractometer with Cu Kα radiation. The thermal stability was analyzed by differential scanning calorimetry using a NETZSCH–STA449C calorimeter at a heating rate of 20 K/min under argon atmosphere to study crystallization behavior. The values of onset crystallization temperature T_x were determined from the DSC traces with an accuracy of ±1K. Magnetic measurements were carried out using a Quantum Design Physical Property Measurement System (model PPMS-9) with the field direction in the plane of the ribbons, therefore the demagnetization factor was neglected. The magnetocaloric properties of the materials were calculated by the indirect-measurement method from the M–H curves. Results: The onset crystallization temperatures (T_{x1}) are 620, 568 and 555 K for $Gd_{55}Co_{35}M_{10}$ alloys with M=Si, Zr and Nb, respectively, which implies that these amorphous ribbons are stable at room temperature. The thermal properties of these amorphous alloys are summarized in Table 1. The T_{x1}/T_m can be understood as the reduced glass transition temperature (T_g/T_m) of these alloys. Relatively high T_{x1}/T_m and small T_m make $Gd_{55}Co_{35}M_{10}$ (M=Si, Zr and Nb) alloys possess excellent glass forming ability. Fig.1 shows the magnetic entropy change as a function of temperature for $Gd_{55}Co_{35}M_{10}$ (M=Si, Zr and Nb) amorphous alloys at a maximum magnetic field change from 0 to 2T. All three $(-\Delta S_M)$–T curves exhibit a typical λ-shape, indicating that the magnetic transition near the T_C of the $Gd_{55}Co_{35}M_{10}$ (M=Si, Zr and Nb) amorphous alloys is a second-order phase transition. For an applied field change of 2T, the maximum values of magnetic entropy change $(-\Delta S_M)^{max}$ for $Gd_{55}Co_{35}Si_{10}$, $Gd_{55}Co_{35}Zr_{10}$, and $Gd_{55}Co_{35}Nb_{10}$ are 2.86, 4.28, and 4.05 $Jkg^{-1}K^{-1}$, respectively. These values are much higher than those of $Gd_{55}Co_{20}Fe_5Al_{20}$ BMG alloy (2.24 $Jkg^{-1}K^{-1}$ at 20 kOe) [8], $Gd_{55}Co_{35}Fe_{10}$ (1.72 $Jkg^{-1}K^{-1}$ at 2T) [6] and $Gd_{65}Fe_{20}Al_{15-x}B_x$ glassy ribbons [9]. Conclusion: Good thermal stability, large relative cooling power (RC) and considerable magnetic entropy change make $Gd_{55}Co_{35}M_{10}$ (M=Si, Zr and Nb) amorphous alloys attractive candidates for magnetic refrigerant applications.

I. INTRODUCTION Magnetocaloric effect (MCE) has recently gained wide attention in both fundamental research [1, 2], and application in magnetic refrigeration (MR) systems. It is promising as an efficiently competitive technology for the replacement of the potentially environmentally risky gas compression/expansion refrigeration [3-5]. Ericsson cycle implementation of MR is one of the most suitable thermodynamic cycles for enhanced performance. However, its requirement that magnetic entropy change ($-\Delta S_M$) of the magnetic refrigerant is constant (table-like MCE) over the operating temperature range severely limits the availability of appropriate magnetocaloric materials (MCMs). The search for MCMs with such property is a daunting challenge. Some proposed research approach include multilayered and powder composite mixtures but the low density of powder composites significantly deteriorates the magnitude of $-\Delta S_M$. Moreover, the lifespan of sintered or glued layer refrigerants is shortened by repeated differential expansion and contraction at the interfaces. Single bulk multiphase alloys with table-like feature could be a solution to overcoming the issues associated with layered and ex-situ composite mixtures. However, the challenge of identifying such alloy systems with temperature independent $-\Delta S_M$ or improved refrigerant capacity (*RC*) can be overwhelming. Their discovery is strictly dictated by the nature of the related phase diagrams. Several Ho(Co, Al)-based binary and quasi-binary crystalline alloys are known to have good magnetocaloric properties. Therefore, we examine the Ho-Co-Al system to identify a suitable multiphase region for study in expectation of a single bulk multi-crystalline alloy that exhibits table-like MCE. In particular, $HoCo_2$, HoCoAl, and Ho_2Co_2Al compounds have good magnetocaloric properties [6-8]. Consequently a carefully selected region of the Ho-Co-Al system, bounded by the three compounds and expected to contain all three phases, was studied. Results show that the title multiphase alloy, which comprises the $HoCo_2$, HoCoAl, and Ho_2Co_2Al main phases, exhibits table-like MCE. The effect of interatomic substitution on the magnetic properties of relevant phases and its contributions to the attainment of the table-like MCE and *RC* are discussed in detail. II. EXPERIMENTAL DETAILS Stoichiometric proportions of Ho, Co and Al all of purities 99.99 wt.% were arc melted in a water cooled crucible under Ti-gettered argon environment. The sample was flipped over and re-melted three times to enhance homogeneity while minimizing weight loss. Powder X-ray diffraction (XRD) data was collected at room temperature for phase characterization. Rietica software was used for Rietveld refinement for the crystal structure and phase composition analysis. Magnetization measurements were performed with a superconducting quantum interference device (SQUID) magnetometer. III. RESULTS AND DISCUSSIONS The four sets of vertical bars (blue) of Rietveld refinement shown in Fig. 1 correspond to the HoCoAl, Ho_2Co_2Al, $HoCo_2$ main phases and trace amount of Ho_2O_3, respectively from top to bottom. Lattice parameters and EDS analysis indicate that Al substitution for Co occurs in the $HoCo_2$ phase while the HoCoAl phase has higher Co content than the Co:Al ratio for equiatomic HoCoAl. Temperature dependence of magnetization under field cooled (FC) condition shows a broad transition, which is beneficial for obtaining table-like MCE. Maximum magnetization of isotherms reaches 172 emu/g at 7 K under applied field of 50 kOe. Small magnetic hysteresis is observed at 7 K but disappears with increasing temperature and is not visibly evident from 13 K. Again, no step-like magnetization could be seen for all the measured isotherms. It indicates that the first-order metamagnetic transition associated with $HoCo_2$ and its low Al-substituted counterparts is absent. The order of magnetic phase transitions in the $Ho(Co_{1-x}Al_x)_2$ alloys changes from first-order to second-order for x > 0.06 [9]. Therefore, the suppressed hysteresis and absence of the first-order transition are attributed to the high content of Al in the $HoCo_2$ phase. Table-like MCE is attained for the studied alloy under different applied field changes (ΔH) as shown in Fig. 2. The $-\Delta S_M$ platforms become flatter with decreasing field. When ΔH = 5 T, the magnitude of the platform is about 8.5 J/kg K, which is among the highest known for MCMs with table-like MCE. The plateau spreads over the temperature range from 20 K to 50 K. At the decreased field of 2 T, $-\Delta S_M$ = 2.9 J/kg K and spands from 20 K to 57 K. In addition, large *RC* of 525 J/kg and 180 J/kg are obtained for the ΔH = 5 T and 2 T, respectively. IV. CONCLUSIONS The single bulk multiphase $Ho_{36}Co_{48}A_{16}$ alloy with three main crystalline phases, HoCoAl, Ho_2Co_2Al and $HoCo_2$ has been prepared and its magnetic and magnetocaloric properties studied. The well distributed transition temperatures and accompanying $-\Delta S_M$ result in table-like MCE with magnitude of 8.5 J/kg K under ΔH = 5 T. The large magnitude of the table-like MCE and its relatively wide temperature span of up to about 40 K, coupled with its large *RC* of 525 J/K under ΔH = 5 T make the alloy a competitively good candidate for MR using Ericsson cycle and suitable for use with permanent magnets at 2 T. Thin films of Fe-rich transition metal aluminide $Fe_{60}Al_{40}$ (at. %) are very promising for implementation in modern technology due to a possibility of having tailored magnetic properties. Being weakly ferromagnetic at room temperature in the chemically ordered B2 phase, $Fe_{60}Al_{40}$ films can be reversibly transformed into the ferromagnetic chemically disordered A2 phase with much higher magnetization in a well controlled way by means of ion irradiation. Prior studies point on important influence of created chemical disorder on static and dynamic magnetic properties of $Fe_{60}Al_{40}$ films while achievements in magnetic patterning and studies of magnetization reversal have shown their perspective for further use in spin-transport devices [1–3]. Detailed studies performed on a local scale can clarify hidden mechanisms of disorder induced ferromagnetism phenomena in $Fe_{60}Al_{40}$ films via understanding the influence of the local surrounding and features of Fe-Al hybridization on the magnetic properties. In our work, element-specific X-ray absorption spectroscopy (EXAFS, XANES, and XMCD) in hard- and soft energy ranges together with synchrotron-based XRD (SR-XRD) have been applied to probe the local rearrangements and related magnetic and electronic properties of Fe and Al atoms in bare $Fe_{60}Al_{40}$ thin films of 40 nm thickness through the order-disorder (B2 → A2) phase transition initiated by 20keV Ne^+ ion irradiation with low fluences (~10^{14} ions cm^{-2}). Extended X-ray absorption fine structure (EXAFS) spectra recorded at the Fe and Al K edges at room temperature (RT) and low temperature of 5K (LT) and SR-XRD have shown significant changes in the local environment of Fe and Al absorbers before and after the irradiation. In the course of the transition a number of Fe-Fe nearest-neighbors grew from 3.47(7) up to 5.0(1) for the ordered B2 and the fully disordered A2 phases, correspondingly, and ~1% of the unit cell volume expansion was found. Distinct changes of Fe and Al coordination due to disordering resulted in increased Fe 3d spin and 4p orbital polarizations and characteristic changes in electronic structure of Al atoms as was demonstrated by RT XMCD at the Fe $L_{2,3}$ and Fe K edges as well as LT XANES at the Al K edge, respectively [4,5]. A unique possibility to probe the magnetism of 3d states by hard X-rays has been realized by recording the XMCD signal at ~ 60eV above the Fe K edge where so-called magnetic multi-electronic excitations (MEE, secondary processes) are present [6,7]. The analysis of MEE peak amplitude and its integrated intensity has revealed similar tendencies in their changes with fluence as for 3d effective spin and 3d orbital magnetic moments obtained from XMCD spectra at the Fe $L_{2,3}$ edges, respectively. Moreover, this analysis points towards increased localization of Fe 3d states in A2 phases created by fluencies of $(0.75 - 6) \times 10^{14}$ ions cm^{-2}. Element-specific hysteresis loops (ESHL) recorded by XMCD either at the Fe K or L_3 absorption edges have confirmed the preferential in-plane magnetic anisotropy of irradiated films; the variations in coercive fields depending on temperature and irradiation fluence have been checked by ESHL at the Fe L_3 edge. The specific shoulder related to hybridization effects between Fe and Al has been uncovered with the help of *in-situ* hydrogen plasma treatment. It has been also illustrated that the reduction of the top oxide layer leads to increase or decrease of Fe 3d spin magnetic moments in the surface region depending on the time of treatment. This suggests that the use of a capping layer could either protect the films from continuous uncontrolled oxidation or further increase the macroscopic magnetization of films that is much more favorable for technological applications. A theory support was provided by self-consistent DFT calculations using the VASP program package applied to relaxed model systems. A clear variation of local configurations in B2 and A2 phases followed by sizable changes in Fe and Al magnetic moments has been found. The work was partially funded by Helmholtz Association (Young Investigator's Group "Borderline Magnetism", VH-NG-1031). The authors thank the ESRF (ID12 beamline) and HZB-BESSY II (UE46_PGM-1 and KMC-2 beamlines) for provision of synchrotron radiation facilities and allocation of synchrotron radiation; Swedish National Infrastructure for Computing (SNIC) is acknowledged for providing high performance supercomputing time.

FE-02. Anomalous Nernst and Hall Effects in $Co_x(MgO)_{1-x}$ Granular Thin Films.

P. Sheng[1] and M. Mizuguchi[1,2]
1. Institute for Materials Research, Tohoku University, Sendai, Japan;
2. CREST, Japan Science and Technology Agency, Kawaguchi, Japan

From the discovery of the spin Seebeck effect, many researches in spin caloritronics have been reported. Significant roles of anomalous Nernst effect (ANE) in spin caloritronics regarding not only physical aspect but also application to thermoelectric devices are now recognized. ANE is the thermal analogue of anomalous Hall effect (AHE). So far ANE in metallic multilayers attracts a lot of interest due to the enhancement of ANE [1-3]. On the other hand, giant AHE is observed in ferromagnetic-insulator (FM-I) granular films, such as $Fe_{1-x}(SiO_2)_x$ [4]. In strongly disordered systems such as granular films, the mechanism of longitudinal and anomalous Hall transports are not simple [4,5]. To understand ANE in nano-structured systems further, it is interesting to investigate ANE in FM-I nano composite granular films. Here we systematically study the electrical and thermal transport properties in $Co_x(MgO)_{1-x}$ granular films with Co volume fractions (x) changes. The films with different x were fabricated by co-sputtering method on MgO substrates at RT by changing the sputtering powers for Co and MgO targets. Thickness of all the films is 100 nm. In the electrical measurement, the longitudinal (R_{xx}) and transverse resistance (R_{xy}) decrease with increasing x. In addition, the AHE angle (ρ_{xy}/ρ_{xx}) increases with x increases, it shows maximum value for pure Co film. On the otherhand, for the thermal measurement, the longitudinal (Seebeck) voltage and transverse (ANE) voltage increase with increasing x. Interestingly, ANE angle (S_{xy}/S_{xx}) nonmonotonically changes with x increases. It shows maximum value when large amount of Co is included in MgO matrix, which is 1.9 times larger than that of pure Co. It means that significant enhancement of ANE angle can be obtained in $Co_x(MgO)_{1-x}$ films compared with pure Co. ANE angel can be tuned through changing the amount of Co into MgO. The comparison between ANE and AHE will be discussed in detail. Our results provide a new way to enhance ANE angle and it is helpful for realizing the applications of ANE-based devices. FE-03. ***Zero Field Cooled Exchange Bias Effect in Nano-Crystalline Mg-Ferrite Thin Film.***

H. Roy Dakua[1,2], N. Venkataramani[3] and S. Prasad[4]
1. physics, Indian Institute of Technology, Mumbai, India; 2. physics, National University of Singapore, Singapore; 3. Metallurgical Engineering and Materials Science, Indian Institute of Technology, Mumbai, India; 4. physics, Indian Institute of Technology, Mumbai, India

The applicability of Exchange Bias (EB) effect systems in magnetic devices, such as data storage devices, spin valve devices and voltage control magnetic devices is the main motivation of the research in this topic[1-5]. So far, many EB systems have been studied such as Ferromagnetic (FM)-Antiferromagnetic (AFM), FM-Spin Glass (SG) and Ferrimagnetic (FIM)-AFM heterostructures[1, 6, 7]. These systems show EB shift in the M-H loop as a result of field cooling through the Néel temperature or glass transition temperature of the AFM or SG phase. Apart from the Conventional Exchange Bias (CEB) effect, Wang *et al.* had reported an unusual exchange bias effect in the $Ni_{50}Mn_{50-x}In_x$ (x = 11-15) bulk alloy in 2011[8]. Here, unlike the CEB systems, this material showed a large exchange bias in the M-H loops even in the zero field cooled (ZFC) sample. Subsequently, Nayak *et. al.* had reported ZFC EB effect in bulk Heusler alloy Mn_2PtGa [9]. Recently, some other groups have also reported ZFC EB effect in bulk Ni-Mn-Sn, $Ni_{50}Mn_{36}Co_4Sn_{10}$ and $La_{2-x}Sr_xCoMnO_6$[10-12]. All these studies have broadly pointed out that a unidirectional anisotropy is introduced to the FM state during the initial magnetization process which caused the ZFC EB in the system. In this paper, we report Zero Field Cooled (ZFC) Exchange Bias (EB) effect in nanocrystalline Mg-ferrite thin film. The film of this material was deposited on amorphous quartz substrate using pulsed laser ablation technique. The deposition was carried out in oxygen atmosphere at a pressure 0.16 mbar at the 500^0C substrate temperature using a Nd-YaG pulsed laser. The thickness of the film was ~135 nm. This film was ex-situ annealed at 250^0C for 2 hours. The crystal structure, elemental purity, and the microstructural properties of the film was studied using X-ray Diffraction (XRD), X-ray Photoelectron Spectroscopy (XPS), Atomic Force Microscopy (AFM) and Scanning Electron Microscopy (SEM). These studies confirm that the film is nanocrystalline $MgFe_2O_4$. The magnetic properties of the film was studied using Vibrating Sample Magnetometer (VSM). Figure 1 shows enlarged view of ZFC M-H loop of the film, measured at 10 K by sweeping the magnetic field from 0 Oe → +50 kOe → -50 kOe → +50 kOe. In the inset of figure 1 we show full M-H loop within the field range ± 50 kOe. The spontaneous magnetization of the thin film (~160 emu/cc at 10 K) is comparable to that of the bulk Mg-ferrite. The ZFC M-H loop of our film is asymmetric and shifted along the negative field axis. This shift indicates the presence of ZFC EB effect in the film. The exchange bias field (H_E) of the film is defined as $H_E = |H_{C1}+H_{C2}|/2$; where H_{C1} and H_{C2} are the lower and upper cut-off fields. The highest value of ZFC H_E obtained by us in this Mg-ferrite thin film, is ~230 Oe at 10 K. This value is higher than the reported value of ZFC H_E (H_E ~ 120 Oe at 10) in heterostructure thin films by Murthy *et. al.*;[13]. The ZFC H_E our film is comparable to that of the bulk $Ni_{50}Mn_{50-x}In_x$ (H_E ~200 Oe for ±50 kOe field sweep at 10 K for x = 11, 12, 14, 12, 14, 15) reported by Wang *et. al.*;[8]. Figure 2 shows the variation of the ZFC EB field (H_E) with temperature. The highest value of H_E ~230 Oe was obtained at 10 K. The ZFC EB field (H_E) decreased with increasing temperature and tends to be zero as the ZFC M-H loop become symmetric at high temperature (T > 70 K). We have also measured the low temperature M-H loop after Field Cooling (FC) with 50 kOe magnetic field. The 50 kOe FC M-H loop shows a much lower H_E (~110 Oe at 10 K) as compared to the ZFC M-H loop. A decrease in the FC EB field compare to the ZFC EB field was also reported by Wang *et. al.*[10]. The FC EB field of our film decreased with increasing temperature and tends to be zero as the FC M-H loops become symmetric for T > 70 K. The 10 K FC H_E value of our film is comparable to the FC H_E of Ni-Mn-Sn and the Conventional Exchange Bias (CEB) H_E of the $(MnZnFe)_3O_4$ thin films[14]. Alaan *et. al.* and Venzke *et. al.* have observed CEB effect in ferrite thin films and it was attributed to the presence of disordered region (namely, AFM or SG) in the boundary of the FIM crystallites[14, 15]. Similarly, our Mg-ferrite thin film may also contain disordered regions in the FIM nanocrystalline boundary. The coexistence of disordered regions and the FIM phase could lead to the observed Zero Field Cooled (ZFC) Exchange Bias (EB) effect in the film. The details of this ZFC EB effect will be presented in the paper.

Antiferromagnetic spintronics has been recently investigated intensively in the view of realising a new device without suffering from the cross-talks between cells due to no net magnetic moment for example. Such a study requires the development of a new antiferromagnetic materials with (i) room temperature (RT) antiferromagnetism, (ii) large (out-of-plane) anisotropy and (iii) large grain volume in a thin-film form. One of the candidates to satisfy these criteria is a Heusler alloy [1]. In this study, we have grown polycrystalline hexagonal $D0_{19}$-Mn_3Ga and $D0_{22}$-Mn_3Ge films using sputtering and characterised their magnetic and structural properties systematically. Polycrystalline binary Heusler alloy Mn_3Ga and Mn_3Ge films were grown on thermally oxidised Si(001) substrates by high-target utilisation sputtering system (HiTUS). A seed layer of Ta (5 nm)/Pt (35 nm) was used as it promotes a Mn_3Ga(0002) crystalline orientation as reported by Kurt *et al.* [2]. A Mn_3Ga layer was then deposited with varying the thickness between 3 and 20 nm, followed by the deposition of a ferromagnetic $Co_{0.6}Fe_{0.4}$ layer (3.3 nm) and a Ta capping layer (5 nm). All the layers were deposited at RT and the films were not annealed during and after the deposition to maintain their well-defined interfaces. Polycrystalline Mn_3Ge films were grown using the same stack structure as Mn_3Ga. The Mn_3Ge layer thickness was varied between 3-100 nm. For the Mn_3Ga films, XRD intensities confirms that all films are in their $D0_{19}$ phase. The 100 nm Mn_3Ge films annealed at 500 show the Mn_3Ge(222) peak, indicating that the increase in film thickness reduces the hexagonal crystallisation strain-induced by the seed layer. The corresponding magnetisation curves for Mn_3Ga are shown in Fig. 1(a). The 6-nm-thick Mn_3Ga film shows the largest exchange bias of 430 Oe at 120K. By increasing the Mn_3Ga thickness, the exchange bias is found to decrease, which agrees with the crystallisation degree. PEEM measures the Mn_3Ga films shows that there is magnetic contrast in both CoFe and Mn_3Ga layers which indicates that the CoFe layer polarises a part of the Mn atoms at the interface. The blocking temperature of these samples were then measured using the York Protocol [3] as shown in Fig. 1(b). Here, the magnetisation curves were taken at 100K after thermally activating at elevating temperatures between 100K and 350K in the presence of a negative saturating field of 20 kOe. Figure 1(b) plots all the exchange bias values measured after thermally activating at elevating temperatures. For the 6-nm-thick film, the blocking temperature is determined to be 225K. The blocking temperature is again found to decrease with increasing the Mn_3Ga thickness. The grain size of the Mn_3Ga was measured using transmission electron microscope, the mean grain size is 13.2 nm hence the magneto-crystalline anisotropy was determined to be. These results confirm that the hexagonal binary Heusler alloys can exhibit a reasonable magnetic anisotropy and the corresponding exchange bias. By further optimising the growth conditions and the compositions, the polycrystalline binary Heusler alloy films can exhibit RT antiferromagnetism, which can be be used in antiferromagnetic spintronics.

FE-05. Emergent dynamic chirality in a thermally driven artificial spin ratchet.

S. Gliga[1]
1. Physics and Astronomy, University of Glasgow, Glasgow, United Kingdom

The study of emergent phenomena in two-dimensional artificial spin ices is presently the focus of intense research. Artificial spin ices are composed of geometrically frustrated arrangements of lithographically patterned single-domain nanomagnets and have so far mainly been used to investigate fundamental aspects of the physics of frustration [1-8]. Recently, it has become clear that artificial spin ice has the potential to become a class of functional material with technological applications. I will present a spin ice based active material – consisting in a repeating pattern of chiral units (shown in Figure 1) – in which energy is converted into unidirectional dynamics, thus functioning like a ratchet [9]. Measurements combining photoemission electron microscopy (PEEM) with X-ray magnetic circular dichroism (XMCD) show that following saturation by an external field, thermal relaxation proceeds through the rotation of the average magnetization in a unique sense (Figure 2). Throughout the evolution, the rotation of the net vertex magnetization (sketched in the gray inset of Figure 2) starts at the edges of the array and propagates towards its center. The rotation continues until the magnetization in the array has mostly rotated by 180 degrees with respect to the initial state, and is approximately aligned with a weak applied bias field. Our micromagnetic simulations demonstrate that this emergent chiral behavior is driven by the topology of the magnetostatic field at the boundaries of the nanomagnet array, resulting in an asymmetric energy landscape. This opens the possibility of implementing a Brownian ratchet [10], which may find applications in nanomotors, actuators or memory cells. I will also discuss other routes towards applications that aim to combine artificial spin ice lattices, which were found to display localized spectral features based on topological defects [11-12], and magnonics, in which propagating spin waves in patterned magnetic thin films are manipulated [13], potentially leading to the creation of metamaterials for spin waves [14]. Finally, I will discuss perspectives for functionalizing artificial spin ices in three dimensions in light of recent experimental advances in magnetic x-ray based nanotomography [15]. SG is funded by the European Union's Horizon 2020 research and innovation programme under the Marie Sklodowska-Curie grant agreement No. 708674.

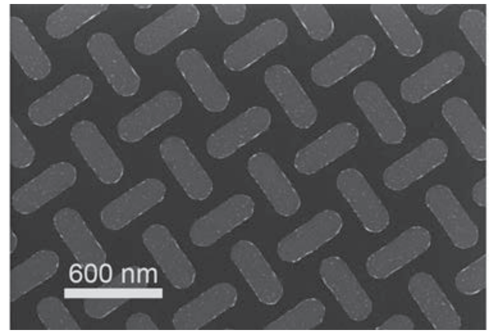

Fig. 1. Scanning electron microscopy image of a region of the investigated system.

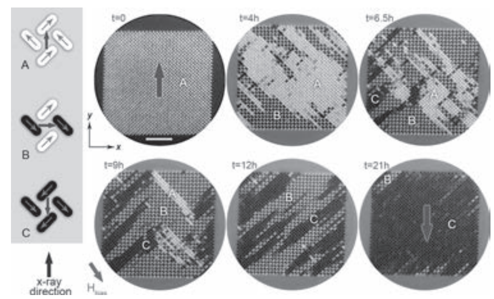

Fig. 2. Thermally-activated evolution of the system following saturation by an external magnetic field along the x-ray direction (+y axis). The schematic evolution of the magnetization at an individual vertex is sketched in the gray box. The the white or black colour, respectively, indicates the direction of the magnetization *M* toward the positive or negative y axis. The thin orange arrows represent the magnetization within the nanomagnets while the net magnetization at each individual vertex is indicated by the large brown arrows. The thermal relaxation at room temperature takes place stepwise via a clockwise rotation of the net magnetization by 90 degrees from state A (after saturation) to state B. When the system is heated above room temperature in the presence of a weak bias field, the average magnetization can locally rotate further to state C. On the right of the figure, the experimentally-measured evolution using XMCD-PEEM over a period of 21 hours is shown, indicating the regions in states A, B and C.

Artificial spin ice (ASI) are arrays of nanoislands (NIs), composed of in-plane ferromagnetic material, which are magnetically frustrated due to the intrinsic geometric ordering. Each NI can be regarded as two opposing out-of-plane Ising-spins and the ASI conforms into macro-ordered magnetic patterns to minimise the net-energy at each geometric junction. ASI are thermally stable, yet susceptible to external agitation into many magnetic metastable (MMS) states. Thus, they are primed for applications in high-density magnetic memory, reconfigurable magnonics, and logic devices [1]. In this work we use Magnetic Force Microscopy (MFM) to map the stray-field distributions emanating from ASIs with high resolution (<10nm). As a standard MFM image is a convolution of the sample's magnetic properties and the probe's imaging property, to obtain true stray field values the image needs to be corrected for the latter contribution. We use a fast-Fourier transform based procedure to calibrate the probe through its tip-transfer function (TTF) (Fig. 1a) [2], [3]. By convolving the TTF with magnetisation models of the ASI in its different MMS states, we can access the real magnetic field values for ASI and confirm the methodology's validity. Both ASI presented are 100×100μm^2 arrays of NIs (380×100nm) composed of [Py(25nm)/Pt(2nm)]. Design ASI-1 is adapted from [4] (Fig. 1b, left); whereas the ASI-2 is a new design (Fig. 1b, right) comprised of three vertex-junctions [symbols X, Y and λ] (Fig. 1c). Despite their different 2D geometries, the MMS states for both ASIs can be characterised into the same "types" from their four-fold Ising-spin groupings [5] (Fig. 1d), making them directly comparable. To create the different states, we apply in-plane magnetic fields, then image with MFM at remanence. In Fig. 1e (top), uniform low-energy MMS states [type I (left) and type II (right) for ASI-1 and ASI-2, respectively] are generated by vertical demagnetisation (vDM). The bottom two images demonstrate other MMS states: ASI-1 still has a uniform macro-order (type III) configuration (left); and ASI-2 is in a reoccurring complex state, type {II, III, III, II} (right). This unique long-range multi-modal ordering may have important applications in logic devices [4]. We studied the breakdown of long-range ordering in ASI-2 by applying large magnetic fields along the NI hard axis, creating double-domain (DD) states. Fig. 2a-e shows the change in MMS order under increasing horizontal field. Fig. 2f and g are histograms summarising the frequency of different internal magnetic configurations in a 10×10 μm^2 area. Fig. 2 a-b demonstrate mono- and multi-modal ordering as in Fig. 1e (right). By applying larger horizontal field, the system becomes disordered (Fig. 2c), as seen by a small number of individual NIs that break down into DD states. We have classified the DD vertex junctions as "perturbation" in the histograms. Fig. 2f demonstrates the small degree of perturbations in the Y and λ configurations and the total stability in the X-shaped configuration. By further increasing the horizontal field, more of the NIs break into DDs (Fig. 2d), and other junction-types appear, to minimise the global energy. Finally, we apply the same high field in the opposite direction (Fig. 2e), to further agitate the system. In the histogram (Fig. 2f), only the perpendicular NIs are seen to be perturbed, the diagonal NIs magnetically switch to maintain their mono-domain state (i.e. crosses are reversed type II). We also consider the pairs of parallel NIs (Fig. 2g). Whilst some NIs perpendicular to the applied field break down into the DD states in high fields, some configurations are flipping into anti-parallel (AP) states to avoid perturbation. As AP states are more energetically favourable to the parallel equivalent, their frequency increases with disrupting field, and higher fields are required to break AP NIs into DD states; they also give rise to the alternative junction types highlighted in Fig 2f. To summarise, we have introduced a new ASI configuration, which possesses both mono- and multi-modal long-range ordering and have studied its switching behaviour in the presence of strong magnetic fields. Furthermore, quantitative values of the ASI stray field are addressed by calibration of the MFM probe using the TTF approach. The modelling results match the experimental measurements, outlining the reliability of the methodology used.

The B2-ordered equiatomic alloy FeRh has a magnetostructural phase transition at an unusually high temperature of approximately 370 K [1]. This is a first-order transition from an antiferromagnetic (AF) state to a ferromagnetic (FM) state and is accompanied by a 1% uniform volume expansion of the crystal lattice. The transition temperature can be manipulated through magnetic field [2], strain [3,4], chemical doping [5] and spin-polarised currents [6]. Due to this remarkably rich flexibility this material has been extensively investigated in recent years for its potential for technological applications in heat-assisted memory recording [7], memory resistors [8] and magnetocalorics [9]. Most of these potential applications will require thin film material patterned on the nanoscale. The properties of the transition are relatively well understood for bulk forms of FeRh but when it is confined to lower dimensions complications to this picture arise. While there have been many have investigations of sheet film FeRh, few studies have looked at the effects of lateral confinement of the FeRh layer. Electronic transport in FeRh nanowires has been seen to show large supercooling effects and a highly asymmetric transition between heating and cooling [10]. Nevertheless, a resistance measurement averages over the whole sample with no spatial resolution. Due to the first order nature of the transition, the AF and FM phases can coexist in the same sample. Previous successful magnetic imaging of the transition has been done using x-ray photo-emission microscopy (XPEEM) and it has been shown that the transition obeys the expected behaviour of nucleation and growth of FM regions in an AF matrix [11,12]. Lorentz microscopy has also recently been employed [13]. Those studies were all on sheet film samples: here we use XPEEM to image FeRh samples which have been nanopatterned to various length scales well above and close to the typical size for a nucleated FM domain. Previous studies have not imaged the transition in a confined structure. In this work, the antiferromagnetic to ferromagnetic phase transition in nanopatterned islands of FeRh was studied using XPEEM with XMCD contrast. This technique images the ferromagnetic phase regions with contrast arising from the projection of the magnetisation onto the soft x-ray beam direction. The islands were squares with dimensions varying between 5 and 0.5 microns. These were patterned from an FeRh film, sputtered onto MgO with a NiAl buffer layer, using electron beam lithography with a hard mask and Ar ion milling as the pattern transfer method. Quantitative analysis of the magnetically sensitive dichroism images show that the phase domain development in larger structures proceeds in three distinct nucleation, growth, and coarsening stages. Images from a 5 micron square island are shown in Figure 1(a) for both cooling and heating cycles. The material within about 200 nm of the patterned edge has a transition temperature that is lower than the centre of the island, remaining ferromagnetic order for about 20 K below the point at which FM order in the centre collapses. FM order is also restored in this edge region first on warming with a fine, submicron-scale FM domain structure. Such an FM domain structure then also nucleates and grows throughout the island before coarsening into micron-scale domains when it fills the island. Magnetic vector maps of selected stages of this process are shown in Figure 1(c) and (d). The magnetisation of the island as a whole can be determined from the sum of the absolute XMCD contrast, and is plotted in Figure 1(b). This shows a downward shift of approximately 20K with respect to the transition temperature in the unpatterned film. In 0.5 micron square islands, which are smaller than the typical final domain size, the transition temperature was found to be reduced by 30 K. This is because they are small enough to be entirely edge with no centre. The reduction in transition temperature is caused by side wall damage during the mask transfer process. This common problem in nanofabrication will need to be addressed in FeRh which is highly sensitive to rearrangement of the crystalline order.

Prokhorov General Physics Institute, Moscow, Russian Federation; 4. Center for Nanoscale Materials, Argonne National Laboratory, Argonne, IL, United States

Geometrically confined magnetic particles due to their unique response to external magnetic fields find a variety of applications, including magnetic guidance, heat and drug delivery, magneto-mechanical actuation, and contrast enhancement. Highly sensitive detection and imaging techniques based on *nonlinear properties* of nanomagnets were recently proposed as innovative methods applicable in complex, often opaque, biological systems [1,2]. Here we report on enhancement of the detection capability using optical-lithography-defined, ferromagnetic iron-nickel alloy disk-shaped particles. These materials are known to possess a vortex ground state which is characterized by an in-plane curling spin configuration with zero net magnetization in remanece (Fig. 1). The detection mechanism is based the nonlinear magnetic response of the sample subjected to a two-component alternating magnetic field with different amplitudes and frequencies f_1 and f_2, with output signal detected at a frequency $f = mf_1 \pm nf_2$ [1]. During the measurements, the 3x 3 mm^2 sample of 1.5 um FeNi disks was slowly translated through the pick-up coil. As expected, the signal changes continuously when the sample is displaced and reaches a maximum value when the sample is located in the center of the measurement cell. The highest signal-to-noise ratio (SNR) in these measurements was achieved for 30-nm-thick disks. Specifically, as few as 87 particles which amounts to 39.4 pg of permalloy or a magnetic moment of 3.5x10^{-9} emu (3.5x10^{-12} Am^2) could be readily detected against the background noise. This limit of detection is at least an order-of-magnitude better than data published thus far for conventional superparamagnetic particles. To validate our initial findings in a biological system, we performed a series of *in vivo* studies. For this purpose, the 1.5-µm-diameter disks were lifted off the wafer and re-suspended in phosphate buffered saline (PBS) resulting in a concentration of ~2 x 10^9 disks per 1 ml, following the procedures reported elsewhere [3,4]. The *in-vivo* experimental setup was configured to include a detector coil generating the excitation (*ac*) field, and a larger coil that provides an external bias (*dc*) field, see photograph shown in the Fig. 2 (left). The magnetic disks suspended in PBS solution were injected retro-orbitally (that is via the ophthalmic venous sinus) into the blood flow of the animal. The anesthetized animal was placed inside the pick-up coil, which quantified the magnetic content passing through the animal's tail veins and arteries. Figure 2 (right) shows that right after injection the magnetic signal quickly raises as the disks reach the tail blood vessels to the maximum concentration, and then exponentially declines as the disks get cleared by the reticulo-endothelial system. The disks were cleared from the blood stream within <10 min. Interestingly, when an external *dc* magnetic field (of ~15 Oe) was applied in addition to the to the detector's *ac* field one minute after the disks injection, the kinetics of the particles' clearance remained the same, while the signal remarkably increased, and then abruptly decreased upon turning the field off. Both processes can be fitted with exponents having the same decay constant, which suggest that the magnetic particle removal rate is not affected by spatially uniform *dc* magnetic fields. Such responsiveness of the signal produced by the disks readily allows discrimination of the vortex labels from conventional isotropic ones, thereby providing an opportunity to multiplex magnetic labels for various *in vivo* applications and *in vitro* assays. In summary, we show that an irreversible transition between a strongly non-collinear (vortex) and single domain states, driven by an alternating magnetic field translates into a nonlinear magnetic response that enables ultrasensitive detection of these particles. The sensitivity of ~ 3.5 x 10^{-9} emu, which is equivalent to ~39 pg of magnetic material is demonstrated at room temperature for arrays of patterned disks. We also show that unbound disks re-suspended in aqueous buffer can be successfully detected and quantified in real-time when administrated into a live animal allowing for tracing their biodistribution. Use of nanoscale ferromagnetic particles with engineered nonlinear properties opens prospects for further enhancing sensitivity, scalability and tunability of noise-free magnetic tag detection in high-background environments for various applications spanning from biosensing and medical imaging to anti-counterfeiting technologies.

FE-09. Interpreting FORC diagrams beyond the Preisach model: an experimental permalloy micro array investigation.

F. Gross[1], S. Ilse[1], G. Schütz[1], *J. Gräfe*[1] and E. Goering[1]
1. Modern Magnetic Systems, Max Planck Institute for Intelligent Systems, Stuttgart, Germany

First-order reversal curves (FORC) are a powerful tool that is increasingly used in material science and nano-magnetism research [1-4]. Besides its utility for fingerprinting magnetic systems, it can distinguish between different components in a complex magnetic system without the need for a laterally resolving magnetometer [5]. Furthermore, quantitative information about the intrinsic coercivities and interaction fields between magnetic particles can be extracted from FORC measurements. Unfortunately, the interpretation of a FORC diagram as a Preisach distribution is not straight forward as most real system violate the Mayergoyz criteria [6], *i.e.* congruency and wiping-out. In these cases, the interpretation of the peaks in a FORC diagram needs to rely on additional tools like magnetic microscopy [1, 2]. Thus, it would be desirable to extend the interpretability of FORC diagrams beyond the limits set by the Mayergoyz criteria [3, 4]. Here, we systematically design artificial multi-component systems that purposely violates the congruency criterion to gain insights into the interpretability of FORC diagrams of such systems. These systems are made up of 150 μm long Permalloy (Py, $Ni_{80}Fe_{20}$) stripes that are structured by photo lithography and arranged into micro arrays (*cf.* inset in Figure 1). The coercivity of these stripes is tuned by their width (10 – 50 μm), the interaction strength by their spacing (10 – 30 μm). Thus, we are able to specifically determine the coercive and interaction fields of these well-defined systems. Subsequently, FORCs are measured with a customized *Durham Magneto Optics NanoMOKE3* magnetometer. This allows fast acquisition of high resolution FORC diagrams [5], thus, enabling us to systematically investigate a large number of samples. Additionally, 250.000 local hysteresis loops with a spatial resolution of 5 μm are measured per sample to gain an independent measure of the spatial distribution of coercive and interaction fields. Such a comparison between FORC diagram and the spatial coercivity distribution is shown in Figure 1. The two coercivities of the wide (1 Oe) and narrow (3 Oe) stripes are reflected in the FORC diagram. However, an additional peak-dip feature (marked as A in Figure 1) appears in the FORC diagram that cannot be individually attributed to a magnetic element in the system. Looking into the magnetization configuration during each minor loop, it becomes evident that this peak-dip feature is a consequence of the wide stripes (smaller coercivity) to reverse their magnetization at different applied fields when the initial magnetization is aligned parallel or anti-parallel to the narrow stripes (larger coercivity). This additional signal in the FORC diagram arises purely from the interaction when the system violates the Mayergoyz criteria. More precisely the interaction field, between narrow and wide stripes, which switch at different fields respectively. Following the evolution of this interaction peak while tuning the interaction strength of the system, a clear change in the peak size and position is observed. Figure 2 shows the integral of the interaction peak in dependence of the stripe spacing, which governs the interaction strength. As the interaction strength decreases, the peaks' integrated FORC density also decreases. Finally, the peak vanishes when the interaction strength is sufficiently decreased and the system fulfils the Mayergoyz criteria again (not shown in Figure 2). Thus, it can be deduced that here the integrated FORC density of the peak is also a quantitative measure for the interaction strength. We have used a systematic study of artificial micromagnet arrays that intentionally violate the Mayergoyz criteria, to investigate FORC diagrams beyond the Preisach interpretation of discrete hysterons. The combination of magnetic microscopy and fast FORC measurements to get to independent measures of coercive and switching field distributions allowed us to reliably interpret these FORC diagrams. Thereby, we identified an interaction peak that arises from the strong interaction of magnetic elements in the system. When such an interaction peak occurs, it is a mere manifestation of an interaction field. With this knowledge, interaction peaks in FORC diagrams of unknown system like NdFeB magnets can be interpreted. This opens up a pathway to fully interpreting FORC diagrams and elevating FORC beyond mere fingerprinting.

The demand on high data transfer and storage capacities requires smaller devices to transmit or save data. Forming well-defined ferromagnetic and electrically conducting volumes within a non-magnetic and insulating matrix in the dimensions of several nanometers can pave a way to the production of such small devices. It has been demonstrated that the reduction of oxygen in Co_3O_4/Pd multilayers is possible via local proton irradiation resulting in ferromagnetic and conducting Co embedded in a nonmagnetic and insulating Co_3O_4 matrix [1]. However, the physical mechanism behind the ion irradiation-induced oxide reduction was not addressed clearly. There are two possible mechanisms suggested to play a role behind this oxide reduction. The first one is the chemical reduction of oxygen by reacting with implanted H^+ ions, while the second possible mechanism is atomic displacements induced by ion irradiation. To address this issue, we analysed cobalt oxide thin films after irradiation with H^+ and Ne^+ ions at different doses. The irradiation parameters for Ne^+ were chosen to give the same displacements per atom (dpa) as that of H^+ which is required to reduce cobalt oxide. We also confined irradiated areas on the films in the range of microns to sub-micron, in order to ascertain the lateral distribution of oxygen after irradiation. We prepared single layer films of CoO (6-12nm) and Co_3O_4 (10nm) capped with Pt protection layers. Broad-beam H^+ irradiations were performed at 0.3 keV for ion doses ranging from 10^{15} to 10^{17} ions/cm^2 on unpatterned films. After irradiation the films were characterized structurally and magnetically and compared to un-irradiated films. Extended films showed approximately 7% of the Co bulk metal saturation magnetization (M_S) after irradiation at a dose of 5 x 10^{16} ions/cm^2 (fig. 1a inset). The increase is more pronounced with Co_3O_4 than CoO (fig. 1a). A sample was also prepared with a striped irradiation mask of 40 μm pitch. These films showed a higher magnetization after irradiation at lower doses as compared to unpatterned films, 0.14 MA/m for a dose of 10^{16} ions/cm^2 (striped) as opposed to 0.025 MA/m (extended) for a dose of 10^{17} ions/cm^2. Figure 1 (b) shows the effect of stripe width (0.5, 5, 10, 20 μm) on the resulting magnetization after H^+ irradiation at the same energy with a dose of 10^{17} ions/cm^2. No clear correlation between stripe width and M_S was seen in either oxide phase for stripes down to 0.5 μm. However, the CoO sample with 0.5 μm stripes and a thinner oxide thickness of 6 nm (gold line) as opposed to 12 nm exhibited larger M_S after irradiation, indicating oxygen displacements occur in the first few nanometers of the oxide. We also performed 5 keV Ne^+ irradiations with the helium-ion microscope (HIM) varying the ion dose from 10^{14} to 10^{16} ions/cm^2. After Ne^+ irradiations magnetic force microscopy (MFM) images were taken along with a topography image in the remnant state (fig. 2). Starting from the ion dose of 5x10^{14} ions/cm^2, a magnetic contrast could be observed by MFM, suggesting that oxygen atoms were successfully removed locally by reducing paramagnetic CoO to ferromagnetic Co. The formation of topographical bubbles was observed upon increasing the ion dose from 10^{15} ions/cm^2 to 10^{16} ions/cm^2. The lateral and horizontal sizes of the observed bubbles show a clear dependence on the ion dose with a narrow size distribution. In conclusion, our results show that, oxygen removal by means of H^+ irradiation is more efficient in Co_3O_4 films as opposed to CoO. Additionally, although there is little dependence of the resulting M_s on the pitch of the stripes (in the range of 0.5 - 20 μm), the use of a stripe mask has a more pronounced effect on the oxygen removal process as compared to the irradiations on extended films. Therefore, the physical mechanism behind the ion-irradiation induced oxide reduction process cannot purely be a chemical reaction between oxygen and hydrogen. As an outlook, the lateral size and spacing of the ferromagnetic regions generated by H^+ irradiation is only limited by the resolution of EBL. This method and the successful formation of ferromagnetic regions upon Ne^+ irradiation using the HIM can be exploited to print smaller, closer and synchronized contacts for nanocontact spin torque oscillators. Spintronic devices based on spin waves are promising alternatives to the CMOS technology and have high potential for power and area reduction per computing throughput[1,2]. The information can be encoded in either the amplitude or the phase of the wave, while the logic operation is based on the interference of spin waves, which is a keystone for the realization of logic gates. Different logic systems based on spin waves have been proposed e.g. Mach Zender interferometers[3], magnonic transistors[4], or spin wave majority gates[1] (SWMGs). The SWMG is the most promising concept since it posesses a higher expressive power with respect to e.g. NAND or NOR gates and thus may reduce circuit complexity. The basic functionality of a such device has already been proved at a mm scale using YIG[5] films, while the device scalability to micro- and nanometer dimensions was demonstrated by micromagnetic simulations[6,7]. However, these SWMG devices are based on a "trident" shape, which leads to issues due to spin wave reflection at the bending area[6] and a difficult implementation in scaled CMOS technology due to lithography limitations. In this work, we investigate the spin wave interference in micron-sized ferromagnetic waveguides using a sequential "in-line" layout of input and output antennas (Fig. 1(a)). The waveguide consisted of a 4 μm wide and ~ 40 μm long CoFeB stripe of 30 nm thickness. The waveguide was covered with 40 nm of SiN for electric isolation. Spin waves were excited by the Oersted field produced by RF currents flowing through U-shaped antennas and detected by a single wire antenna (see Fig. 1(a)). The antennas were 500 nm wide and made of 100 nm of Au patterned by electron-beam lithography and lift-off. This design provided a very low direct electromagnetic parasitic coupling between neighboring input antennas, as well as between the input and output antennas, as shown both by experiments and electromagnetic simulations[8]. Furthermore, electromagnetic simulations of the Oersted field distribution have shown that the U-shaped antennas can excite spin waves with wavelengths down to 700 nm. To study spin wave interference, the magnetic waveguide was magnetized by applying a transverse magnetic bias field (Damon–Eshbach configuration) and the spin wave transmission was measured by a vector network analyzer. Initial experiments determined the propagation characteristics of spin waves emitted from each of the three input antennas towards the output antenna. A typical frequency-field dependence of the S_{21} parameter from input I_1 towards output O (corresponding to a spin wave propagation distance of 4.8 μm) is shown in Fig. 1(b). It can be seen that the device allowed a wide operating frequency range between 3 GHz and 22 GHz depending on the external applied field. For a given magnetic field, the spin wave transmission signal existed only above a certain frequency and stayed detectable within a frequency transmission band of width Δf. The dispersion relations calculated using parameters extracted from experiments (see Fig.1 (c)) indicated that the lower threshold frequency matched well the ferromagnetic resonance frequency. The upper limit was given by the maximum wavenumber of the spin wave that antenna could excite (k_{max} ~ 8.9 rad/μm). Further experiments were aimed to study the interference of the spin waves generated simultaneously by multiple input antennas. Microwave currents with the same frequency were applied to all three inputs and the output signal was studied as a function of the input frequency, bias field, and relative phase difference between the input signals. For a given set of field-frequency parameters, an oscillatory signal was detected by varying the phase of the input signals corresponding to the constructive or destructive interference of the three generated spin waves. For example, Fig. 1(d) shows the detected signal for a phase rotation of the signal at the input I_1 up to 720 degrees, while I_2 and I_3 were kept in-phase. The position of the maxima/minima could be tuned by varying the applied frequency, which changed the spin wave wavelength and thus modified the interference pattern. In conclusion we succesfully measured interference in CoFeB waveguides by employing an all-electrical detection method using a sequential in-line antenna arrangement. This represents the first step towards the experimental demonstration of (sub-)micrometer spin wave line majority gates with a scalable geometry, overcoming spin wave reflection issues in bent regions of trident designs.

FF-02. Voltage-controlled reconfigurable spin wave nanochannels and logic devices.

B. Rana[1] and Y. Otani[1,2]
1. Center for Emergent Matter Science, RIKEN, Wako, Japan; 2. Institute for Solid State Physics, The University of Tokyo, Kashiwa, Japan

Spin waves (SWs) i.e. collective precessional motion of localized magnetic moments in ferromagnetic thin films may be used as potential information carrier in future non-volatile spintronics devices with lower power consumption. Quanta of SWs are known as magnons. Following this a new sub-field of spintronics called 'magnonics' [1] is rapidly evolving. One of the essential tasks for successful implementation of SWs in future magnonics devices is guiding SWs through reconfigurable nanochannels (NCs), formed on a waveguide (WG), to send them to a desired position. This is generally done by geometrically patterning the WGs into a stripe [2]. However, the SW path can't be further manipulated in this case, which is essential for reprogrammable magnonic devices [3]. Several reports also show SW channeling by using internal demagnetizing field [2,4], ferromagnetic domain wall [5] and SW caustics [6,7]. In practical magnonic devices, we need to selectively control a number of closely spaced spin wave nanochannels (SWNCs) simultaneously, which is very difficult to execute by using all the methods mentioned above. Moreover, the NC with any arbitrary pattern can't be realized by above means. An immediate solution to this problem could be recently discovered voltage-controlled magnetic anisotropy (VCMA), which allow us to tune interfacial perpendicular magnetic anisotropy (PMA) of an ultrathin 3d-ferromagnet by voltage i.e. electric field [8,9] without flow of charge current. Moreover, the localized nature of VCMA is suitable for nanoscale magnonic devices. We propose reconfigurable NCs generated by electric field i.e. voltage-controlled magnetic anisotropy (VCMA) in an ultrathin ferromagnetic WG for SW propagation. We perform micromagnetic simulations by using Object Oriented Micromagnetic Frameworks (OOMMF) [10] to demonstrate the confinement of exchange dominated magnetostatic forward volume like spin waves (MSFVW) in NCs by VCMA. We choose a 1.3 nm ultrathin Co20Fe60B20 (CoFeB) film with width w (100 nm, 200 nm & 800 nm) and length L (2 μm) as a model WG for simulation. Practically NCs can be formed by placing a top gate electrode on the WG and applying voltage across gate electrode and WG (Fig. 1a). The applied voltage creates a sharp potential well (i.e. channel) of PMA on the WG, underneath the gate electrode, with dimension same as gate electrode. We demonstrate that the NCs, with width down to few tens of nanometer (Fig. 1b), can be configured either into straight or curved structure (Fig. 1c) on an extended SW waveguide. Our results show that either a single NC or any combinations of a number of NCs can be easily configured by VCMA for simultaneous propagation of SWs either with same or different wavevectors (Fig. 1d) according to our needs. Furthermore, we demonstrate logic operation of voltage-controlled magnonic XNOR and universal NAND gate formed by using Mach-Zehnder interferometer based on geometrically structured WGs. Our results show that universal NAND gate can be developed even by using voltage-controlled reconfigurable NCs (Fig. 2). These voltage-controlled logic devices are more suitable for nanoscale devices due to the localized nature of electric field unlike previously reported charge current induced Oersted field controlled logic devices [11]. We also propose voltage-controlled reconfigurable SW switch for development of multiplexer and demultiplexer. We find that the NCs and logic devices, developed by using ultrathin ferromagnetic film with PMA, can even be functioning in absence of external bias magnetic field reducing power consumption to a great extent. Our results are a step towards the development of all-voltage-controlled low power nanoscale magnonic devices.

Fig. 2. Schematic diagram shows the device structure of a voltage-controlled universal NAND gate consists of two parallel NCs (NC1 and NC2) with dimension 2 μm (L) × 200 nm (d), formed by applying voltage across two top gate electrodes. A phase shifter with dimension 300 nm × 200 nm is formed on top of NC1 at x = 300 nm for adding 2π/3 phase to the SWs in NC1 with respect to the SWs in NC2. This phase shifter is designed by reducing the thickness of the dielectric (MgO) layer in 300 nm × 200 nm rectangular area by physical ion etching before depositing gate electrodes. The truth table for NAND gate is also shown on the right hand side.

Max Planck Institute for Intelligent Systems, Stuttgart, Germany

Spin waves are promising candidates as a building block for future electronic devices. Having full control over the spin waves is fundamental for the realization of such devices. Interference phenomena of spin waves can be used to localize the information at distinct points in space [1]. Recently it has been shown that stacked vortex structures are efficient emitters of spin waves with tunable wavelengths [2]. We investigate spin wave interferences in merged vortex stacks by scanning transmission x-ray microscopy (STXM) at the MAXYMUS microscope of the BESSY II synchrotron in Berlin, Germany and micromagnetic simulations. The magnetic vortex state forms in ferromagnetic nanodisks of suitable geometry. The magnetization curls in the plane around the vortex core in the center region where the magnetization points out-of-plane [3]. The vortex is described by two state parameters: the polarization *p* of the magnetization in the core region pointing either up or down, and the circularity *c*, the sense of the in-plane magnetization curling either clockwise or counterclockwise. A stack of two vortices can serve as spin wave emitter with tunable wavelengths [2,4]. For the emission of spin waves with small wavelengths the circularities of the upper and lower disks have to be aligned antiparallel. The propagation direction of the spin waves hereby depends on the absolute orientation of the two circularities [2]. We investigate a stack of two merged disks in the vortex state. Each layer of the stack contains two vortices leading to an overall number of four vortices in the structure (see Fig. 1). For the excitation of spin waves the structures are placed upon a coplanar waveguide. A high-frequency current sent through the waveguide leads to a unidirectional high-frequency magnetic field H_{rf} that excites the magnetization dynamics (Fig. 1(a)). The disks are merged and therefore exchange coupled [5] with an overlap o = 300 nm and have a radius r = 800 nm (Fig. 1(b)). The stacks consist of permalloy ($Ni_{80}Fe_{20}$) layers that are separated and covered by silicon layers (Fig. 1(c)) [6]. In Fig. 2(a) a snapshot of an exemplary STXM measurement is shown, where the black and white contrast corresponds to the *z* component of the altering magnetization. The vortices are excited with a high frequency magnetic field H_{rf} with a frequency of 5 GHz. The vortices in the left stack emit outwards propagating spin waves with a wavelength of 120 nm. The vortices on the right side emit spin waves that propagate inwards with the same wavelength. It is observed that the amplitude of these spin waves varies in the structure. On the left side a cone-like region with high-amplitude spin waves is surrounded by a low-amplitude region. The spin wave dynamics can be explained by comparison with micromagnetic simulations [7]. Figure 2(b) depicts a snapshot of a micromagnetic simulation where the structure is excited with a frequency of 6 GHz. In the simulation the vortices on the left emit outwards propagation spin waves, while the vortices in the right stack emit inwards propagating spin waves. The spin waves interfere with each other leading to an interference pattern similar to the measurement. The ground state magnetization configuration of this simulation is illustrated in Fig. 2 (c,d). The observed spin wave dynamics correspond to a diamond magnetization configuration. The vortices on the left and right side have opposing circularities as well as the upper and lower vortices. The polarizations of the upper and lower vortices differ as well (Fig. 2 (d)). As the propagation direction of the vortices depends on the absolute orientation of the circularities in a stack, inwards and outwards propagating spin waves are observed. The inwards propagating spin waves result from spin wave modes with long wavelengths that are non-reciprocally reflected at the edges of the structure [2]. It is thus possible to directly observe spin wave interference in two merged stacks of vortices. Due to the interference, the amplitude of the spin waves varies in the structure with distinct areas of low and high spin wave amplitudes. This is an important feature for the use of vortices as spin wave emitters in e.g. spin wave based signal-processing devices. A cascade of the investigated structure could serve as an efficient way to carry information in such a device.

FF-04. Protected Chiral Spin-Wave Modes for Backscattering-Immune Magnonic Transport.

M. Mohseni[1], T. Brächer[1], Q. Wang[1], D.A. Bozhko[1], B. Hillebrands[1] and P. Pirro[1]
1. Physics, TU Kaiserslautern, Kaiserslautern, Germany

Protected transport of energy and information as an emerging realm of research and technology has gained a tremendous amount of interest during the last decade [1-2]. Indeed, one of the biggest challenges in reducing the level of energy consumption and increasing the efficiency of information technology devices arises from various mechanisms of energy loss and signal distortion. Among them, defects, disorders and inhomogeneities that are induced inside or at the surfaces of the used materials, e.g., during the fabrication processes, play an important role. This motivated, inter alia, many contributions to the field of topological states of matter because topology opens the possibility to create protected and unidirectional transport [1-4]. In this contribution, we study the protection of spin waves and their quanta, the magnons, which are the low energy excitations of the spin ensemble of a magnetically ordered system. They are considered as a promising counterpart of electrons, photons and phonons to serve as information carriers in future wave-based data processing devices [5,6]. This stimulated a lot of theoretical works on the potential topological protection of spin waves in different systems like, e.g., magnonic crystals have been proposed to host topological spin wave bands [7-9]. Nevertheless, protected transport is still a great challenge since most of the proposed systems obtain their protection from Dzyaloshinskii-Moriya interaction or strongly inhomogeneous magnetic ground states which are properties that are hard to realize experimentally. Here, we demonstrate that backscattering-immune spin-wave modes exist even in simple thin film systems which have homogeneous magnetic parameters and feature no DMI. By micromagnetic simulations, we investigate the transmission of different spin-wave modes in YIG films of varying thickness after scattering of the waves by different kinds of defects and inhomogeneities. In particular, we show that chiral waves known as Magneto Static Surface Waves (MSSW, compare sketch in Fig 1a) whose reciprocity is broken because of the symmetry-breaking part of the dynamic dipole-dipole interaction with respect to the inversion of the propagation direction [7, 10] can be robust against even large inhomogeneities and defects. As an example, Figure 1b shows the micromagnetically calculated band structure of spin waves propagating perpendicular to the static field in a film of Yttrium Iron Garnet (YIG) with thickness d =100 nm. Here, the protection of MSSW against scattering is particularly strong since the MSSW frequency (red curve) is located in the band gap of the volume modes (black curve) which is opened due to the quantized exchange energy. Figure 2 compares the transmission for a topographical defect of height h for this band structure (red squares) with the case of MSSW in thicker films (d =1000nm, yellow triangles) and the Backward Volume Magneto Static Waves (BVMSW, blue circles) for the same film thickness d =100nm. It is apparent that the MSSW in the thinner film is robust against defects up to 40% of the film thickness whereas the other modes undergo strong scattering. Similar trends have been observed for inhomogeneities of the effective magnetic field and saturation magnetization. The observed protected spin waves open the possibility for designing highly efficient magnonic elements. From a more general point of view, the strong protection related to the interplay of dipole-dipole and exchange interaction should stimulate further investigation of the topology of these waves.

The investigation of spin-wave phenomena, also referred to as magnonics, plays an important role in present magnetism research [1]. This holds true, in particular, as spin waves are seen as signal carriers for future spintronic information and communication technology devices, with a high potential for further device miniaturization and reduced power consumption. Yet a successful implementation of magnonic technology will require the usage of spin waves with nanoscale wavelengths. So far, spin-wave excitation was mainly realized either by patterned transducers with sizes of the order of the desired wavelengths (current striplines or point-contacts) or by parametric pumping via a spatially uniform double-frequency microwave signal [1-3], where both concepts suffer from severe scaling problems to achieve a local excitation of ultrashort waves. Recently, however, novel spin-wave excitation mechanisms were found [4-7], which overcome the minimum excitable wavelength limit imposed by the smallest patterning size. In particular, one of those methods utilizes the translation of layered topological magnetic defects, i.e. the gyration of coupled spin vortex cores, to locally generate short wavelength propagating spin waves in a controlled way (cf. Fig. 1) [7]. In this contribution we will show that the vortex core driven excitation mechanism discovered in a highly specific trilayer system earlier [7] can be generalized to that of a plain magnetic film, in our case a $Ni_{81}Fe_{19}$ layer with 80 nm thickness [8]. The resulting spin waves were directly imaged by means of time-resolved scanning transmission x-ray microscopy (cf. Fig. 2). Here, a 7.4 GHz excitation led to the emission of concentric spiraling spin waves with ~140 nm wavelength. Furthermore, it was found that the emitted wavelength can be efficiently tuned by the excitation frequency in the range between 5 GHz and 10 GHz, resulting in ultrashort wavelengths of ~80 nm for the highest frequencies. Remarkably, at the given frequencies, the spin waves observed exhibit much shorter wavelengths than those expected for the common Damon-Eshbach mode that is characterized by a propagation perpendicular to the equillibrium in-plane magnetization and a quasi-uniform precession amplitude over the film thickness. By means of analytic calculations based on earlier predictions [9] we identified the emitted spin waves to belong to the first higher order mode of the Damon-Eshbach geometry, which is known to be antisymmetric in amplitude over the film thickness (bearing a precessional node in both dynamic components) for the case of ferromagnetic resonance -or equivalently- for infinite spin-wave wavelengths. In contrast to the latter, our calculations show that for the short wavelengths observed in our experiment, multi-mode hybridisation leads to a heterosymmetric spin-wave thickness profile with a node only in one of the dynamic magnetization components. This peculiar profile coincides with a cross-sectional line of pure linear magnetic oscillation as well as of regions with reversed (anti-Larmor) magnetization precession sense.

In magnonics research, capabilities of data processing mediated by spin waves are of current interest for beyond-CMOS data processing technologies, promising non-Boolean computing algorithms or majority gates substituting several tens of CMOS transistors and making this an exciting candidate for next level computing [1-3]. Furthermore, due to the short wavelength of magnons at technological relevant radio frequencies, smaller structural elements and, thus, miniaturization of various devices will be possible [4]. However, for magnonic logic operations, reliable spin wave guides are indispensable. Here, we use scanning transmission x-ray microscopy (STXM, MAXYMUS@BESSY II) with magnetic contrast and a spatial and temporal resolution of 18 nm and 35 ps respectively to investigate such wave-guides. These were structured in 50 nm thin Py stripes with a width of 350, 700 or 1400 nm and a length of 11 μm. A coplanar waveguide (Cr/Cu/Al) was deposited on top to allow RF excitation of spin waves in the structures (*cf.* Fig. 1 for a schematic sketch and a microscopy image). After time-domain STXM acquisition of the magnetization movie under RF excitation, a temporal Fourier transformation is performed to gain the spatial distribution of the spin wave amplitude and phase. This is shown exemplary in Fig. 2(a) for a 1400 nm wide Py stripe under CW excitation at 4.6 GHz and in an external field of 15 mT applied parallel to the long axis of the wave-guide (BV configuration). One can clearly observe that highly directed spin waves emerge from the edges of the wave-guide [5]. Due to the emission from both edges, a standing wave forms along the Py stripe. To quantify the spin-wave properties a spatial Fourier transformation was performed to derive the k-space distribution of the wave vectors, which is shown in Fig. 2(b). Here, two components stand out beside the DC peak in the center showing that these microstructures act as multimode wave-guide. The first spin-wave modes has a wave vector $k_1 = 4.7\ \mu m^{-1}$, which corresponds to a wavelength of $\lambda_1 = 210$ nm, and a second mode with a k-vector $k_2 = 10.5\ \mu m^{-1}$ is visible. Thus, we are able to microscopically observe a spin-wave with a wavelength of $\lambda_2 = 95$ nm and experimentally break through the 100 nm limit. Furthermore, we have performed a systematic variation of excitation frequency and applied external field for the different wave-guide widths. By varying these parameters, the wavelength as well as the propagation direction are tuned, indicating also diagonal and curved propagating of spin-waves that resembles the propagation of light in a graded-index fiber. Additionally, we recreated a data transmission scenario by using a Burst excitation scheme, *i.e.* four periods of RF excitation followed by a free decay time. Thereby, simultaneously excited multiple modes are carried by the Py wave-guide. They are interleaving without disrupting each other, further confirming the multimode properties of the wave-guide. Surprisingly, these modes did not disperse in frequency during the decay time making this system an ideal candidate for data transmission. In summary, we have directly observed sub-100 nm spin waves in a Py wave-guide by time-resolved STXM. The simple wave-guides were found to be able to non-dispersively carry multiple modes simultaneously. Thus, they are ideal candidates for magnon based data transmission between logic elements and provide a promising basis for future technology developments.

Spintronics based devices have found broad applications, for instance in sensors and in storage as read-heads of hard disk drives. Device prototypes, exploiting the effect of spin-torque, are anticipated to enhance the functionalities of Boolean logic circuits by integrating logic and memory functions. Despite successes, devices utilising ferromagnetic materials and spin-polarised charge currents have a number of drawbacks; parasitic magnetic stray fields, intrinsically low characteristic frequencies, and large magnetic damping and ohmic losses that respectively limit density integration and operation speed, and increases power consumption. The two key challenges are thus to design devices that remove stray fields and charge transport. Theoretically it was predicted that pure spin currents could be generated, transported and employed in antiferromagnetic insulators to enable such new devices[1–3]. However experimentally, only a few systems have been investigated, most relying on coupled ferromagnet(FM)/antiferromagnet (AFM) layers[4–7]. A key limiting factor for the transport of a spin-current in insulating antiferromagnets has been the reported spin-diffusion length of only a few nanometers and spin currents mediated by evanescent waves when generated by spin-pumping[5–7] or the spin Seebeck effect in adjacent ferromagnets[8]. Here, we demonstrate for the first time spin transport in insulating antiferromagnets over micrometer distances, which is 2-3 orders of magnitude larger than what has been previously reported when using a ferromagnet for spin injection. We obtain unprecedented long-distance spin transport by injecting spin currents from Pt contacts into selected single crystal antiferromagnets and thus open antiferromagnetic insulator systems to novel spintronics devices. In our study, we employ a non-local geometries (see Fig. 1) to study high frequency magnon propagation in an antiferromagnetic insulator. Our devices consist of platinum (Pt) strips, deposited on different 3d insulating antiferromagnetic compounds like the prototypical antiferromagnet NiO[4,9], in which ultralow magnetic damping has been reported ($\alpha < 5.10^{-4}$). When we apply a direct current in a platinum stripe, we inject magnons by both the spin Hall effect (SHE) and ohmic heating of the injector, generating magnons via the spin Seebeck effect (SSE) in the AFMI, and detect their cumulative propagation via the inverse SHE in a non-local Pt stripe. We can ascribe the first harmonic signal of the recorded voltage (linear term) to the spin transport signal and the second harmonic (quadratic term) to the thermal signal. We apply an in-plane field and note that the first harmonic voltage (see Fig. 1.i), related to the spin conductance, presents a maximum at the spin-flop reorientation, whilst the second harmonic signal, related to the spin Seebeck coefficient, is linear with the applied magnetic field (see Fig. 1.ii). In contrast to the conventional behaviour in ferromagnets[10], our spin transport signal displays a 90 degree shift whilst still displaying the characteristic π-periodicity previously observed as the field is rotated in-plane relative to the applied current direction. However, we observe an angular dependence identical to the ferromagnetic case for the thermal signal indicating different origins of the two signals. The transport signal is dependent upon the relative orientation of the Neel vector and injected spin accumulation whilst the thermal signal depends on the degeneracy of the magnon modes. Based on the geometry of our system, we also unambiguously distinguish long-distance transport based on equilibrium (Bose-Einstein condensate) or non-equilibrium magnons. The underlying physical mechanisms in our experiments allows us to observe the persistence of the two signals for distances larger than a micron, i.e more than two orders of magnitude larger than previous reports in antiferromagnetic thin films (see Fig. 2). Those results demonstrate the possibility of propagating long distance magnons in antiferromagnetic insulators, opening the way to spin-electronics devices with antiferromagnets.

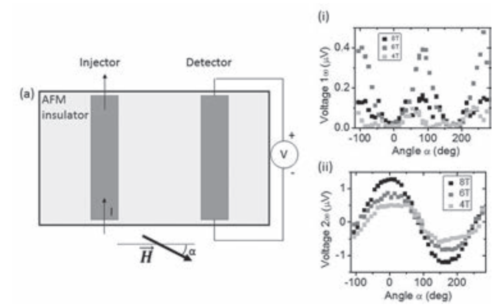

Fig. 1. (a) Schema of the experimental setup. (i) When applying a current in the injecting platinum stripe, the spin Hall Effect induces a spin accumulation oriented perpendicular to the bar, which can generates propagating magnons when the Neel vector has the appropriate symmetry. Those magnons are then detected at the 1st harmonic of the signal by ISHE. Below 6T, the direction of the Neel vector is pinned along the platinum stripes. The optimal orientation of the Neel vector is obtained at the spin-flop field, around 6T, for a magnetic field applied along the platinum stripes. (i) When applying a current in the injecting platinum stripe, a thermal gradient is also generated perpendicular to the magnons. Thermal magnons are excited by the Spin-Seebeck when an applied magnetic field lifts the degeneracy of the magnon modes. (i) Those propagating magnons are detected by ISHE at the 2nd harmonic ($\propto I^2$) when the magnetic field lifts the degeneracy of the magnon modes.

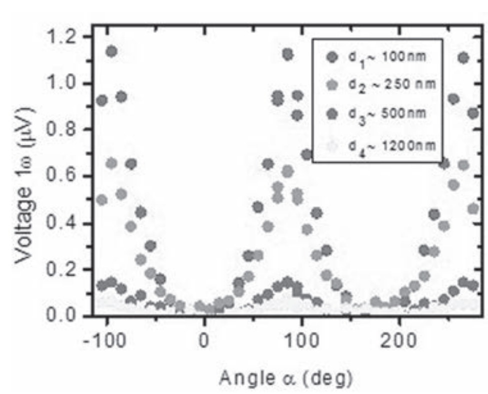

Fig. 2. Angular dependence of the 1st harmonic signal, corresponding to the propagated magnons generated by the spin-accumulation in the injecting platinum stripe, for four different distances (from 100 nm to 1.2 µm).

FF-08. Variable effective magnetization and spin wave velocity in low magnetic damping metallic multilayers.

J.M. Shaw[1], E.R. Edwards[1], T. Silva[1] and H. Nembach[1,2]
1. Quantum Electromagnetics Division, NIST, Boulder, CO, United States;
2. JILA, University of Colorado, Boulder, CO, United States

We used broadband ferromagnetic resonance spectroscopy and Brillouin light scattering to measure the damping, effective magnetization, and spin-wave velocity in multilayer metallic samples that exhibit exceptionally low values of the damping parameter. We show that we are able to vary the effective magnetization from 2.6 T to values approaching 1 T while maintaining a total damping parameter of approximately 0.002 for a 20 nm film. This is achieved by careful choice of the layers in the multilayer stack that intrinsically are low damping materials and/or minimize spin-pumping contributions. Some proposals for alternative computation technologies are based on the generation, interaction, and propagation of spin excitations. Such proposals ultimately rely on the such spin excitations having long lifetimes and therefore low values of the damping parameter. The recent discovery of simple metallic CoFe systems that exhibit ultra-low damping show promise since these systems have trivial fabrication constraints relative to half-metallic and insulating low damping materials. [1] However, the CoFe system also has an exceptionally high magnetic moment since it lies at the peak of the Slater-Pauling curve. A high effective magnetization ($\mu_0 M_{eff}$) can be beneficial by providing high spinwave velocities for magnonic structures. In fact, it is conceivable that even higher spinwave velocities and therefore high values of $\mu_0 M_{eff}$ may be desired. [2] On the other hand, the high values of $\mu_0 M_{eff}$ may be prohibitive in system that require the magnetization to be arbitrarily oriented. Therefore, tunability of $\mu_0 M_{eff}$ would be desired while at the same time maintaining the low magnetic damping properties. Such tunability is a challenge since we have previously shown that in the case of CoFe, changing alloy composition rapidly increases the density of states at the Fermi energy, thereby increasing the damping. [3] An alternative approach is to vary $\mu_0 M_{eff}$ through multilayer and interfacial effects, which typically exploits the phenomenon of interfacial anisotropy. In this case, $\mu_0 M_{eff}$ can straightforwardly be tuned by varying the thicknesses of the layers in the multilayer stack.[4] However, careful choice of the materials in the multilayer or superlatice is needed to maintain a low damping parameter. [5,6] We have found that superlattice structures composed of alternating layers of $Co_{25}Fe_{75}$ with Cu and $Co_{90}Fe_{10}$ can be used, while maintaining a total damping parameter of approximately 0.002. In order to increase $\mu_0 M_{eff}$, the use of $Co_{25}Fe_{75}/Co_{90}Fe_{10}$ structure was used, which has a negative value of the interfacial anisotropy (favoring an in-plane magnetization). Figure 1 shows that $\mu_0 M_{eff}$ can be increased from 2.3 T to 2.6 T by decreasing the bilayer thickness. Also shown is the damping parameter which is scattered around a value of approximately 0.002. In contrast, the use of $Co_{25}Fe_{75}$/Cu superlattice structures can be used to decrease $\mu_0 M_{eff}$ since the interfacial anisotropy is positive (favors an out-of-plane magnetization). Figure 2 shows that the use of Cu in the multilayer stack can reduce $\mu_0 M_{eff}$ from approximately 2.3 T to almost 1 T before the damping parameter begins to increase significantly. Finally, the spinwave group velocities were measured with wavevector-dependent Brillouin light scattering (BLS). Figure 3 is an example of the measured spinwave velocities as a function of the wavevector. We find that the spinwave velocities vary with the effective magnetization as expected. These results open up new approaches to achieve low magnetic damping while maintaining the ability to vary other static and dynamic magnetic properties.

FF-09. Finite Speed of Propagation of Spin Waves in the Inertial Regime.

C. Serpico[2], M. d'Aquino[1], V. Scalera[2] and M. Lo Bue[3]
1. Dipartimento di Ingegneria, Università degli Studi di Napoli "Parthenope", Napoli, Italy; 2. DIETI, University of Naples Federico II, Naples, Italy; 3. SATIE, CNRS, ENS Paris-Saclay, Université Paris-Saclay, Cachan, France

In this work, we discuss small wavelengths, exchange interaction dominated, spin waves in a ferromagnetic media which oscillate in the THz frequency range. This type of spin excitations is of considerable interest in the area of ultrafast (subpicosecond) magnetization dynamics [1],[2]. In this respect, it has been pointed out that ultrafast magnetization dynamics can be considerably affected by inertial effects. This idea was proposed originally in the framework of nonequilibrium thermodynamics [3], and later discussed by other authors from a more fundamental point of view [4], [5]. In this work, we discuss inertial effects in connection with the issue of speed of propagation of spin-waves. In the first part of the discussion, we consider usual spin waves analysis in a uniaxial ferromagnetic media subject to a constant external field in the limit when the magnetostatic field is negligible with respect to the exchange field. The exchange field, as it is usually done, is taken proportional to the Laplacian of the magnetization vector field. In these conditions, the equation governing spin wave oscillations can be transformed into a Schroedinger equation which can be analytically solved. This leads to the fact that spin-waves perturbation propagate with infinite speed. More specifically, if we solve the Schroedinger equation with an initial condition such that the wave function is zero outside a certain finite region, at any arbitrarily small time after, the wave function is different from zero anywhere in space. This fact leads us naturally to question about relativistic consistency of the model. In this respect, it is evident that the usual spin waves theory includes approximations which leads to the neglecting of fast phenomena which are normally not relevant for the range of physical situations to be analyzed. The situation is similar to the use of quasi-static Maxwell Equations in which fast dynamics connected to the propagation of electromagnetic waves are negligible due to the fact that the system under consideration is small with respect to the wavelength of the electromagnetic radiation. In the area of ultrafast magnetization dynamics, for magnetization dynamics in the THz frequency range, it might be important to understand in which sense the usual model of exchange dominated spin waves is a low frequency approximation of a more general model. In comparison with the electromagnetic field theory, the situation is less clear because we do not have currently a well accepted theory for high-frequency spin-wave propagation. In general terms, the theory could be modified in two respects. First, one could modify the expression of the exchange field in terms of magnetization vector fields, given the fact that the Laplacian operator is only a low wavelength approximation of a more general linear operator. Second, one could consider the fact that usual Larmor precessional dynamic equation is a low frequency limit of a more general equation. In this work, we explore this second possibility considering inertial terms in the equation governing spin waves dynamics. In the last part of the work, we derive the dispersion relation in the inertial regime which consists of two branches as represented in Fig.1. On the basis of this dispersion relation, we are able to prove that this generalization of spin dynamics equation leads to a finite speed of propagation of spin waves, and thus it removes the inconsistency of the usual theory. We conclude our contribution by showing that the maximum speed of propagation of the spin waves in the inertial regime is given by the formula $u=l_{ex}/\tau_I$, where l_{ex} is the exchange length of the media, and τ_I is a time constant related to the intertial effect (which has been estimated to be in the picosecond range [3]).

FF-10. The general Boltzmann method for magnon transport with full scattering process.

Y. Li[1], T. Liu[1], W. Wang[1] and *J. Zhang*[1]
1. School of Physics, Tongji University, Shanghai, China

Information transport with the spin degree of freedom was adapted to revive electronic devices. In particular, magnon, the flow of quantized excitations of the spin system have been considered as the ideal carrier because of its excellent transport characters. Ferromagnetic insulators (FMIs) was most promising material for magnon devices to generate, process, and transport spin information over long distances[1]. Some phenomena explored in insulating spintronics include spin pumping, the spin Seebeck effect, the spin Peltier effect, magnon drag effect, and magnon spin transport (MST)[2-6]. While, a precise magnon transport picture in FMIs thin film was still demanded. A novel complete picture of magnon transport in FMIs was builded with a new Boltzmann equation which combined magnon, phonon and spin-polarized electron system together. In three magnons scattering, we found the N-process scattering which due to dipole-dipole interaction, dominated the decay dynamics of magnon group. To conduct N-process scattering, a new spatial dependent magnon draft field U was introduced, which was describing collective local motion field in magnon. We also found N-process scattering is the physical origin that why coherence magnons can transfer to thermal magnons in FI relaxation process. With those effects, we proposed a new method try to modify generation, amplification and controlling of magnon transport and the conversion to other particles (phonon). In our state of art Boltzmann equation, we analyses three-magnon scattering with a new spatial dependent magnon interaction field U, and construct the effective magnon temperature. We also find that three-magnon scattering causes at least two physical effects. First, it takes part in the thermal conductivity adjustment as anther heat carrier in addition to phonon. Second, it is also the physical origin that why coherence magnons can transfer to thermal magnons in FI relaxation process. Beside we also fund nonlinear effect of magnon in transport length(see attach figure). With those two effects, we find a brand new method to effectively generate, amplify and control magnon transport and the conversion with other particles. Furthermore, three-magnons scattering engender a novel collective dynamic of magnon, which is the extending of global decay length of spin information. In this framework, we also provide the methods to adjust the magnon distribution, with applying the gradient magnetic field and temperature field. This work was supported by NSFC

Bose Einstein condensation (BEC) is an ensemble of (quasi-)particles occupying a single state in momentum space. BECs have not only been observed in clouds of ultracold atoms but also the BEC of different bosonic quasi-particles like exciton polartions [1] and magnons [2,3], the quanta of spin wave excitation, have been experimentally reported. This has opened up a manifold of research directions and allows for the realization of coherent macroscopic states in a solid state material at room temperature. Recent advances like the observation of room-temperature magnonic supercurrents are just one example [4] for the rich physics of quasi-particle BEC. Here, we report on a fundamentally new way to create such a quasi-particle BEC using magnons in the ferromagnetic insulator yttrium iron garnet (YIG) as a model system. In previous realizations of quasi-particle BECs, a large number of 'hot' quasi-particles has been injected into the respective quasi-particle system either by microwave pumping (magnons) or, for instance, by optical pumping (polaritons). In our experiment, we demonstrate that the interaction of magnons with the phonon bath can provide a very simple way to achieve a magnon BEC at room temperature: By cooling down a previously heated nanostructure made of YIG in contact with Pt and Au heat sinks on a time-scale that lies below the lifetime of dipolar magnons, a non-equilibrium state is induced in the magnon subsystem. Using time-resolved Brillouin light scattering spectroscopy, we demonstrate that this results in the formation of a magnon BEC manifesting itself by a large magnon intensity at the bottom of the spectrum during the cooling of the magnetic structure. In my presentation, I will reveal the influence of the heating time and the achieved maximum temperature. I will demonstrate that a high cooling rate on the order of 20 K/ns is crucial for the realization of the quasi-particle BEC. This research has been supported by the ERC Starting Grant 678309 Magnon-Circuits, the ERC Advanced Grant 694709 Supermagnonics, and by the Deutsche Forschungsgemeinschaft (DU 1427/2-1).

FF-12. A Magneto-elastic Correlator Using Acoustic Wave Pumping of Spin Waves.

I. Lisenkov[1], M. Hansen[1], J. Davies[2], P. Dhagat[1] and *A. Jander*[1]
1. Electrical Engineering and Computer Science, Oregon State University, Corvallis, OR, United States; 2. NVE Corporation, Minneapolis, MN, United States

The group velocity of both acoustic waves and spin waves in crystals are orders of magnitude less than those of electromagnetic waves. As a result, complex analog signal processing tasks that span multiple periods of a signal can be implemented more compactly with acoustic or spin waves than with electromagnetic waves. Acoustic wave devices have thus become common in RF communications circuits, realizing complex linear filter functions in a compact and efficient manner. Although spin-wave-based devices could, in principle, perform many of the same functions as acoustic wave devices, the much higher losses and non-linear effects have limited the practical application of spin wave signal processors. However, we propose that for *nonlinear* signal processing functions, such as signal correlation, the combination of acoustic and spin wave signals in a single device may prove advantageous. We have developed a magneto-elastic device that exploits the nonlinear interactions between acoustic waves and spin waves to implement a microwave signal correlator. The device, illustrated schematically in Fig. 1a, uses an acoustic wave signal generated by a piezoelectric transducer to parametrically pump [1-3] a signal spin wave launched into a thin-film yttrium-iron-garnet (YIG) waveguide by an antenna. The resulting idler spin wave is picked up by an output antenna. The frequencies of the three waves are related $f_p = f_s + f_i$. In our experiments, the acoustic pump signal is at a frequency of f_p=2.4 GHz while the signal and idler spin wave frequencies, f_s and f_i, are a few MHz above and below 1.2 GHz. It can be shown that if the microwave input signal and pump signal are modulated with signals S(t) and P(t) respectively, the generated idler signal is modulated by the combination of the two signals as $I(t)=\int_0^{t_o} S(2\tau-t)P(\tau)\, d\tau$, thus implementing a signal correlator. The correlation time window, t_o, depends on the length of time that the spin wave transits the pumping region. The correlation signal processing is used to increase the signal-to-noise ratio of weak signals in a presence of an interference. In our proposed scheme the weak signal is used to generate spin-waves via the input spin-wave transducer, while the “reference” code is applied to the pumping acoustic transducer. We created a theoretical formalism, which allows us to predict the characteristics of the output idler signal taking into account the features of the magneto-elastic parametric interactions, magnetic damping and the non-linearities in spin-waves associated with the pumping process. As an example we calculate the distribution of the spin-wave amplitude under the transducer for two orthogonal Walsh codes, while the pumping signal is modulated with one these codes. Fig. 2a demonstrate the distribution of two “signal” spin-waves, while Fig.2b shows the corresponding two “idler” spin-waves under the influence of the the pumping signal. Our simulations show, that i) the output idler power is enhanced when the signal spin-wave code matches the reference and suppressed otherwise, ii) the non-linearity introduced by a relative high pumping amplitude does not spoil the correlation process, and iii) the spin-wave damping does not spoil the correlation processing. We have fabricated such a device, and sample results of its operation with a continuous pump are shown in Fig. 1b. The input microwave pulse of duration t_s = 30 ns on the signal channel generates an idler pulse that appears after some delay at the output. Since the pump is continuous, the output spans a time $t_s + t_o$, where t_o is approximately 200 ns, the time required for the pulse to traverse the 2 mm long device. We are currently implementing the ability to modulate the pump signal as well, so that the convolution of two signals, such as in Fig 2, can be demonstrated. Such a signal correlator could be used to great advantage at the input to a code division multiple access (CDMA) communications receiver, such as a cellular telephone, to de-correlate the incoming code sequence in the analog domain. Shifting this function to the analog domain could result in significant power savings and may improve the receiver’s resilience to interfering signals.

FG-01. Design and Analysis of a Hybrid Stator Permanent Magnet Biased Bearingless Switched Reluctance Motor.

Y. Yuan[1], Y. Sun[1], Y. Huang[1], J. Yan[2] and F. Yang[1]
1. School of Electrical and Information Engineering, Jiangsu University, Zhenjiang, China; 2. School of Automation, Nanjing University of Science and Technology, Nanjing, China

Introduction: High integration, low loss and high-reliability are the main development trends of flywheel battery [1]. Magnetic bearings (MB) [2] with several advantages, such as eliminating of a lubrication system, friction-free operation and low power consumption can be promoted in various practical industrial applications, especially in flywheel batteries. The structure of MB is similar to that of the switched reluctance stator (SRM) [3]. Thus, the bearingless technology can be applied to SRM to extent its high-speed limitation. The bearingless SRM (BSRM) [4] rotates and levitates simultaneously by integrating magnetic levitation winding into the stator of a motor. However, one common problem in these existing structures [5-7] is that there is strong coupling between torque and radial force. Moreover, the copper loss and temperature rise of windings are also a problem that cannot be ignored [8]. Thus, this study presents the first prototype of a hybrid stator permanent magnet biased (HSPMB) BSRM with the advantages of weak coupling and low power consumption. The structure, operation principle and main electromagnetic characteristics of the HSPMB BSRM are analyzed. The proposed motor exhibits the following advantages: 1) High integration. The proposed motor can realize energy conversion and two degrees of freedom(2-DOF) radial suspension through the torque and suspension systems, correspondingly. 2) Low loss. The biased flux is provided by the permanent magnet which leaves out the extra biased winding correspondingly. 3) Weak coupling. Self-decoupling is realized between the torque and the suspension systems according to the structural design. 4) Favorable controllability. The suspension force is only related to the current and has no relation to the rotor position, thereby increasing controllability. New Machine: The structure of the proposed bearingless motor is illustrated in Fig. 1. Fig. 1(a) presents the HSPMB BSRM, which mainly consists of a outer stator with twelve poles, a rotor with eight poles and a hybrid inner stator. The windings with condition current i_{TA} on the poles of the outer stator can produce rotational torque. The configuration of torque winding in *A* phase of the outer stator is drawn as an example. Fig. 1(b) presents the structure of the inner stator, which consists of a left inner stator with four poles, a permanent magnet (PMR) and a right inner stator with four poles. The biased flux for generating a suspending force is provided by the PMR with axial magnetization and forms a closed loop through the left inner stator poles, the rotor and the right stator poles. As shown in Fig. 1(c), the winding with condition currents i_{RFy} and i_{LFy} on the poles of the hybrid inner stator can produce 2-DOF suspension forces and the configuration of it in the *y* direction is drawn as an example. Fig. 1(d) depicts the control magnetic flux and biased flux paths. By adjusting the directions of the control flux Φ_{RFy} and Φ_{LFy} to superposing or reducing the biased flux Φ_m, the suspension force can be produced in 2-DOF. Main Electromagnetic Characteristics: Fig. 2 depicts the main electromagnetic characteristics of the TSPMB BSRM. Fig. 2(a) presents the distribution of biased flux and the value and of air-gap flux density. It can been seen that the biased flux distributes in the rotor and hybrid inner stator symmetrically and evenly, and the value of the inner stator air-gap flux density is approximately 0.5 T. As shown in Fig. 2(b), the air-gap flux density in the *y* positive direction decreases with the increase in the current value when i_{LFy} and i_{RFy} are conducted with 2 A, 2.5 A, 3 A, and 3.5 A. Therefore, the air-gap magnetic flux density can be regulated by controlling the magnitude and direction of the suspension current, and the required suspension force can then be generated. Fig. 2(c) and Fig. 2(d) present the values of suspension force and torque. Fig. 2(c) demonstrates the values of suspension force with i_{LFy} and i_{RFy}= 2 A, 2.5 A, 3 A, and 3.5 A in the *y* direction. The values of the suspension force are approximately 34 N with 2 A, 42 N with 2.5 A, 49 N with 3 A, and 54 N with 3.5 A conduction. The suspension force value in the *y* direction is approximately linear with the value of suspension current. This analysis denotes that the controllability of the magnitude of radial suspension forces in the 2-DOF direction can be achieved by adjusting the suspension force winding current magnitude. Fig. 2(d) depicts the torque values when the rotor rotates at a 2π mechanical angle with different suspension current operations. The maximum torque value is approximately 0.003 Nm which can be ignored when the suspension system is conducted in the *y* direction. Thus, the self-decoupling is realized between the torque and the suspension systems.

FG-02. Weight reduction of the damper coils in the superconducting magnetically levitated bogie.

S. Ohashi[1]
1. Electrical and Electric Engineering, Kansai University, Osaka, Japan

A Superconducting magnetically levitated (Maglev) transportation system has been developed in Japan. Fig .1 shows a cross section of the system. The null flux eight figure levitation coils are set on the ground[1][2]. And Superconducting (SC) coils that are used for both secondary of the linear synchronous motor and the levitation magnet are installed on the side of the bogie. This system which is based on the side wall electrodynamic suspension (EDS), keeps the air-gap length at about 100 mm. When the bogie passes below the center of the levitation coil, current is induced on the levitation coils, and its value depends on vertical position and velocity of the SC coils on the train. Interaction between this current and flux of the magnet, levitation force is generated. Although the EDS system has the advantage of stable levitation without active control, results of the numerical simulation show that the damping factor of the levitation system is small. Thus additional damper system has been proposed to increase damping of the system against oscillation of the bogie. Although the mechanical dampers are installed between the bogie and the cabin, the primary damping factor is needed. As the train runs with levitation, it is impossible to install the mechanical damper for the primary one. The damper coils are installed in front of the SC coils. From the results of the three-dimensional running simulation, it is shown that the damper coils works effectively[3]. The specifications of the damper coils are decided by the damping effect against the natural vertical oscillation of the bogie. The weight of the conventional damper coils is heavy. So weight reduction of the damper coils is needed. In this paper reduction of the damper coil weight is studied. The weight reduction damper coils are introduced. And its damping characteristics are shown by the numerical analysis. Levitation force is generated by passing the SC coils on the bogie. The eight-figure null-flux connection is used for the levitation coil on the ground. If the bogie passes under the center of the eight-figure coils, levitation force is generated. We use virtual displacement method to calculate levitation force. Current induced in the levitation coils is calculated as follows [4]; the EDS system is given as an air-core coil system, and modeled as electric circuits. Mutual inductance between SC coils and levitation ones are calculated, and the electric circuit equations are given. Then solving the electric circuit equations, we can calculate the current of the levitation coils. The motion of the bogie is calculated by putting these electromagnetic forces. Iterating these procedures, the transient motion of the bogie is given. We use Eular method to solve differential equations. In the conventional system, weight of the damper coils reaches about 2.5% of the bogie. It affects motion of the bogie. Also, increment of the total weight of the bogie changes levitation gap of the train. So it is important to reduce the weight of the damper coils. They are set in front of the SC coils. Two damper coils are installed for each SC coil. Change of the linkage flux generates electromotive force on the damper coils. Then interaction between the current of the damper coils and flux of the levitation coil causes electromagnetic force. This force acts to decrease vibration of the bogie. Same as the calculation for the levitation force, we regard the SC coils, the levitation coils and damper coils system as electric circuits. Then the current induced in the damper coils is given. As one bogie has eight SC coils, sixteen damper coils are set for one bogie. Reduction of the damper coils weight are studied. Target weight of the damper coil is half as much as the conventional one. The diameter of the coil is fixed at 4 mm, and number of turn is 2. Then width and height of the coil is changed as parameters. These parameters are defined as follows; energy consumed in them is calculated when the bogie oscillates vertically at natural oscillation. The damper coils that energy takes maximum is defined as the optimal one. Fig.2 shows dependence of the energy on the height of the coil. The negative value means the damper coils absorb the vibration energy. As shown in Fig.2, the energy takes maximum value at coil height = 0.35 m. (The width of the coil is defined automatically from the weight of the damper coil). Running simulations with the weight reduction have been undertaken. The weight of the reduction model becomes half as that of the conventional one. This means size of the damper coils becomes small, and effect of the damper coil should decrease. The number of operation type of the damper coil is two. One is the passive mode, and the other is semi-active one. In the passive mode, the damper coils are used just as the short circuit coil. The effect of the conventional damper coil becomes large in this mode. In the semi-active mode, the switching device are installed, and damper coils are switched depends on the vibration velocity of the bogie and current of the coil. When the switch is ON, the damper coils are short circuited, and OFF, open circuited. In this semi-active mode, oscillation of the bogie converges faster than that by the conventional one.

Abstract—This paper deals with the analysis and optimization of radial, coaxial magnetic gears. Multi-objective optimizations of the modulator shape of two magnetic gears with and without outer rotor iron yoke will be presented and discussed. To guarantee comparable results, equal start geometries, optimization parameters, objectives and constraints are considered. After the optimization process the geometries of the two gears show different optimal modulator shapes and therefore different flux and force distributions. The optimized gear without yoke will then be analysed in more detail. It achieves a comparable torque capability in comparison with the optimal gear with yoke but reduces losses by 70% estimated by 2D FEM Calculations. *I. Introduction* In recent years the interest in contactless torque transmission is growing and a lot of research and publications were conducted in the field of magnetic gears and magnetic geared drives. Present motor-gear solutions are in most of the cases electrical drives combined with mechanical gears to transform the high speed side of the motor to the *low speed/high torque* side of the application. When low speeds and high torques are required a Direct Drive can be a good solution, but with the disadvantage of lower efficiencies and bulky structures. The combination of a high speed motor and an efficient gear can give a rise to system power densities and reduce the space of the whole configuration [1]. At the moment mechanical gears are limiting the use of high speed motors as input speed source [2]. Magnetic gears show many advantages in comparison with mechanical gears. The biggest advantage is the contactless transmission. Due to friction, maintenance costs in mechanical gears are quite high and are reducing the lifetime of a gearbox drastically. A lot of research focuses on the topology presented in Fig.1, which is a combination of an inner rotor with few pole pairs p_1, a flux modulator and an outer rotor with a high number of pole pairs p_3. Fig.1 shows the topologies of the presented gears with the pole pair numbers p_1=1 and p_3=17 and the modulator teeth n_2=18 and different modulator geometries. The rotational speeds are presented by $\omega_1=\omega_h$, $\omega_2=\omega_l$ and $\omega_3=0$ (Index l and h represent the low and high speed side). In the last years many topologies and variations were investigated ([3], [4], [5], [6] and [7]) to improve the torque transmission capabitity. Although a lot of papers were published since the key publication in 2004 [8] just few papers picked a high speed pole pair number p_1 of 1 [9] and in general there are not many publications that focus on magnetic gears in combination with motor speeds beyond 10.000 rpm [1]. *A. Modulation Effect and Gear Ratio* High input speeds $\omega_h=\omega_1$ require a high gear ratio G_r to adjust the motor speed to low speed ω_l applications. In magnetic gears with modulation effect the equation $n_2=p_1+p_3$ has to be satisfied. When the outer rotor is stationary the ratio results in $G_r=\omega_h/\omega_l=\omega_2/\omega_1=-n_2/p_1$}.The detailed derivationof these equationes and all necessary relations can be found in [8]. A low pole pair number p_1 and a high number n_2 of modulator teeth result in a high gear ratio. In contrast to previously set up prototypes higher motor speeds can be transfomed to the necessary application *speed/torque* due to the higher ratio. *II. Influence of Modulator Geometry* The conventional gear G_1 with iron as outer rotor yoke material shows the highest losses in the back iron yoke of rotor 3. In order to reduce these losses the outer rotor back iron is set to vacuum in a second gear configuration G_2. This section will describe the optimization of the gears and it will be introduced with the description of the start geometry, followed by the optimization parameters, objectives and constraints. Besides high torque, also low losses, low ripple and low flux density in the gear surrounding are requirements. The optimized gears (G_1, G_2) will be analysed and then the influence of the different modulator shapes on the force and torque generation at G_1 and G_2 will be presented. *III. Outlook* The introduction briefly explains the chosen topology. A more detailed description will be given in the full paper. Especially the reduction of losses by equal torque generation capabilities of the gear without rotor yoke (G_2) is of particular interest and requires further analysis of the gear characteristics. Finally, the conclusion of the paper will summarize the results and give an outlook on future work and developments.

INTRODUCTION A popular approach to achieving robotic actuation is to use a high-speed motor connected to a rotary gearbox [1]. Mechanical gearboxes with volumetric torque densities in excess of 300 Nm/L are achievable [2, 3]. However, mechanical gearboxes need regular servicing and lubrication. Some gearing systems are not back-drivable and most offer limited compliance capabilities. The mechanical gearing system can also often be noisy. The main alternative to the use of a gearbox is to use a direct-drive (DD) permanent magnet (PM) motor. The use of the DD-PM motor removes the reliability concerns with regard to the mechanical gearbox failures and maintenance needs. DD-PM motors can also be designed to be quiet in operation. However, the torque density of a DD-PM motor is thermally limited (by current) and therefore a PM motor does not normally achieve volume torque densities greater than 50Nm/L [4] and mass torque densities higher than 6Nm/kg [5]. Hydraulic and pneumatic actuators are capable of creating extremely high force densities. Mass torque densities in the range of 96Nm/kg [5] have been reported. However their dependence on non-portable pressure supplies limits their range of application. Hydraulic and pneumatic actuators are typically also only efficient over a limited operating range [5]. Review articles [1, 5] discuss other actuator technologies such as shape memory actuators and engineered muscle tissue actuators. However most newly proposed actuators operate with low efficiency [1, 6]. A robot actuator that could combine the features of high efficiency, high torque density and high reliability would be most desirable. Recently a number of authors have proposed that a magnetic gearbox (MG) could potentially meet these requirements [7, 8]. A MG uses a contactless mechanism for speed amplification. Initial MG designs tried to mimic their mechanical counterparts [9, 10] however such approaches only resulted in a fraction of the magnetic fields being utilized for torque production. In 2004 Atallah showed that the coaxial MG shown in Fig. 1 could operate with a torque density of up to 100Nm/L. This is approximately twice the peak torque density of a DD generator [11]. The speed relationship for the coaxial MG is $\omega_1 = (n_2/p_1)\omega_1 - (p_3/p_1)\omega_3$ [11], where the subscripts denote rotor number. If the outer rotor is held stationary the speed ratio will be $\omega_1 = (n_2/p_1)\omega_2 = G_{12}\omega_2$ where G_{12} is the gear ratio. Along with not needing gear lubrication and offering the ability to potentially increase efficiency a MG offers unique features such as inherent overload protection. A number of authors have proposed using a Halbach magnetic rotor [12, 13] to improve the MG torque density [14-16]. However, the Halbach rotor is difficult to fabricate. Recently a 3-D printed housing for a Halbach rotor was presented by Laimer [17] for a motor application. Laimer design however, required support bridges to be placed between magnet segments and this then greatly reduces the air-gap field. In this paper a new 3-D printed Halbach rotor retaining structure is presented and the Halbach rotor MG is optimized for peak mass and volumetric torque density. The Halbach rotors do not need ferromagnetic material and since only the central modulation rotor is required to be made of ferromagnetic material it is shown that the 3-D printed MG structure can have a high mass torque density. MAGNETIC GEARBOX ANALYSIS The Halbach typology being investigated is shown in Fig. 2. Table I shows the fixed geometric MG parameters. The pole pair combination selected is (p_1, n_2, p_3)=(3,17,14). This pole combination gives a gear ratio of G_{12}=5.67. As both p_1 and n_2 are prime numbers the torque ripple is low. The outer radii and axial length of the MG have been fixed at r_{o3} = 60mm and d=75mm respectively. The three radial parameters that were varied are shown in Table II and defined in Fig. 3. These three radial length parameters have the largest impact on the torque density. Note that since the outer radii was fixed at r_{o3} = 60mm when the modulation length l_2 is changed the outer rotor radii length r_{i3} is also changed (since $r_{i3} = r_{o1} + l_2$). The volumetric torque density and mass torque density for each design was computed. The torque density trade-off plot is shown in Fig. 4. A clear trade-off between maximizing mass torque density (design A) and volumetric torque density (design B) is apparent. The design parameters for the peak torque density designs are shown in Table III. Also shown is a trade-off design, design C, in which both a relatively high mass and volumetric torque density is obtained. Design C was chosen to construct. The impact of axial length on torque density is shown in Fig. 4. The 3-D design approaches that of the 2-D design as axial length increases. The axial length of 75mm was selected as this achieves a high torque density. 3-D PRINTED ROTOR STRUCTURE The mechanical design utilizes 3-D printed parts. The design object was to fabricate a mechanical structural design in which the entire MG could be assembled first without any magnets. Following this magnets could be inserted. Such a design approach can be achieved by using 3-D printing. The 3-D printed structural part drawings are shown in Fig. 6. The modulation rotor is shown in Fig. 7. The full paper will present the experimental testing results as well as provide much more design drawing details [18] on the 3-D printed design approach.

FG-05. A Disc-type Contra-rotating Permanent Magnet Synchronous Motor for Marine Electrical Propulsion System.

Z. Rao[1], S. Huang[1] and C. Luo[1]
1. College of Electrical and Information Engineering, Hunan University, Changsha, China

I Introduction The contra-rotating propeller (CRP) has the ability of keeping the navigation posture of the ships and recovering energy from the circumferential flow of its main propeller [1], which can raise the efficiency of propulsion system by 15%. Thus it is widely used in the electrical propulsion system of torpedoes and unmanned underwater vehicles. A double-rotor DC motor, whose stator and rotor can move in opposite direction to drive CRP, has two sets of brushes and slip rings. So the reliability and torque density are relatively low. A radial-flux PMSM with two contra-rotating rotors is presented in [2-3]. However, the output torque of one rotor is not the same as that of the other one, which poses a great challenge for motor control. A novel disc type contra-rotating motor (DTCRM)is proposed in this paper to solve the above problem. The 3-D FEA is used for modeling of the DTCRM. The two prototypes are built and the preliminary measurements of the torque and no-load output voltage are done. II Structure and Operating Principle As shown in Fig.1(a-b), the stator of DTCRM sandwiched between two PM disc rotors has a slotless toroidally wound strip-iron core and the armature coils wound in a toroidal cross fashion. And the two PM rotors are coaxially connected by CRP. The DTCRM can be regarded as an integration of two identical disc type motors being connected together, which are characterized by sharing a common winding in series. Since the two working surfaces of the stator are both fully utilized, the DTCRM has a higher torque-to-weight. The end windings are quite short, which leads to lower copper loss and higher efficiency for this topology. As shown in Fig.1 (c), the phases A and B have an opposite spatial displacement against the phase C, and thereby two synchronous contra-rotating magnetic fields(CRMF) will exist in annual air gaps if the stator winding is fed by a symmetric three-phase current. The two synchronous CRMF interact with the field generated by the magnets, then the two rotors move towards opposite direction with the same speed. III Analysis Of The DTCRM To obtain the characteristic of output torque of the two rotors, a transient-magnetic 3-D FEA with one rotor position leading the other one by 0°, 22.5°, 45°, 67.5° and 90° deg in electric angle is investigated. In these cases, the phase angle of the currents is set to such a value that the rotor with lagging position produces a maximum torque. As shown in Fig.2(a), owing to the slotless structure of the stator core, the output torque ripples of the two rotors are relatively small and the average torques of the two rotors are almost the same (20.5N.m) when they are the same position (0°). With the leading angle getting bigger, the torque of the leading rotor decreases. Its value approaches to zero when the leading angle reaches 90° deg. However, the torques of the lagging rotor are basically the same, as shown in the lower part of Fig.2(a). To acquire the relationship between the amplitude of back-EMF and the position of the two rotors, a transient-magnetic analyses of the 3-D FEA model with different rotor positions is performed. As illustrated in the Fig.2 (b), the blue lines represent the total back-EMF waveforms with one rotor position leading the other one by 22.5°, 45°and 90° deg in electric angle, respectively. The amplitude of back-EMF decreases with the growth of the leading angle, especially in 90°deg. The peak of the three-phase no-load back-EMF has a slight deviation owing to the different end length of the winding.

FG-06. Comparative Analysis of a Coaxial Magnetic Gearbox with a Flux Concentration Halbach Rotor and Consequent Pole Rotor Typology.

D.H. Wong[1], S. Modaresahmadi[2], *J.Z. Bird*[1] and W. Williams[2]
1. Portland State University, Portland, OR, United States; 2. University of North Carolina at Charlotte, Charlotte, NC, United States

INTRODUCTION By utilizing magnetic field space modulation magnetic gearboxes (MGs) are able to create speed amplification without any physical contact [1-3]. An example of a flux-focusing coaxial MG is illustrated in Fig. 1. This coaxial MG consists of an inner rotor 1 that contains $p_1 = 4$ pole-pairs an outer rotor 3 with p_3 =13 pole-pairs and a central ferromagnetic segment central rotor 2 that consists of $n_2 = 17$ pieces. The n_2 ferromagnetic segments serve to modulate the inner and outer rotor magnetic fields. In order to create the highest level of field coupling between the inner and outer rotors the number of ferromagnetic segments must be chosen to satisfy n_2=p_1+p_3. With this condition satisfied the rotor angular velocity relationship between each rotor is w_2p_2=w_3p_3+$w_1p_1$where the subscript denotes rotor number. If the outer rotor is fixed (ω_3 = 0) the torque will be maximized and the gearing ratio will be w1=Gw_2 where G = n_2/p_1. For the example MG shown in Fig. 1 the gear ratio is G=4.25. In order to try to increase the torque density of a MG a range of different coaxial type rotor typologies have recently been investigated [4-14]. Along with the flux focusing MG design two other coaxial radial type MG rotor typologies that have been shown to create high torque density are the flux concentration Halbach rotor typology [15] and the consequent pole triple-PM rotor MG typology [16]. In this paper, these two design typologies are compared for the first time. The objective is to provide an idealized comparative analysis of the two competing typologies and then present the experimental design and testing of the best design. ROTOR DESIGN ANALYSIS The pole combinations for both designs was selected to give a gear ratio of G = 7.5. The outer diameter and stack length was held fixed at 110mm and 75mm respectively. The fixed geometric and material properties for both designs are summarized in Table I. The flux concentration and consequent pole MG design typologies are shown in Fig. 2 and Fig. 3. Note that the consequent pole MG has a flux concentration inner rotor and consequent pole outer and central rotor. This typology increased torque. The pole combinations used for both designs are given in Table II. The consequent pole design is unique in that the slots can be used to create torque as well as the magnets. This is because $p_3 = n_3$ and $p_2 = n_2$. As an example, the inner rotor magnet poles (p_1=4) will be modulated by the n_2 = 30 ferromagnetic segments and therefore interact with the outer rotor pole pairs since p_3=n_2-p_1=26. At the same time the modulation rotor's p_2=30 pole pairs can be modulated by the outer rotor n_3=26 ferromagnetic slots to give $p_1 = p_2 - n_3$ = 4 pole pairs. In contrast the flux concentration MG typology cannot create torque interactions through the outer rotor slot numbers since $p_3 \neq n_3$. In order to provide a fair comparison between both typologies the outer rotor number of slots n_3 was kept the same. To enable the gear ratio to be equal for both typologies this then meant that the inner rotor pole pair number had to be different. This is shown in Table II. PARAMETER ANALYSIS Three key parameters were identified that have the greatest impact on the MG designs. These three radial parameters are shown in Table III. The slot width for both designs were kept equal with the magnet width. Fig. 4 and Fig. 5 show the volumetric and mass torque density values for each parameter design. It can be noted that the flux concentration MG can achieve a significantly higher torque density than the consequent pole MG typology. Table IV summarizes the design value and performance metrics. It can be noted that the the flux concentration MG was able to achieve an active region torque density that is twice that of the consequent pole design. It should be noted that higher torque densities for the consequent pole design could be achieve when using a larger outer diameter. However, for small diameter applications the authors was not able to achieve a high torque density. CONSTRUCTION The flux concentration design was further refined by adding bolt support as shown in Fig 6. The torque ripple for this design was shown to be low (0.13% at peak torque) as shown in Fig 7. Unlike the design in [15] bridges are used on the outer rotor so as to enable the magnets to be inserted more easily. The assembly rods on the outer diameter are made of non-magnetic material. This creates a flux barrier for the leakage flux. The leakage through the bridges as well as the effect of the flux barrier is clearly evident in Fig 8. The use of a 75mm axial length will decrease the torque. Using 3-D FEA the torque is shown to decrease to 107Nm (151Nm/L) from 121Nm (170Nm/L). The assembly drawing for this new type of flux concentration design is shown in Fig. 9. The full paper will present the experimental testing results for this new type of flux concentration MG as well as efficiency analysis.

FG-07. A Novel Design Philosophy for Low-Stiffness Magnetic Levitation Gravity Compensation.

H. Zhang[1], Y. Zhou[1], B. Kou[1] and Z. Zhu[2]
1. Harbin Institute of Technology, Harbin, China; 2. University of Sheffield, Sheffield, United Kingdom

I. Introduction This paper presents a novel design philosophy by which the low stiffness performance for the magnetic levitation gravity compensation can be obtained easily. Generally, the absolute levitation is desired in many ultra-precision positioning systems, because the vibration disturbance can be effectively isolated. However, it is very difficult to obtain the low stiffness performance due to the serious nonlinearity of the passive force between two permanent magnets [1-4]. The proposed design method is based on the principle of stiffness counteraction. The magnetic levitation gravity compensator in this paper is combined with two passive units whose stiffness curves are just the opposite, so the resultant stiffness is low enough while the two levitation forces are superimposed. II. Topology and Principle The configuration of the proposed magnetic levitation gravity compensator (MLGC) is shown in Fig. 1(a). The passive levitation force is produced by the interaction between the mover PM rings and the stator PM ring. The active levitation force is produced by the interaction between the mover PM rings and the circumferential current. To realize a low passive levitation force stiffness, the concept of stiffness counteraction is adopted in the proposed MLGC. Actually, the proposed MLGC in Fig. 1 is composed of two passive magnetic levitation units that share the same stator PM ring, as shown in Fig. 1(b) and 1(c). The passive levitation force characteristic curves for the two units are shown in Fig. 1(d). For Unit A, the passive levitation force has a maximum value in the symmetrical position. On the contrary, there is a minimum value for Unit B in the same position. Therefore, the stiffness characteristics for the two units are just the opposite, so the resultant stiffness in theory could be very low, as shown in Fig. 1(e). III. Model Discussion Fig. 2(a) shows the magnetic field intensity produced by a magnetic ring with radial magnetization. Considering the volume integral operation, the charge model is more complex if the volume charge is not zero. Furthermore, multiple integrals, e.g. quadruple or quintuple integral, is also required when calculating the force, which is time consuming. Therefore, the equivalent current method is more suitable for modeling the cylindrical MLGC, in which the PM ring with radial magnetization is contained. Additionally, the errors due to some common assumptions should be considered when modeling the MLGC. To make a quantitative analysis, the MLGC is compared with a linear PM synchronous machine. Fig. 2(b) shows the average points of the PMs in MLGC and in linear machine. The average working points in linear machine are obviously higher than the ones in MLGC. Therefore, the average working point needs to be considered when calculating the magnetic field and the levitation force of MLGC. IV. Design and Optimization To reduce the passive levitation force stiffness as much as possible, two approximate opposite stiffness characteristics are required. From the characteristic curves (not given in the digest due to figure limits), the air-gap length (g) is the most important parameter for Unit A, which strongly impact the maximum stiffness. When the air-gap length of Unit A varies from 5mm to 15mm, the maximum stiffness changes from 2648 N/m to -109 N/m. Compared with g, other parameters contribute less influence on the maximum stiffness. However, the passive levitation force is strongly impacted by other parameters. The force level of Unit B is higher than the one of Unit A at the same air-gap length. The design flow chart for the MLGC is shown in Fig. 2(c), which consists of two blocks. The first block is based on the ideal equivalent current model. The function of the first block is to obtain the approximate parameters quickly. The second block is based on the finite element simulation in which the ideal mathematical model is improved, the zero-stiffness position is adjusted and the accurate values for all parameters are determined. V. Conclusion In this paper, a novel design philosophy for low-stiffness magnetic levitation gravity compensation is proposed. Based on the design philosophy, a new magnetic levitation gravity compensator is put forward, analyzed and designed. Compared with previous topologies, the superiorities of the new MLGC are as follows, (1) Based on the principle of counteraction, the zero-stiffness performance within the effective stroke can be theoretically obtained. (2) The stiffness for each passive levitation unit is not strictly limited. The resultant low stiffness can be obtained, as long as two stiffness characteristics counteract with each other. In other words, the design flexibility is greatly improved. (3) There is only one radially magnetized PM ring, which is difficult to process and very expensive. In addition, the active levitation force density can be improved, because the size of the radially magnetized PM ring is relatively large and close enough to coil in the proposed MLGC. (4) The space for the coil frame is large enough due to the single-layer air gap, which is beneficial for the cooling design.

FG-08. Design of a Novel Halbach-Array Permanent Magnet Motor for Electric Submersible Pumps.

S.F. Rabbi[1] and M. Rahman[2]
1. Electrical and Computer Engineering, Memorial University of Newfoundland, St. John's, NL, Canada; 2. Electrical and Computer Engineering, Memorial University of Newfoundland, St. John's, NL, Canada

Electric submersible pumps (ESPs) are widely used as downhole artificial lift devices in oil and gas production units for improved oil recovery [1]. An ESP is a motor/pump configuration comprised of multi-stage impellers driven by an electric ac motor. Since the inception of ESPs, squirrel-cage rotor induction motors have been the de-factor standard in ESP drive systems. The diameter of an ESP motor is restricted by the outside diameter of the casing which is between 4 and 10 inches [2]. Submersible motors have a small outer diameter and a long axial length to meet the required torque demand. In the case of ESPs, these motors are modular in nature and comprised of multiple rotors. The multi-rotor assembly is supported by intermediate bearings between consecutive rotors [2]. There are two types of most widely used submersible induction motors: IM5 and IM10 [2]. Each of the rotors in IM5 and IM10 are rated as 5-HP and 10-HP, respectively. However, submersible motors operate in a hostile environment and experience severe temperature, high pressure and the presence of debris. Due to its long axial length, submersible motors are often subjected to severe torsional vibration resulting in mechanical failures such as broken rotor bars, shaft breakdowns and bearing failures [2]-[4]. Brushless permanent magnet motors (PMMs) have been recently introduced in the market for use in ESPs which provides better efficiency, smaller dimensions, wide operating range, lower heat generation and superior performance than same size submersible IMs [2],[5]-[6]. Due to the limitation in thermal stability, high power brushless PMMs are typically designed to fit inside a large diameter casing to provide better cooling and avoid saturation [2]. In offshore oil and gas, drilling is expensive and sometimes it is not feasible to drill a well wide enough that can accommodate the brushless PM submersible motor. Thus, submersible induction motors are still the de-facto standard for high power ESPs. In recent years, due to the advancement in rare earth permanent magnet materials, neodymium-boron-iron (Nd-B-Fe) magnets with the addition of dysprosium can handle temperature up to 200^0C [7]. The significant progress in polarization of sintered magnets have made it possible to achieve various types of magnetization in the rotor magnets including radial, parallel, continuous ring and halbach-arrray [8]-[11]. This paper presents the design of a novel permanent magnet submersible motor that is more compact and light-weight than the existing ESP motors. Fig. 1a illustrates the axial view of a 3-phase 6-pole 12 kW/rotor prototype permanent magnet submersible motor. The outer diameter of the stator is 95 mm. The axial length of the stator is 600 mm. The stator is equipped with an integral slot distributed winding. Its back-iron is made of low loss laminated steel with a saturation flux density higher than 2.0 T. The thickness of the lamination is 0.1mm. The stator is skewed to reduce the torque ripple. The length of the airgap is selected as 1 mm. Fig. 1b illustrates the distribution of magnetic flux density inside the motor. The rotor contains a cylindrical ring made of rare earth permanent magnetic material. The ring is magnetized as a continuous halbach array that intensifying the field outside of the cylinder towards the air-gap while minimizing the magnetic field inside the cylindrical ring. Due to this special polarization of the magnets, the motor requires less/no back iron in the rotor. Thus, the motor becomes more compact and light-weight. It also allows more room for the stator windings and return back-iron. The halbach-array arrangement provides more torque per unit rotor length than the available brushless dc permanent magnet submersible motors. It also reduces the outer diameter of the stator, making the motor more slimmer to be able to fit inside offshore subsea wells. Figs. 2a and 2b show performances of the prototype submersible permanent magnet motor. The input dc voltage is considered 400 V. The maximum AC line current is 40 A (rms). This limits the peak current density of the stator windings to 4 A/mm^2. The efficiency and power factor maps of the motor with one rotor are displayed in Figs. 2a and 2b, respectively. The control strategy for the motor is selected as the maximum torque per amp control. The rated speed for the motor is 4000 rpm. The maximum operating speed of the motor is 5500 rpm. The operating zone for the motor is shown in Fig. 2a. The motor is capable to operate with a high efficiency (>96%) over the entire operating region. The efficiency reaches to its peak when the motor is running at a speed over 3000 rpm with a load torque between 50% of the rated torque and rated torque. The motor can operate at the constant torque mode with a rotor speed up to 4250 rpm. It operates in the constant power mode when the speed becomes higher than 4250 rpm. The power factor is over 0.95 in the entire operating zone, and it remains high over a wide range of the load torque. Thus, the designed permanent magnet submersible motor can be driven efficiently with a high power factor for ESP systems. In comparison to the existing 4-inch submersible permanent magnet motors, the proposed motor has higher efficiency, higher torque density, more than 50% shorter in length and has a very high power quality.

FG-09. Modeling and Analysis of Suspension Force of a New Bearingless Reluctance Machine with Independent DC Bias Winding.

L. Yu[1], Z. Zhang[1], Y. Shi[1] and W. Lu[1]
1. Department of Electrical Engineering, Nanjing University of Aeronautics and Astronautics, Nanjing, China

I.INTRODUCTION The bearingless switched reluctance machine (BSRM), free from the mechanical bearings, has advantage of the robust structure, and is suitable for operating in the harsh environment [1]. However, the torque control is tightly coupled with the suspension force control, and the operating point of the BSRM has to be selected to be in compromise between torque and suspension force, which reduces the power density. Meanwhile, the suspension windings are energized by turns according to the conducting phases, thus the BSRM faces the challenge of high-frequency suspension current control in high-speed operation. The rotor angular position detection is indispensable for feedback to the suspension force controller. With an independent field winding in stator, which functions as a dc bias winding, the bearingless doubly salient electro-magnetic machine (BDSEM) exhibits decoupling characteristics. The suspension force control can be independent of rotor angular position detection which increases the reliability [2], [3]. In this paper, the suspension characteristics of BDSEM are analyzed. A prototype BDSEM and controller are developed, and the experimental results are given to verify the analysis. II.CONFIGURATION AND OPERATION PRINCIPLE *A.Configuration* Fig. 1 shows the configuration of the proposed BDSEM. It has the advantages of robust structure. The three phase armature windings W_{ma}, W_{mb}, W_{mc}, are wound around every stator pole. A set of independent dc bias winding W_{dc} wound across three stator poles consists of four coils connected in series. It provides the magnetic flux which is the basis of torque generation and also the basis of suspension force generation. The suspension windings W_{sx} and W_{sy} consist of two coils each. *B.Suspension Force Generation* When the rotor angle is 0^o as shown in Fig. 2 (a), the dominant bias flux ψ_b is generated by the bias current I_{dc}, and the suspension flux ψ_{sy} generated by the suspension current I_{sy} is superimposed upon it. The air gap flux density in the upper half is increased, while the flux density in the bottom half is decreased as shown in Fig. 3. The suspension force is generated along the positive *Y*-axis. The positive suspension force is also generated along the *Y*-axis when the rotor angle is 22.5^o, as shown in Fig. 2 (b). The direction of the suspension force is independent of the rotor angle. III.PERFORMANCE ANALYSIS *A.Mathematical Model* Fig. 4 shows the magnetic equivalent circuit (MEC) model of the BDSEM, neglecting the magnetic saturation. $2N_{dc}I_{dc}$ is the magnetomotive force (MMF) of dc bias winding, $N_{sx}I_{sx}$, $N_{sy}I_{sy}$ are the MMF of suspension windings. N_mI_{ma}, N_mI_{mb}, and N_mI_{mc} are the MMF of armature windings. G_1,…, G_{12} are the permeance of air gap. The standard angle control (SAC) method is adopted to produce the torque [4], and the magnitude of the phase current is I_m. When the rotor angle is $0^o \le \theta_r < 15^o$, the air gap flux density B_1 corresponding to G_1 is described by Eq.1, where μ_0 is the vacuum permeability, and L_{gap} is the air gap length. The suspension force is described by Eq.2, where L is the core length and R is the rotor radius. The composition of the force along the X- and Y-axis is described by Eq.3. The total suspension force is obtained by Eq.4. The corresponding coefficients are shown in Eq.5 to Eq.9. *B.Suspension Force Characteristics* Fig. 5 shows the *Y*-axis suspension force predicted both by the mathematical model and the finite element method (FEM). The suspension force is almost held constant in different rotor position. Thus the angular position feedback to the suspension force controller is not required. The suspension force control is significantly simplified, particularly in the high speed operation of the BDSEM. The results predicted by mathematical model agree well with FEM. The self-inductance of the suspension winding changes slightly as shown in Fig.6. The mutual-inductance among the suspension and armature windings is almost zero. IV.EXPERIMENTAL RESULTS A prototype BDSEM and its suspension current controller are designed and developed to verify the suspension characteristics. The experiments are conducted as shown in Fig.7. The *Y*-axis suspension force is linearly increased with increase of the suspension current I_{sy} as shown in Fig.8, considering the rotor gravity. The experimental results agree well with the results predicted FEM. When the bias current is increased appropriately, the suspension force is increased with the same suspension current. Fig.9 shows the waveforms of the suspension current and radial displacement. V.Conclusion In this paper, the new BDSEM is proposed and implemented. The suspension characteristics are investigated. The mathematical model of suspension force is deduced. The suspension force is independent of the rotor position and the suspension force control is simplified, particularly for high speed operation. The experimental results verify that the rotor can be levitated steadily with the different dc bias current.

FG-10. The influences of lever arm on the stability of a quasi-zero stiffness magnetic levitation vibration isolation system.

N. Kamaruzaman[1], M. Ghayesh[1], B. Cazzolato[1], A. Zander[1] and W. Robertson[1]
1. School of Mechanical Engineering, The University of Adelaide, Adelaide, SA, Australia

Stable quasi-zero stiffness (QZS) magnetic levitation is a key to isolating ultra-low frequency vibration [1]. QZS systems are defined by nonlinear force-displacement relationships in which the operating position is at or near points of zero stiffness. While Earnshaw's theorem [2] governs the stability of a magnetic levitation system in the translational directions, no such theory has been deduced for the rotational degree-of-freedom (DOF). Due to cross-axis coupling, total elimination of active controllers for contactless stable operation is not possible [3]. However, it is anticipated that the system would be less dependent upon the controllers as the number of unstable DOF is minimised. A method to improve the passive stability of the system in the rotational DOF without adding significant stiffness in the translational DOF is by introducing lever arm [4]. Figure 1(a) shows the schematic of the proposed QZS magnetic spring system. The lever arm is a function of the fixed, normalised vertical gap *e* between the levitating magnets, and the normalised horizontal gap *p* between the side-by-side bottom magnets. A single plane constraint was imposed for the analysis of the static behavior of the system with varying horizontal gap *p*. Using the MATLAB© function created by Robertson [4] based on the analytical force expression of Akoun and Yonnet [5], the resultant force exerted on the levitating assembly was computed as the superposition of forces between the attractive and repulsive magnet pairs. Consequently, using a small angle approximation of magnet rotation [3], the moment around the out-of-plane axis was calculated as the cross product of the force and the lever arm. Typically, a QZS magnetic spring system has a quadratic-like force-displacement curve in which the minimum force value corresponding to the QZS position is obtained when the levitating assembly is operated midway between the top and bottom fixed magnets [6]. However, with non-zero horizontal gap *p*, the QZS position shifts towards the bottom fixed magnets, and the load bearing force depreciates (Figure 1(b)) due to the loss of some magnetic interactions between the magnets on opposite side. Investigation into the stability of the out-of-plane and horizontal direction due to the vertical displacement suggests that *p* has little effects on the translational stability of the system, particularly upon operating within close proximity to the QZS position. This ensures that there is no reduction in the range of isolation frequency for the translational DOFs. In contrast, Figure 2 highlights that the rotational stability improves significantly with the lever arm especially for negative vertical displacement. However, with greater stability, the rotational resonance frequency increases and thus, decreases the range of frequency over which vibration attenuation occurs. Therefore, appropriate level of stability must be chosen based on the system requirement. The analyses presented so far considered the centre of mass of the levitating assembly as the centre of rotation. It is assumed that the mass of the rod linking the levitating magnets is negligible, and the levitating magnets are point mass. In practice however, it may be difficult to place the payload at the exact geometric centre of the levitating assembly, especially involving irregular shapes. To examine the effects of non-centred payload position (the pink cube in Figure 1(a) represents the payload) on the rotational stability of the system due to the vertical displacement, the rotational natural frequency versus load force were plotted for different payload position. It is seen that with a relatively small payload position offset (only in the horizontal direction), the rotational DOF remains stable for non-zero horizontal gap *p*. However, as the offset increases to a certain value, even with large *p*, rotational instability appears for positive vertical displacement. As the levitating assembly moves upward, the repulsion force decreases, resulting in a reduction of the moment. Furthermore, with large payload position offset, the centre of rotation is shifted further away from the geometric centre of the levitating assembly, which causes large imbalance between the system clockwise moment and that of the counter-clockwise. In conclusion, the addition of lever arm provides stability in the rotational DOF without deterring the realisation of QZS characteristics in the translational axes. Dynamic analysis will emphasise on identifying the influences of the lever arm on the cross-axis coupling to provide a complete picture of the planar stability of the system.

Introduction: High integration, low loss and high-reliability are the main development trends of flywheel energy storage [1]. Magnetic bearings (MB) [2] with several advantages, such as eliminating of a lubrication system, friction-free operation and low power consumption can be promoted in various practical industrial applications, especially in flywheel batteries. Brushless DC motor is widely used because of its high efficiency and simple control. The bearingless brushless DC motor (BBLDC) has the advantages of the above advantages, while it has the characteristics of small friction loss [3]. The problem of strong coupling between the magnetic field and the torque magnetic field can be solved by the double stator bearingless brushless DC motor (DS-BBLDC) [4]. Halbach permanent magnet structures are suitable for use in permanent magnet motors because they enhance the unidirectional magnetic field [5]-[6]. Thus, this study presents the first prototype of a Double Stator Halbach Permanent Magnet (DSHPM) BBLDC with the advantages of weak coupling and simple control. The structure, operation principle and main electromagnetic characteristics of the DSHPM BBLDC are analyzed. The proposed motor exhibits the following advantages: 1) High integration. The motor can not only realize the problem of energy conversion, but also realize two degrees of freedom (2-DOF) suspension control. 2) Low loss. The biased flux is provided by the permanent magnet which leaves out the extra biased winding correspondingly. 3) Weak coupling. The application of halbach structure can make motor rotor yoke adopt non-magnetic material to completely isolate torque system and suspension system. 4) Favorable controllability. The dual-stator structure of the torque system and suspension system separately control, to achieve a simplified control. New Machine: The structure of DS-HAL-BBLDC is shown in Fig.1. As shown in Fig.1(a), the DS-HAL-BBLDC is primarily made of an inner stator, the permanent magnets of halbach, a rotor and an outer stator. The rotor consists of three layers. The halbach permanent magnets can produce an inward magnetic field. So the rotor is divided into two layers. The inner layer is a magnetic isolating material used to isolate the torque magnetic field and the suspended magnetic field. The outer layer provides the magnetic path of the silicon steel sheet for the suspended magnetic field. The inner stator and the permanent magnet consist of an 8 pole 12 slot brushless DC motor, which is the torque system. A suspension subsystem is composed of the two outer stators with four poles structure and the rotor outer layer. The suspension system can produce 2-DOF suspension. The bias magnetic path provided by the outer stator permanent magnet is shown in fig.1(b). Fig.1(c) shows the torque system of a phase winding connection. The windings are arranged in a centralized manner, with the other two similar. Fig.1(d) shows the control of magnetic circuit. Taking the y-direction magnetic circuit as an example, starting from one pole to the other pole via the stator yoke and forming a closed loop through the rotor from the other pole Main Electromagnetic Characteristics: The operation mechanism of the motor is verified as shown in Fig.2. The static magnetic density of the motor is shown as shown in Fig.2(a). It can be seen that the magnetic field is evenly distributed on the outer stator and the reloaded outer layer. Fig.2(b) changes in suspension force when the motor suspension current is 0A to 4A. The suspension force increases linearly with the increase of current, which proves that the motor can produce a stable suspension force. Fig.2(c) and (d) are the air magnetic density of the y positive direction and the y negative direction respectively. With the increase of current, the magnetic density in the positive direction of y increases and the magnetic density in the negative direction of y decreases. It is that prove the magnetic field generated by the suspension coil has good controllability.

FH-01. Development of a Radial Flux Permanent Magnet Machine with an Amorphous Metal Stator Core.

W. Tong[1], R. Sun[1], S. Wu[1] and R. Tang[1]
1. School of Electrical Engineering, Shenyang University of Technology, Shenyang, China

With the aggravation of the energy crisis, increasingly prominent of the environment issues, techniques to improve electrical machine efficiency continue to be explored. Employing low core loss materials instead of traditional counterparts becomes a valuable way to improve motor efficiency. Amorphous metal has features of extremely low core losses due to its high resistivity and only one twentieth the thickness of the conventional silicon steel sheet (SSS). Amorphous metal has already been shown to reduce core losses dramatically in power transformers [1] as well as in high frequency axial flux motors [2-3]. For radial flux motors, the related research achievements are relatively few, mainly due to the limited physical sizes and manufacturing difficulties of amorphous metal. In order to further promote the application of amorphous metal in electrical machines, radial flux motors should be further investigated. In this paper, a series of typical fabrication processes are adopted to develop a stack amorphous metal stator core (AMSC) for a 2.1kW, 4000 rpm radial flux permanent magnet motor (RFPMM), and the configurations of the stator core and motor prototype are shown in Fig. 1. In order to quantify the magnetization and AC loss characteristics of the AMSC, an experiment is conducted on the AMSC under different supply frequencies according to the standard of IEC 60404-6. The working principle of the experimental model is similar to an electromagnetic transformer. Two sets of winding are wound on the stator core for excitation and flux detection, and the magnetic flux alternates along the stator yoke. In this experiment, the excitation current is kept sinusoidal. On the basis of the experimental system, the magnetization and AC loss characteristics of the stack AMSC are obtained, as shown in Fig. 2. As a comparison, the magnetic performances of typical W270-35 type SSS are given in Fig. 2. It can be seen from the figure that the magnetization curves of the AMSC and SSS are almost the same when B is below 0.8T. Within this range, the permeability of AMSC is a little bit higher than that of W270-35. However, a contrary tendency of the permeability is obtained when B is above 0.8T. The saturation flux density of AMSC is about 1.4T, which is much lower than that of conventional SSS material. The core loss of the AMSC is much smaller than that of conventional SSS material. This result also demonstrates that the magnetic performance of amorphous magnetic material is sensitive to the externally applied stress. In order to demonstrate the advantages of amorphous metal permanent magnet motors over conventional silicon steel permanent magnet motors, two RFPMMs with the same dimensions but different stator core materials are analyzed, manufactured and tested in different conditions. The permanent magnets of the two motors are mounted on the surface of the rotor core, and shaped to make the air gap flux density waveform approach to sine wave. A search coil is placed in the top of the slot for each motor. 3-D finite element method is adopted to analyze the no-load flux density distribution of both motors. According to the calculation results, the flux density of stator teeth in amorphous metal permanent magnet motor is a little bit lower than that in conventional motor. The induced back EMF in the test coils is calculated and compared with the experimental results. In order to identify the difference of the no load iron loss of the two motors, the 3-D finite element method is introduced to analyze the no-load loss distributions of the two motors under both sinusoidal supply and converter supply conditions. The relationships between the no load iron losses and the rotation speeds of the two motors are also investigated. To verify the accuracy of the calculation results and to demonstrate the advantages of amorphous metal permanent magnet motors over conventional SSS permanent magnet motors, the no load loss test is proceeded for both of the motors. The results illustrate that the simulation results are in good agreement with the test results, and the RFPMM with an AMSC has a characteristic of extremely low no-load iron loss, relative to the conventional SSS motor.

I. Introduction Multiphase machines have been widely used in critical applications, such as marine applications, where high density of torque with high quality and fault tolerant capability are required [1]. Thanks to vector control and injection of non-sinusoidal currents, permanent magnet (PM) machines with high number of phases can obtain the same torque density as the three-phase DC brushless machines, moreover with lower torque pulsation [2]. Another important property of multiphase machines is the fault tolerant, due to the more degree of freedom of control [3]. The reason is that, referring to classical wye-coupled three phase machines, which possess the minimum number of independent currents for achieving a rotating field in normal condition, multiphase machines have more degree of freedom than the minimum necessary, thus allowing a rotating field even with one opened phase. Moreover, with injection of high order harmonics of current, an electronic pole-changing effects can be obtained, e.g. the p pair of poles with fundamental current and $3p$ ones with the third harmonic current. The appropriate polarity can be selected regarding the load demand in transient or steady state by changing the levels of first and third harmonics of current, which can also take into account the inverter rating and efficiency or torque quality requirements. Then the flux weakening is no more than the unique solution when maximum voltage is reached and the speed range can be extended by switching between different pole polarities. In order to achieve such property, the multiphase machine should develop the torque with equal share by each first and third harmonic of current and electromotive forces (EMF). In this case, a real degree of freedom for the control can be achieved. An Interior PM five-phase machine is proposed in [4], which has demonstrated this valuable property using different control strategies. In this paper, a novel five-phase surface-mounted PM (SPM) machine with pole-changing effects is investigated. Its specificity is to be able to develop torques of comparable values under three kinds of supply: with only first, third or both first and third sinusoidal currents, due to first (E_1) and third (E_3) harmonic of comparable EMF values. In order to achieve such objective, the configuration of fractional-slot concentrated winding is firstly investigated; Secondly, the shape of magnets is optimized in order to adapt the selected winding configuration; Thirdly, the speed-torque characteristics of whole speed range is investigated through MTPA control strategy and compared to a classical sinusoidal three-phase SPM machine. II. Main Design Consideration A. Winding Configuration Selection As the winding is one of the most complex parts of the process in a classical machine, fractional slot concentrated winding (FSCW) with simple and short end-winding is more and more popular in industry applications, especially for hybrid vehicles where the compactness, high efficiency and easy manufacturing are required. In this part, two criteria are used to make selection of FSCW configuration: 1) the winding factors of both fundamental and third harmonic, and 2) the eddy current losses in the rotor. In order to design a double-polarity five-phase machine, a compromise for the choice of different slot/pole combinations must be achieved by considering a sufficiently high winding factors for both the first harmonic and the third harmonic. The 20-slot/8-pole of 5-phase winding configuration is chosen for the reason with the fundamental winding factor K_{w1}=0.588 and the third harmonic winding factor K_{w3}=0.958, moreover the slot per pole per phase (S_{pp}) is 0.5 which presents low amplitude harmonics and subharmonics of magneto-motive force (MMF), with a consequently low level of eddy current losses [5]. The MMF distribution and its harmonic analysis is presented in Fig. 1, with the injections of both first and third harmonic currents. This machine has 4 pairs of poles with first harmonic current injection and 3×4 pairs of poles with third harmonic current injection. Therefore, an electronic pole-changing effect can be obtained if the machine operates at low speed with 3×4 pairs of poles and 4 pairs of poles at high speed by taking into account the inverter rating, the efficiency and the output torque. B. Rotor structure adaptation A particular trapezoidal magnet shape is determined in order to enhance the contribution of the third harmonic flux density, with a consequently the boost of torque under the third harmonic current supply. Fig. 2(a) shows the machine topology with optimized magnet shape and Fig. 2(b)-(c) shows the no-load back EMF and its harmonic analysis calculated using FEM. As a result, the back EMF of 3rd harmonic is widely increased compared to a sinusoidal machine. For a given rms value of current, Fig. 2(d) shows the output torque with MTPA control strategy under three kinds of current supply: with only the first, the third and both the first and the third sinusoidal. It is proved that the injection of third harmonic current can not only boost the output torque, but also allow changing the polarity of the machine, with a consequently the expansion of the speed range. The detail design consideration will be presented in the full paper, and a comparison of speed-range operation with a sinusoidal machine of the same ratings will also be covered.

I. Introduction U-shape core permanent magnet synchronous motor (PMSM) has the features of small size, simple and robust construction, generally working in the low power and low cost industry applications [1], [2]. Due to the simple structure and the self-starting ability, single-phase PMSM with U-shape core got more attentions in early research and application, however, its development was limited by motor large torque ripple and low efficiency. As one effective way to solve the problem, the PMSM with auxiliary modular design comes out [2], which can obtain a smooth operation feature with shifted magnets array and supply the opportunity for fault tolerant control. Based on the two-phase PMSM with auxiliary modular design, the motor mathematical model and the fault tolerant control configuration are presented in this paper to illustrate motor characteristics and achieve the fault-tolerant ability. Finally, the motor prototype is tested and the experimental results are used to verify the proposed steady operation and the fault-tolerant strategy. II. Motor configuration and control strategy The configuration of the two-phase PMSM with auxiliary modular design is shown in Fig. 1. The proposed motor is designed as a combination of two normal single-phase PMSMs parallel arranged, sharing one shaft of the rotor. Two pairs of ferrite magnets are placed with 90 electrical degrees shifted, and the stator coils wound on two U-shape cores are designed as two independent phases with minor mutual inductance. When two stator windings are fed by two independent voltage sources with 90 degree phase shift, the flux linkage and MMF in the stator cores are alternately produced when rotor rotates. When the MMF is generated in the stator cores by two phase stator currents alternately, the motor obtains a constant electromagnetic torque which is the sum torque of two phases. As a kind of motor modular design, this PMSM with auxiliary modular requires good replaceability and fault tolerant ability during different operation conditions. Therefore, two H-Bridge inverters are used to feed current into two windings of the PMSM respectively. If one phase winding or H-bridge inverter falls in fault, the fault diagnosis and fault-tolerant control method can be used to remove the fault module and drive immediately. That means the motor can work continually by the left modules. A drive block with the fault-tolerant ability is illustrated for the PMSM as in Fig. 1. Fault-tolerant scheme can be automatically selected by a fault detection switch, which acts following the signal from the fault diagnosis circuit in the inverter. During the steady operation, a control scheme with the two-phase space vector modulation technique is used to drive the motor by an eight-switch inverter including two H-bridge inverters as in a conventional two-phase motor [3]. One speed PI controller and two current PI controllers are used to regulate the rotor speed and winding current, respectively. When one H-bridge inverter or one winding fault occurs, the system can still work by the other stator and H-bridge inverter, as well as a simple sinusoid PWM scheme with one speed PI controller. The fault-tolerant control flowchart is presented in detailed as in Fig. 2. The system starts from the mode of speed open loop, the system begins to work under a series steps of speed and position calculation, speed PI regulator, voltage and current sampling and fault tolerant operation. Generally, the system operates on the healthy mode of Clark and Park transformation, current PI regulators, inverse Park transformation and two-phase SVPWM. If any winding falls into fault, the system turns to the fault mode of reference voltage generation and one-phase PWM. In the healthy mode, a two-phase SVPWM scheme is used in the system to achieve a constant switching frequency and a low torque ripple. While in the fault mode, only the traditional single-phase PWM scheme is used for the drive in order to get a continual working ability of motor. The experimental responses of speed, rotor position and currents of two phase windings are achieved in Fig. 3 to illustrate the steady operation process and the fault-tolerant operation of the system. In the paper, the DC-link voltage of the inverter is set to 310V. The reference speed of the motor is set to 300rpm with no load. The PWM switching frequency is set to 20kHz. There is a good dynamic and steady performance of the speed, rotor position, as well as the currents of phase A and phase B. In the steady operation, the rotor speed and two phase currents have a steady and smooth waveform. As in Fig. 3(a), the motor continues working at 300rpm within 0.2second after the fault of phase A winding occurs. Fig. 3(b) shows the steady operation again after fault, where this PMSM operates as the single-phase PMSM with only phase B working. It shows that the proposed drive can achieve a good fault-tolerant ability with the proposed scheme in this PMSM with auxiliary modular design.

FH-04. Experimental Results and Parameter Identification of a Permanent Magnet Assisted Synchronous Reluctance Machine with a Ribless Rotor.

M. Zimmermann[1], A. Lange[1] and B. Piepenbreier[1]
1. Institute of Electrical Drives and Machines, University of Erlangen-Nuremberg, Erlangen, Germany

1.) Introduction Synchronous Reluctance Machines attracted a lot of interest in the past decades because of the simple rotor manufacturing and low costs. However, this machine type suffers from a low power factor and the design is sensitive to torque ripple. Furthermore, the mechanical limits have to be considered carefully. In general, this machine type is not used in high speed applications because the increasing rib thickness influence strongly the electromagnetic behaviour of the machine. Sensorless control strategies are often focused on the full exploitation of the allowed operating area of the machine. Nowadays there is an increasing demand for variable speed drives. The omission of a position sensor provides a smaller machine size, reliability and lower costs. A common approach is to use the Back-EMF to detect the rotor position. This approach fails at low speed. A remedy are signal injection methods which are well known. The magnetic anisotropy (saliency) is needed to get information of the rotor position. This paper addresses the previously described problems in the following way: The machine design is introduced. By using ferrite magnets the low power factor of a SynRM can be increased. These magnets are low-priced, corrosion- and temperature-resistant. The machine design is also focussing on a saliency in all current operating points. A ribless approach, which was introduced by Villet [1], is used and extended by an glass fiber-reinforced sleeve to ensure mechanical stability. The rotor design was supported by Finite Element Analysis (FEA). A identification of the flux linkages and the inductances will be provided to compare it to the FEA results. Furthermore, the saliency and a efficiency will be evaluated. *2.) Machine Design* The idea of a ribless rotor is surveyed. This rotor design has two advantages for the PMaSynRM which was not researched sufficiently yet. A part of the PM-flux is not short-circuited along the ribs. The utilisation of the permanent magnets is higher. A ribless design provide less leakage. Especially, L_q is influenced by the ribs. In a SynRM the ribs have a strong influence on the inductances. These tend to be strongly current-dependent [5]. A saturation of these ribs enables the desired anisotropy of the machine. For the PMaSynRM the saturation of the ribs is provided due to the permanent magnets and the current. However, both aspects do not lead to a optimal machine design with respect to utilisation or saliency at low currents. The ribs have to be adjusted to withstand the desired speed. A mechanical-electromagnetic trade-off has to be found. The design of high-speed machines is limited because larger ribs cause a huge impact. The first manufacturing step for this design is to insert the magnets in the flux barriers of the bonded lamination stack. Non-corrosion ferrites are advantageous here. Afterwards the rotor will be filled and cast by glass fiber/ epoxy resin. The ribs are removed by milling. Finally, the unstable rotor structure is protected by an glass fiber sleeve to withstand speeds up n_{max} = 3000 rpm. However, the rotor sleeve enlarge the electromagnetic air gap and lower the d-inductance. Though a good magnetic anisotropy can be achieved. A cross-section of the rotor is illustrated in the Figures. The electromagnetic design is described in [9]. *3.1) Measurement routine* The device under test is operated in current control mode with an industrial converter using a conventional field oriented control. The speed was kept constant with a DC-load machine (speed control). For one operation point the measurement data is sampled ten periods of the fundamental frequency with f_s = 8 kHz. Afterwards the data is averaged. The temperature-dependent stator resistance is considered for the determination. The temperature in the machine is measured with the help of three PT1000 temperatures sensors. The end-winding temperature is taken for further calculation. The voltages are the control signals and are not measured directly. A compensation of the inverter voltage errors are implemented similar to [13]. The voltage errors are caused by non-ideal switching, forward voltage drop due to power electronics an on delay time to prevent DC-link short circuiting. *3.2) Parameter Identification* The equations will be given in the full paper. The result is illustrated in the Figures. A strong magnetic anistropy is visible. *3.3) Differential Saliency Analysis via Rotating Test Signal* Test signal injection is a common used technique for sensorless control at low or zero speed. A rotating voltage testsignal is superimposed on the fundamental voltage signals at the output of the PI-controllers. The current response of a rotating voltage testsignal gives an excellent visual representation of the machine saliency. In a salient machine the current response ideally depicts an ellipsis in the dq-reference frame. The centre of the ellipses is the fundamental current operating point. The more formed the ellipsis are, the higher is the saliency. A circular current response means L_{dd}=L_{qq}. When the orientation of the ellipsis is not vertical, an impact of cross-coupling is visible. Measurements show nearly equal ellipsis. No saliency loss over the whole current range is visible. Moreover, the ellipsis are almost vertical due to nearly no cross-coupling. The highlighted red rectangle is the operating area of SynRMs, where usually a loss of saliency occurs.

FH-05. Magnetic materials and technologies enabling an even brighter future for electrical machines.

P. Upadhyay[1]
1. US Corporate Research, ABB Inc., Raleigh, NC, United States

About 50% of the total energy on Earth is utilized through electromagnetic devices. Transformers, for the long distance power transmission and energy distribution, large AC motors and low voltage (LV) motors, for energy generation and utilization are the major electric power equipment driving today's technologies. The presentation will review past innovations and developments, as well as remaining major technical challenges in motors, generators, and transformers. The discussion on market needs and present snapshots will provide essential driving factors for the research community for the future technology developments. The cost and performance factors and the evolution of relevant industrial standards, government regulations, and their impacts on associated technologies will be discussed. Introduction: The major form of the energy consumption is by means of electricity. About 50% of the energy used on Earth is utilized through electromagnetic devices. Motors, generators, and transformers have been commercial products for over a century. These electromagnetic power products play a vital role in energy transformations from non-electric forms to electricity, in short and long distance transmissions, and final utilization and energy conversion for the end use. The historical development indicates that for power generation and transmission (large AC generators and power transformers), no major technology revolution has occurred. The transformer stepped core technology used in the 1950s is still a base technology with life expectancy of more than 50 years and having continuous duty operation. Costumers of power product companies still demand conventional synchronous generators across the globe. However, the technology in the energy utilization market has evolved significantly over the past 100 years. 65% of total electricity at industrial sites is consumed by electric motors and distribution transformers, which are majorly influenced by political, economic, social and technology revolutions. *Market needs:* The global electrical energy demand is predicted to be at about 5 percent compound annual growth rate (CAGR) which includes about 4.2 percent increase in the motor market. Unlike consumer products like cellphones and computers, the power product industry demands lower cost and higher performance. The power range of the motors and transformers vary from a few watts for fractional horse power machines to hundreds of MW. *Past innovation, trends in machines and role of magnetic materials* The magnetic material evaluation has gradually reduced the size of the induction motor as shown in Hitachi's motor technology evolution over a hundred years. This indicates that materials having higher magnetic saturation and lower magnetic losses can be deployed to both motor and transformer products. ABB's wound core transformers using amorphous metal (AM) core material drastically reduces core losses by 20%, and magnetizing current to $1/10^{th}$ versus the stepped cores enables the US Department of Energy to implement higher efficiency standards. Magnetic material such as soft magnetic composites and AM also enables deployment of axial flux, transverse flux or conical gap machines for direct drive applications to replace conventional induction motors (IM) and permanent magnet (PM) motors. The capital cost for the PM machines represents only 10% of the total life cycle operational costs of the motor. The increased cost of rare-earth magnets and challenges in supply chain in certain global regions also restricts the PM machine to be accepted for high efficiency needs set up by regulation. Recycling of the magnets will further improve acceptance of PM motors in the global market. With present material technologies and optimized designs, IM can achieve up to IE4 efficiency standard for medium and large powers. That exaggerates the demand for PM machine technology to grow and it may cover 25% of the world motor market by 2020. Reliable motors with a high efficiency level ensure the lowest life cycle costs. European Commission predicts that the efficiency of EU's motor systems could be improved 20-30% by 2020. Standardization initiatives have resulted in the harmonization of energy-efficient requirements, testing methods and certification schemes in the electric motor markets. More than 90% of the motor market is supplied through Synchronous, DC, Induction and PM machine topologies. PM assisted Synchronous reluctance machines (SynRM) is another alternative using low cost ferrite magnets to enables higher power factor at a competitive cost and footprint for some industrial applications in fan, pump, HVAC and marine propulsions. Transverse flux (TFM), axial-flux, homo-polar (HPM), flux switching (FSM), flux reversal (FRM), switched Reluctance (SRM), spoke type flux focusing (SFM), spherical, linear, conical gap, oscillatory generator, hysteresis and stepper motors are some interesting and promising machine topologies investigated in academia and industries for niche market segments where cost is not a primary consideration. *Conclusions:* The motor technology is matured over more than 100 years. Induction motors, synchronous motors and PM motors are key topologies accepted globally. Recycling of the magnets will further improve acceptance of PM motors in the global market. The innovative steps in magnetic material development not only supports conventional technologies but also enables new motor and transformer topologies which improves performance and reduces size and total ownership cost.

FH-06. Analysis of a Novel Double-sided Dual-PM Hybrid-excitation Switched-flux Linear machine.

Z. Zeng[1] and Q. Lu[1]
1. College of Electrical Engineering, Zhejiang University, Hangzhou, China

Introduction: Hybrid-excitation switched-flux linear machine (HESFLM) has been studied increasingly due to the advantages of high force density, flexible flux controllability, robust secondary, etc. Existing HEFSLM structures have excitation winding, armature winding, and PMs entirely accommodated on the single-primary [1], [2]. Consequently, both flux-regulation capability and PM force density are restricted. In order to solve the aforementioned problem, this paper proposes a novel double-sided dual-PM HESFLM (DSDP-HESFLM) featuring dual-PM and double-sided primaries, hence both excitation and armature windings can be separately amounted with corresponding slot areas augmented simultaneously [3-5]. As a result, electromagnetic performances can be improved effectively. Based on 2-D finite-element (FE) analysis, the operating principles of the proposed machine from both generator- and motor-oriented perspectives are systematically investigated, and then its electromagnetic performances are studied. Topology and Operation Principle: Fig. 1(a) shows the topology of the proposed 6-slot/7-pole (6s/7p) DSDP-HESFLM. Apparently, the primary is partitioned into two asymmetrical parts and concentrated non-overlapping armature and field windings can be observed. Moreover, armature-PM is sandwiched between two U-shaped steel lamination while field-PM is inset in the field teeth. It is worth mentioning that magnetization direction of armature-PM is parallel to moving direction, while that of field-PM is perpendicular to moving direction. Besides, magnetization direction of two adjacent field-PMs and their middle armature-PM should resemble clockwise or anti-clockwise to make armature flux-linkage caused by armature-PM and field-PM the same polarity. Actually, the proposed machine can be taken as a combination of double-sided HEFSLM with armature-PM and field-PM, respectively. Fig. 1(c) shows the operation principle of the proposed machine from generator-oriented perspective, which is based on flux-switching mechanism. Namely, armature coil PM flux changes periodically with secondary position, where an electrical circle corresponds to a secondary-pitch movement. Hence, brushless AC operation is also suitable for the proposed machine. Alternatively, the operation principle from the perspective of motor-oriented, emphasizing the interaction of PM and armature reaction fields, can be illustrated in Fig. 1(d) and (e). As is shown, the modulation of salient secondary pole to both PM and armature reaction source MMFs produces lots of harmonics. Specifically, apart from source PM MMF harmonics with pole-pair number $(2i-1)P_{PM}$, where i=1,2,3..., new dominant PM flux-density harmonic components with pole-pair number of 2, 4, 10, 16 ($|(2i-1)P_{PM}\pm jN_s|$, j=1, i=1,2) are also produced. Similarly, apart from source armature reaction MMF harmonics with pole-pair number, dominant new-emerging flux-density harmonics are also produced with pole-pair number 3, 5, 9, 11 ($|2k\pm jN_s|$, k=1,2, j=1). In other words, after the modulation effect of secondary poles, stable thrust force can be generated by the interaction of PM and armature reaction flux-density harmonics with same speed and pole-pair number, which is called magnetic-gearing effect [6], [7]. Feasible slot/pole combinations of DSDP-HESFLM can be 6s/4p, 6s/5p, 6s/7p and 6s/8p, among which 6s/5p and 6s/7p structures exhibit larger winding coefficient. Furthermore, 6s/7p has relatively large thrust force constant compared with its 6s/5p counterpart. Hence, it is reasonable to choose 6s/7p as the optimal slot/pole combination. Electromagnetic Performance Investigation: For the globally optimized 6s/7p DSDP-HESFLM, electromagnetic performances are comprehensively investigated. As is shown in Fig. 2(a) and (b), *d*-axis flux-linkage can be easily adjusted by field current, and its DC components can be adjusted from 75.38% to 116.66%. The detent force is shown in Fig. 2(c), indicating it mainly derives from end effect. Besides, force waveform under rated condition is shown in Fig. 2(d), and corresponding PM force density is 1.38N/cm^2, which is high for hybrid-excitation linear machine. Flexible average force regulation capability by armature copper loss or field current can be also observed in Fig. 2(e). As shown in Fig. 2(f), relatively smooth inductances can be observed, which benefits smooth output force. Conclusion: A novel DSDP-HESFLM has been proposed and its operation principles are analyzed from both generator- and motor-oriented perspectives, which demonstrates that it also operates on magnetic–gearing effect. Then, electromagnetic performances are investigated, showing the proposed machine exhibits good flux-adjusting capability and high PM force density.

FH-07. Study of efficiency characteristics of Interior Permanent Magnet Synchronous Motors.

S. Feng[1], W. Jiang[1], Z. Zhang[1], J. Zhang[1], Y. Li[2] and Y. Wang[1]
1. Department of Electrical Engineering, Nanjing University of Aeronautics and Astronautics, Nanjing, China; 2. Nanjing YueBoo Power System Co.,Ltd, Nanjing, China

I.Introduction Interior Permanent Magnet (IPM) synchronous motor configuration is preferred in electric vehicle (EV) traction system. Efficiency map is a common tool to describe the performance of a traction motor [1]. For each operating point (torque and speed), the excitation (current amplitude and angle) must be defined to evaluate its efficiency. If brute force method is applied to search for current excitations, the process of developing the efficiency map for an IPM machine can be time consuming. In this study, the relationships between operating points and corresponding optimal current excitations are summarized. Therefore, the process of searching for the optimal current excitations can be simplified. A script in ANSYS Maxwell has been developed to find the current excitations for optimal operating condition automatically. The efficiency performance of an IPM motor can be evaluated using finite element (FE) method with the optimal current excitations, and the efficiency map can be obtained rapidly. The effectiveness of the proposed method was validated by comparing efficiency maps created based on FE analysis results and experimental results of an IPM machine. II.IPM machine analysis A 70kW 8-pole/48-slot IPM machine for EV traction has been studied. Maximum torque per ampere (MTPA) and flux weakening (FW) are used as control strategies. As Fig.1 shows, for any given current amplitude, torque is a function of current angle (Gamma), which suggests there is only one optimal current excitation for the IPM machine to produce certain torque at a speed. In the figures below, torque is denoted as T; amplitude and angle of the current excitation are denoted as Ipeak and Gamma respectively. For the optimal current excitations of operating points at a certain speed, some conclusions have been drawn: (1)The relationship between torque and current amplitude for optimal operating condition is near linear regardless of speed, as shown in Fig.2. (2)The relationship between torque and current angle for optimal operating condition can be well fitted by a cubic polynomial if speed is below a certain value. As the speed exceeds the value, the relationship is no longer monotonic, as shown in Fig.3. III. Automatic calculation of optimal current excitations A method to simplify the search process of current excitations for optimal operating condition has been summarized with a script written in ANSYS Maxwell. Operating steps of the script are as follows: (1)Set a revolution speed and a series of typical current values in ANSYS Maxwell. Analyze corresponding current angle for optimal operating condition with step searching. (2)Call MATLAB. Fit the T-Ipeak curve of optimal excitations with a linear function and fit the T-Gamma curve with a cubic function. An exemplary fitting process in MATLAB is shown in Fig.4. (3)Process and record the data of other several typical speeds with steps (1)(2). Obtain the characteristic data of optimal current excitations at each speed and record them in a document package. (4) For an arbitrary torque at a certain speed, the corresponding current amplitude and angle can be obtained immediately by solving the recorded fitted equations reversely. If T-Gamma curve is not monotonic at this speed, the current amplitude still can be calculated with the fitted T-Ipeak function, whereas the current angle will be found by step searching. Newton interpolation will be adopted if the characteristic data of optimal current excitations at the required speed have not been analyzed before. The time of searching for the current excitations is shortened significantly. Select a certain amount of operating points and calculate the efficiency of each operating case. Then, the efficiency map can be obtained. IV.Experiment and Verification A prototype IPM machine for EV traction was designed and fabricated. The experiment bench has been established as shown in Fig.5. MTPA and FW are adopted control strategies. Several current excitations for optimal operating condition of the IPM machine were calculated with the script and with brute force method respectively. Corresponding T-Ipeak curves and T-Gamma curves are compared as shown in Fig.6 and Fig.7. The results prove the feasibility of automatic calculation with script. The efficiency map obtained through experiment is shown in Fig.8 a). In the simulation, more than 100 optimal current excitations were automatically calculated by script. Efficiency of every corresponding operating point was calculated and the efficiency map is shown in Fig.8 b). The good correspondence between two efficiency maps proves the accuracy of automatic calculation with the script. V.Conclusion A study has been conducted to simplify the steps of searching for the optimal current excitations of IPM machines. The rules between operating points and corresponding optimal current excitations have been summarized. A method to simplify search process of optimal current excitations was proposed and a script for ANSYS Maxwell has been developed. The excitations for optimal operating points at lower speed can be calculated rapidly through fitting, function solving and interpolation. For the operating points at higher speed, the optimal current amplitude can be obtained by solving fitting functions, the corresponding current angle will be searched with step searching. The automatic calculation reduces the search time of optimal current excitations and accelerate the procedure for creating the efficiency map significantly. In addition, the effectiveness of this method is validated with experiments.

FH-08. Consequent Pole Hybrid Brushless Wound Rotor Synchronous Machine.

A. Hussain[1] and B. Kwon[1]
1. Electronic Systems Engineering, Hanyang University, South Korea, Ansan, The Republic of Korea

1. Introduction Several brushless topologies for wound rotor synchronous machines (WRSMs) have been presented in recent years to replace the brushes and slip-ring assembly in conventional WRSMs [1-4]. The brushless operation of the WRSM presents these machines as an alternative to the permanent magnet synchronous machines (PMSMs) because of their low cost and competitive performance as compared to the PMSMs. However, the drawback of the brushless wound rotor synchronous machines (BL-WRSMs) is their low starting torque because of the absence of the excitation source on their rotor. Although, the BL-WRSM achieves the rated torque at the base speed but low starting torque under the base speed makes these machines less suitable for variable speed applications. A PM assisted BL-WRSM was presented in [5] to overcome the problem of the low starting torque and to provide better performance under full-load conditions. However, the presence of the PM on each pole increases the cost of the machine. Moreover, the leakage flux is increased in PM assisted machines. These issues can be resolved by the consequent pole (CP) machines [6]. In this paper, a consequent pole hybrid brushless wound rotor synchronous machine (CPH-BL-WRSM) is proposed to overcome the problem of low starting torque, and to reduce the PM usage as compared to the PM assisted machines. A 2-D finite element analysis is performed to validate the proposed CPH-BL-WRSM and its performance is compared with the existing BL-WRSM and PM assisted BL-WRSM. 2. Proposed machine configuration and Operation Principle The single inverter fed brushless excitation topology applied to the proposed CPH-BL-WRSM is shown in Fig. 1(a). In this brushless topology, the sub-harmonic component of stator magneto-motive force (MMF) is generated and utilized to excite the rotor field winding as discussed in [4]. The proposed CPH-BL-WRSM with windings and PMs on the alternate poles of the rotor helps the machine with smooth startup without any external aid. Initially, the proposed machine will start as the consequent pole permanent magnet synchronous machine because there will be no induced current in the harmonic winding. Therefore, at the startup, the excitation flux is provided by the PMs only for the torque production. With the increase of the speed, the current is induced in the harmonic winding which is then rectified and supplied to the rotor field winding. At this stage, the machine operates as the CPH-BL-WRSM with the flux from both the PMs and rotor field windings. The configuration of the 2-D models of the existing PM assisted BL-WRSM and proposed 8-pole, 48-slot CPH-BL-WRSM are shown in Fig. 1(b) and Fig. 1(c) respectively. The proposed machine is designed such that its outer dimensions, rated power, rated speed and other specifications are same as the existing BL-WRSM [4] and the PM assisted BL-WRSM [5]. The stator and rotor winding configuration is kept same as the winding configuration shown in Fig. 1(a). For the fair comparison, both rotors were optimized using the Kriging method based Latin hypercube sampling and a genetic algorithm. The detailed optimization process will be explained in the full paper. Finally, the proposed CPH-BL-WRSM was manufactured to verify the operation of the machine. The stator and rotor of the prototype are shown in Fig. 1(d) and Fig. 1(e) respectively. 3. Simulation Analysis 2-D finite element analysis is performed to analyze the performance of the proposed CPH-BL-WRSM and existing BL-WRSM and PM-assisted BL-WRSM. Fig. 2(a) shows the back-EMF comparison of the machines compared in this paper. It can be observed that the back-EMF of the proposed machine is 34.5% and 9.5% higher as compared to the back-EMF of the existing BL-WRSM and PM-assisted BL-WRSM respectively. Fig. 2(b) shows the comparison of the induced current in the field winding. The torque comparison is shown in Fig. 2(c). The proposed CPH-BL-WRSM exhibits 11% higher torque than that of the existing BL-WRSM and 9.5% higher torque than that of the PM assisted BL-WRSM with 44.6% less PM usage. The overall performance comparison of both machines is summarized in Fig. 2(d). It is observed that the proposed CPH-BL-WRSM exhibits high starting torque, high torque density with less PM usage. Detailed simulation analysis of both machines will be presented in full paper. Finally, the prototype of the proposed CPH-BL-WRSM will be experimented to validate the brushless operation and verify the simulation analysis.

I. INTRODUCTION Flux-switching machines (FSM) have attracted a lot of attention by researchers over the last decade due to their high torque density and sinusoidal back-EMF in addition to robust, magnetless and cost effective rotors. The theory of flux switching can be applied to axial, radial, linear and transverse flux machines. Axial-flux machines in general have advantages such as short axial length, better heat dissipation and high efficiency compared with radial-flux machines [4]. Furthermore, flux switching machines proposed in the literature so far are mostly radial-flux structures [1, 2]. A limited number of FSM papers deal with axial gap flux switching topologies due to difficulties in the design and analyses in 3-dimensional space [3-5]. In this study, a new double-rotor-single-stator, axial-gap, flux switching permanent magnet (PM) synchronous (AGFSPM) machine with hybrid excitation is proposed for the first time in literature. The proposed hybrid-excited AGFSPM machine combines the advantages of PM machine and the wound-rotor synchronous machine. II. OPERATION PRINCIPLE, ANALYSIS AND EXPERIMENTAL RESULTS *A.Structure and Operating Principles* The proposed AGFSPM motor has double-rotor-single-stator with 12-slot 10-pole configuration with hybrid excitation. The structure of the AGFSPM is displayed in Figure 1. AC windings are placed in the slots openings on both sides of the stator core. DC windings, on the other hand, are placed inside the stator core in a back-to-back (or toroidal) manner in order to ease the stator manufacturing. Permanent magnets are placed in the slot openings in a consecutive manner so as to help the flux reverse the polarity as the DC winding is energized. When the rotor pole and the stator tooth are in full alignment as in Figure 2a, the flux is switched. Thus, the flux passing through the air gap encircles the phase-A windings. When there is no excitation current, some of the magnet flux passes through the air gap and some passes through the stator yoke short-circuiting the magnetic circuit. If a sufficient amount of positive DC current is applied (Figure 2c), the magnetic flux generated by the excitation current together with all of the magnet flux will also pass through the motor airgap for energy conversion. When the rotor pole reaches at the next stator tooth, the flux direction passing through the airgap is reversed as illustrated in Figure 2b when MMF is 0 AT and Figure 2d when MMF is 1100 AT. *B.Optimization of Design Parameters and 3D Finite Element Analyses* To design of the flux switching machine, the number of stator slots and rotor poles, shape and width of the poles, slots and magnets are critical parameters of the AGFSPM motor [6]. Electrical output power of such disc motor can be expressed as $P_{out} = (2m/T)\int e(t)i(t)d(t)$ (1) $P_{out} = mE_{max}I_{max}$ (2) $P_{out} = ((\sqrt{2}\pi^2)/240)A_sB_{g\,max}\,K_dK_f(P_r/P_s)D_on(1+\lambda)/2[(\pi/4)D_o^2(1-\lambda^2)-P_rL_{pm}W_{pm}]$ (3) The main parameters of the proposed designed AGFSPM machine are given in Table 1.3D modeling of the proposed AGFSPM has been made according to Table1. Figure 3 shows mesh profile and flux distributions for positive MMF. *C. Prototype Motor and Experimental Results* The picture of the prototype AGFSPM motor, stator with both AC and DC windings and magnetless rotor are all illustrated in Figure 4. The test results and the comparison with the FEA will be provided in the final version of the paper. III. CONCLUSION In this paper, a new axial-gap, flux switching PM machine with AC and DC hybrid excitation is proposed. Motor principles, initial design equations, some 3D FEA results are provided. Proof-of-concept motor is manufactured based on the design and experimental work has started. Detailed results and comparison between the FEA and test data will be provided in the final version of the paper.

FH-10. Design of a ▽+U shape Interior PM Machines for Electric Vehicle Applications.

M. Sheng[1]
1. Nanjing University of Aeronautics and Astronautics, Nanjing, China

I. Introduction Interior permanent magnet (IPM) machines are widely used in electric vehicle (EV) applications because of outstanding performance characteristics such as the wide constant-power speed range, high power density, and low magnet eddy-current loss [1], [2]. A parameterized finite-element analysis model is adopted to optimize the pole-arc to pole-pitch ratios to maximize the fundamental air-gap flux density (model I) and minimize its total harmonic distortion (model II). The torque density, torque ripple, *d*- and *q*-axis inductances, iron losses, power, and efficiency are analyzed and compared of the two models. II. Main Body Fig. 1 shows the core loss density and the iron loss segregation of two ▽+U shape IPM machines, where V_{am} is the amplitude of phase voltage, I_{em} is the amplitude of the phase current. The ▽+U shape IPM machine with maximize the fundamental air-gap flux density is model I, the ▽+U shape IPM machine with minimum THD of air-gap flux density is model II. The rated power of the machines is 48 kW, and the maximum speed of the machines is 12000 r/min. The core loss density at the stator teeth of model I is significantly higher than the model II, the rotor core loss densities of the two models are almost the same. The eddy current loss is larger than hysteresis, and the stator eddy current and hysteresis loss of the model II are significantly lower than that of the model I. The PM eddy current losses of the two models are almost the same. At 12000 r/min, the total iron loss of the model I is 1636.6 W, and model II is 1089 W which reduced 50 % than the model I. The *d*- and *q*-axis inductances and the saliency ratio ρ of the two models under the limitation of inverter voltage are investigated. A prototype IPM machine with model II is manufactured to verify the results of the analysis. Fig. 2(a) shows the photographs of the rotor. The measured EMF of the prototype machine are shown in Fig. 2(b). The FEA predicted and measured torques, and efficiencies of model II are shown in 2(c), and exhibit good agreement. III. Conclusion This paper proposed a ▽+U shape IPM machine for electric vehicle applications. A parameterized finite-element analysis model is adopted to optimize the pole-arc to pole-pitch ratios to maximize the fundamental air-gap flux density and minimize its total harmonic distortion. The ▽+U shape IPM machine with minimized THD of air-gap flux density can reduce the torque ripple and iron losses with only slight reduction of the average torque. Finally, the prototype ▽+U shape IPM machine with the minimum THD of air-gap flux density is fabricated, and the experiments are presented to verify the results of FEAs.

FH-11. Optimal Design and Experimental Test of Surface-Mounted Permanent Magnet Motors with Cost-Effective Magnet Utilization to Suppress Torque Pulsations.

W. Zhao[1], H. Shen[1], W. Chai[2], X. Wang[1] and B. Kwon[2]
1. School of Electrical Engineering, Shandong University, Jinan, China; 2. Department of Electronic Systems Engineering, Hanyang University, Ansan, The Republic of Korea

I. Introduction The surface-mounted permanent magnet (SPM) motors with NdFeB magnets, offering high torque density and high efficiency, have been widely applied to various domestic and industrial applications [1]. However, the adoption of NdFeB magnets not only brings high torque density, but also leads to high torque pulsations and high magnet cost. The approaches to suppress torque pulsations in SPM motors have been heavily investigated through drive control or motor design methods [2], [3]. In particular, the suppression of cogging torque has received great attention along with numerous methods, such as skewing [4], auxiliary slots [5], teeth notching [6], and slot-opening shifting [7], etc. However, most of the methods to suppress cogging torque may not result in low torque ripple due to the effects of armature reaction fields. Hence, the approaches to suppress both cogging torque and torque ripple simultaneously are more desired. It is well known that the magnet flux density distribution has a significant effect on torque performance. Accordingly, extensive magnet shaping methods, such as magnet pole shape optimization [8] and sinusoidal magnet poles [9], have been reported to obtain a sinusoidal magnet flux density distribution, thus to reduce torque pulsations. However, these reported methods inevitably lead to manufacturing difficulty and performance degradation. Regarding to the magnet cost saving, the approaches by using ferrite magnets, or hybrid ferrite and NdFeB magnets are investigated, but generally neglecting the issues on torque pulsations [10]. In this paper, an optimal design is proposed for the SPM motor to reduce the cogging torque and toque ripple, and save the magnet cost using multi-grade NdFeB and ferrite magnets. Based on a conventional SPM motor with single-grade NdFeB magnets, the proposed SPM motor is designed with three-grade NdFeB and ferrite magnets, and then optimized to further reduce torque pulsations and save the magnet cost by maintaining the high average torque using the Kriging method and a genetic algorithm. All the motor characteristics are first predicted using the finite element method (FEM) at the same operating conditions. Then the experimental test is performed for the optimized model to validate the optimal design and analysis results. II. Modeling, Optimal Design, and FEM Analysis Results The conventional SPM motor with arched magnet shape is referred as the basic model as shown in Fig. 1 (a). The rotor is mounted with single-grade NdFeB magnets (0.5 T) with radially magnetized direction. Theoretically, the basic model produces a rectangular airgap flux density waveform, which contains extensive harmonics as shown in Fig. 1(b). The proposed SPM motor exhibits the feature of multi-grade magnets as shown in Fig. 2(a). Ideally, a sinusoidal airgap flux density can be obtained when the remanence of magnets varies in a sinusoidal manner diminished from the middle piece as shown in Fig. 2(b). To avoid excessive manufacturing difficulty and cost, the proposed model herein adopts two-grade NdFeB magnets (1-0.67 T and 2-0.61 T) and one-grade ferrite magnet (3-0.375 T). To obtain the superior performance with the limited magnet pieces, the proposed model is optimized by the Kriging method and a genetic algorithm by selecting the angular width of the magnets as the design variables. The cogging torques are compared in Fig. 3. The proposed and optimized model can highly reduce the cogging torque, while the optimized model reduce the cogging torque by 68.4%, as compared to the basic model. Fig. 4 compares the electromagnetic torques, which indicates that the proposed and optimized models exhibit not only lower torque ripple, which is reduced by 46.1% in the optimized model, but also higher average torque when compared to the basic model. Although the proposed and optimized models adopt better grade of NdFeB magnets, their magnet costs are much lower than the basic model due to the utilization of low-cost ferrite magnets and low-volume NdFeB magnets. The magnet cost of the optimized model is decreased by 39.7%, when compared to that of the basic model, as listed in Table I. III. Experimental Test The optimized model is manufactured for experiments to verify the analysis results as shown in Fig. 5. Fig. 6 shows the comparison of the simulated and measured phase back EMFs at 600 rpm, and Fig. 7 displays the corresponding harmonic analysis. The results indicate that the measured back-EMF waveform agrees well with the simulated result, whereas there exists a discrepancy around the peak points and fundamental values because of the distorted radial magnetization attributing to the relatively small angular width of NdFeB magnet "2". Therefore, the simulated and measured cogging torques exhibit good accordance in waveforms, but with a slight difference in peak-to-peak values, as revealed in Fig. 8. IV. Conclusion This paper has proposed an optimal design for a SPM motor to reduce cogging torque and torque ripple, as well as the magnet cost by using multi-grade NdFeB and ferrite magnets. The results obtained by the FEM show that the optimized model obtained through the Kriging method and genetic algorithm has greatly reduced cogging torque by 68.4%, torque ripple by 46.1%, and magnet cost by 39.7%, as well as the increased average torque when compared to the basic model. Finally, the experimental results have validated the optimal design and analysis results, which sufficiently demonstrated the effectiveness of the proposed SPM motor in terms of minimization of torque pulsations.

FI-01. Recovery of long-range magnetic order by Rh substitution in spin glass compound $Mn_{0.7}Fe_{0.3}NiGe$.

S. Samatham[1], A.K. Patel[1] and K. Suresh[1]
1. Department of Physics, Indian Institute of Technology Bombay, Mumbai, India

Introduction Heusler alloys have continued to be on the frontline research for their multi-functional properties such as shape memory effect, large magnetocaloric effect, exchange bias, negative thermal expansion, spintronics, spin-filters etc. Some of these are reported to show complex magnetic behavior with various magnetic ground states such as ferromagnetic, antiferromagnetic, ferromagnetic, coexistence of two magnetic phases, short-range order such as spin-glass, magnetic glass and re-entrant spin glass. Though, many potential compounds have resulted from the interchanging of 3d-transition metals, recently heavy metal (Rh and Pt) based Heusler compounds haven been reported to be good fertile for the technological applications by showing large spontaneous exchange bias [1] and skyrmion characteristics [2]. In the present paper, we discuss the properties of $Mn_{0.7}Fe_{0.3}NiGe$ in which Rh is doped for Fe. We present the combined results of structural, dc-magnetization and ac-susceptibility measurements. In particular, the evolution of long-rang magnetic order with increase of Rh concentration for Fe and manifestation of short-range magnetic correlations are addressed. Experimental Techniques Polycrystalline $Mn_{0.7}Fe_{0.3-x}Rh_xNiGe$ with nominal compositions of x = 0.1, 0.2 and 0.3 are prepared by arc melting the constituent elements (of at least 4N purity) in Argon gas flow-environment. Room temperature X-ray diffraction patterns are recorded using powder specimens using Cu-K_α radiation. Magnetization as a function of temperature and magnetic field is measured using 7 T-SQUID-Vibrating Sample Magnetometer down to 2K and in fields up to 70 kOe. Results and discussion $Mn_{0.7}Fe_{0.3}NiGe$ is a derived compound from MnNiGe [3] (Fe doped for Mn) which undergoes a structural transition from TiNiSi-type orthorhombic to Ni_2In-type hexagonal at a particular concentration [4]. Figure 1(a) shows the temperature dependent magnetization $M(T)$ measured from 2-300 K in 100 Oe for nominal compositions with x = 0, 0.1, 0.2 and 0.3 of $Mn_{0.7}Fe_{0.3-x}Rh_{x}NiGe$. A finite difference between zero-field cooled (ZFC) (hallow symbols) and field-cooled warming (FCW) (solid red-line) curves is evident for all the compounds. However, $Mn_{0.7}Fe_{0.3}NiGe$ shows spin-glass transition (T_g) below 82.8 K which is in agreement with the literature [4]. T_g values for $Mn_{0.7}Fe_{0.2}Rh_{0.1}NiGe$ and $Mn_{0.7}Fe_{0.1}Rh_{0.2}NiGe$ are 66.0 K and 61.05 K respectively. On the other hand $Mn_{0.7}Rh_{0.3}NiGe$ orders ferromagnetically below $T_C \sim 120$ K. A cursory look at temperature dependent magnetization of $Mn_{0.7}Fe_{0.3-x}Rh_xNiGe$, from Fig. 1(a) and (b), reveals that Rh substitution in place of Fe recovers the long-range magnetic order which is a second order phase transition from paramagnetic to ferromagnetic within austenite phase. Magnetization isotherms from -70 to 70 kOe are shown in Fig. 1(b) measured at 2 K. Magnetization shows non-saturating behavior for x = 0, 0.1 and 0.2, as expected for spin-glass compounds while x = 0.3 saturates above 13 kOe with 2.18 μ_B/f.u. Under a magnetic field of 70 kOe, magnetization is found to decrease for x = 0.1 and 0.2 as compared to x = 0 with an exceptionally sudden increase for x = 0.3. Shown in Fig. 2 is the expanded-view of low-field isothermal magnetization curves of $Mn_{0.7}Fe_{0.3-x}Rh_{x}NiGe$ measured after cooling the specimen to 2 K in 0 kOe. Commonly, it is noticed that $M(H)$ of spin-glass compounds x = 0, 0.1 and 0.2 is asymmetric around H = 0 kOe, indicating the exchange bias (EB) behavior. However, the ordered compound $Mn_{0.7}Rh_{0.3}NiGe$ does not show hysteretic behavior. Coercive magnetic field (H_{Coerc}) and EB (H_{EB}) are estimated as $H_{Coerc} = (H_2-H_1)/2$ and $H_{EB} = -(H_2+H_1)/2$ where H_1 and H_2 are the zero-magnetization points on negative and positive field axes. H_{Coerc} and spontaneous H_{EB} are found to increase with Rh substitution. Conclusion In the full paper, we discuss the effect of heavy 4d-metal Rh substitution on the spin glass behavior of $Mn_{0.7}Fe_{0.3}NiGe$ using the combined results of X-ray diffraction, dc-magnetization and ac-susceptibility measurements. At room temperature, all the compounds are found to crystallize in Ni_2In-type hexagonal austenite structure. The austenite high-temperature paramagnetic to low-temperature spin-glass-like transition is observed for x = 0, 0.1 and 0.2. A long-range ferromagnetic ordering is achieved upon complete replacement of Fe by Rh. Importantly, the spin-glass compounds are observed to show spontaneous exchange bias i.e., in zero-field cooled mode.

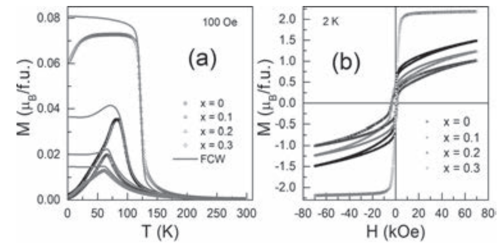

Fig. 1. (a) Temperature dependent magnetization $M(T)$ of $Mn_{0.7}Fe_{0.3-x}Rh_{x}NiGe$ with x = 0, 0.1, 0.2 and 0.3, measured in ZFC and FCW protocols. $M(T)$ of x = 0, 0.1 and 0.2 resemble spin-glass-like behaviour whereas x = 0.3 shows a typical ferromagnetic transition below 120 K. (b) Magnetic field dependence of magnetization of $Mn_{0.7}Fe_{0.3-x}Rh_xNiGe$ measured isothermally at 2 K. Non-saturation along with hysteretic behaviour for x = 0, 0.1 and 0.2 indicate the spin-glass-like nature as suggested by $M(T)$. x = 0.3 is a ferromagnet with saturation magnetization of about 2.18 μ_B/f.u.

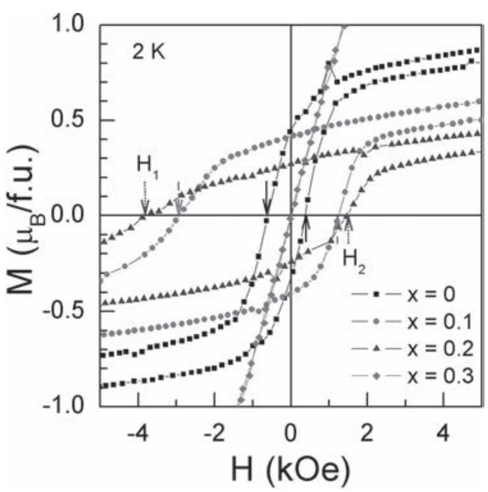

Fig. 2. Expanded low-field $M(H)$ of $Mn_{0.7}Fe_{0.3-x}Rh_xNiGe$. H_1 and H_2 are the zero-magnetization points on negative and positive field axes. ZFC/spontaneous exchange bias is about 117.6, 835.5 and 897.9 Oe respectively for x = 0, 0.1 and 0.2.

School of Physics and Astronomy, University of Glasgow, Glasgow, United Kingdom

Artificial Spin Ice (ASI), consisting of a two dimensional array of nanoscale magnetic elements [1], provides a fascinating opportunity to observe the physics of out of equilibrium systems. Initial studies concentrated on the static, frozen state, whilst more recent studies have accessed the out-of-equilibrium dynamic, fluctuating state [2, 3, 4]. This opens up exciting possibilities such as the observation of systems exploring their energy landscape through monopole quasiparticle creation, potentially leading to ASI magnetricity, and to directly observe unconventional phase transitions. In this work [5] we have measured and analysed the magnetic relaxation of thermally active ASI systems by means of SQUID magnetometry. We fabricated and measured square Artificial Spin Ice samples formed by nanoimagnets made of Permalloy ($Ni_{80}Fe_{20}$) with lateral dimensions of 68nm x 22nm, with two different thicknesses: 5nm and 6nm, and three different lattice spacings: 138nm, 175nm and 208nm, forming a total of six samples. We have investigated the effect of the interaction strength on the magnetization dynamics at different temperatures in the range where the nanomagnets are thermally active and have observed that they follow an Arrhenius-type Nèel-Brown behaviour. An unexpected negative correlation of the average blocking temperature with the interaction strength is also observed, which is supported by Monte Carlo simulations. The magnetization relaxation measurements show faster relaxation for more strongly coupled nanoelements with similar dimensions. The analysis of the stretching exponents obtained from the measurements suggest 1-D chain-like magnetization dynamics. This indicates that the nature of the interactions between nanoelements lowers the dimensionality of the ASI from 2-D to 1-D. Finally, we present a way to quantify the effective interaction energy of a square ASI system, and compare it to the interaction energy calculated from a simple dipole model and also to the magnetostatic energy computed with micromagnetic simulations.

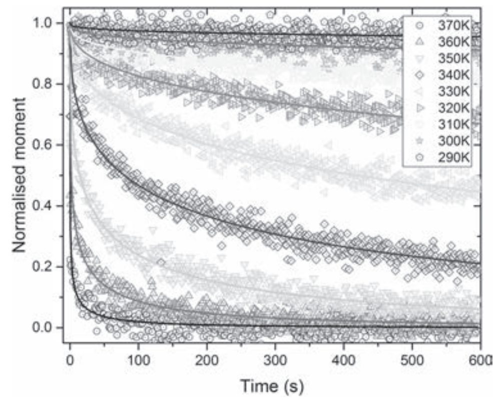

Fig. 1. Measurements of the magnetization relaxation dynamics of one of the samples studied. Each scatter plot corresponds to the measurement of the time evolution of the magnetic moment of the sample at a fixed temperature. The moment is normalised to the magnetic moment of the lowest temperature measured (frozen sample). The superimposed lines correspond to the stretched exponential model fitted to the data to extract the relaxation time and the stretching exponent.

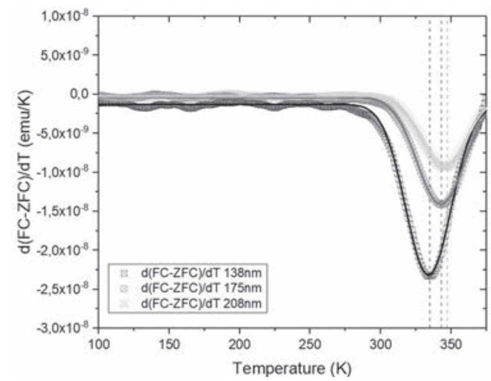

Fig. 2. Plots of the derivative of the difference between the Field Cooling (FC) and the Zero Field Cooling (ZFC) curves measured for three of the samples with different lattice spacings (138nm, 175nm and 208nm) studied (similar nanoisland volumes). The position of the peak indicates the average blocking temperature of each sample. The trend observed in the peak positions indicates that the average blocking temperature decreases with the interaction strength.

FI-03. Electron Accumulation and Emergent Magnetism in LaMnO3/ SrTiO3 Heterostructures.

Z. Liu[1]
1. School of Materials Science & Engineering, Beihang University, Beijing, China

Emergent phenomena at polar-nonpolar oxide interfaces have been studied intensely in pursuit of next-generation oxide electronics and spintronics. Here we report the disentanglement of critical thicknesses for electron reconstruction and the emergence of ferromagnetism in polar-mismatched $LaMnO_3$/$SrTiO_3$ (001) heterostructures. Using a combination of element-specific x-ray absorption spectroscopy and dichroism, and first-principles calculations, interfacial electron accumulation, and ferromagnetism have been observed *within* the polar, antiferromagnetic insulator $LaMnO_3$. Our results show that the critical thickness for the onset of electron accumulation is as thin as 2 unit cells (UC), significantly thinner than the observed critical thickness for ferromagnetism of 5 UC. The absence of ferromagnetism below 5 UC is likely induced by electron overaccumulation. In turn, by controlling the doping of the $LaMnO_3$, we are able to neutralize the excessive electrons from the polar mismatch in ultrathin $LaMnO_3$ films and thus enable ferromagnetism in films as thin as 3 UC, extending the limits of our ability to synthesize and tailor emergent phenomena at interfaces and demonstrating manipulation of the electronic and magnetic structures of materials at the shortest length scales.

FI-04. Complex Magnetic Structure of Tb_3Ni.

S. Goswami[1], P. Babu[1] and R. Rawat[2]
1. Magnetism, UGC-DAE Consortum for Scientific Research, Mumbai Centre, Mumbai, India; 2. UGC-DAE Consortium for Scientific research, Indore, India

Rare-earth rich intermetallic compounds of the type R_3T (R = rare earth, T = transition metal) received much less attention although rare-earth (RE) intermetallic compounds in general have been well studied. This is because R_3T compounds, which crystallize in orthorhombic Fe_3C type structure exhibit complex magnetic behavior.[1] A number of magnetic transitions as function of temperature and sometimes magnetic field have been observed in these compounds. In this study, one such compound, Tb_3Ni, is explored to unravel its complex magnetic behavior. Tb_3Ni is prepared by arc melting in Ar atmosphere and studied by dc magnetization, specific heat and neutron diffraction techniques. Magnetization results show Tb_3Ni orders magnetically below ~77K and the 'zero-field cooled' (ZFC) and 'Field Cooled' (FC) magnetization curves show (Fig.1) large bifurcation below 75K or so. ZFC exhibits two consecutive peaks at around ~ 77K and ~ 53K before rapidly falling towards low magnetization as T is decreased. It again shows a sharp peak at ~ 3K and it falls rapidly as 2K is reached. On other hand, FC curve continues to increase as T is lowered and 3K peak is observed in FC curve also. Curie-Wiess analysis of inverse susceptibility obtained from ZFC curve above T_C yields an effective paramagnetic moment of μ_{eff} = 4.75 μB /atom and θ_P = 88K. The effective paramagnetic moment turns out to be much less than the free ion moment of Tb^{3+}. The virgin magnetic isotherms measured at some selected temperatures show metamagnetic transition for T < 65K. The behavior of critical field at which this metamagnetic like transition takes place is different for T < 45K and for 50K < T < 65K, clearly indicating spin reorientation around 50K. M-H loops suggest that a strong anisotropy is present in the compound in the lower temperature region which is reported earlier also.[2] Magnetic saturation was not observed up to highest field of 9T that could be because of canted spin like structure in the compound. All these results are indicative of presence of a complex magnetic order. The measured MH isotherms between 2 to 120K are used to obtaine magnetocaloric effect (MCE) using the standard equation generally used. The magnetic entropy change thus derived is shown in the inset of Fig.1 at different magnetic field intervals. We found the maximum value of change in magnetic entropy is ~6.9 J/Kg-K for the maximum field change of 9T at T = 60K. To understand magnetic structure more clearly, temperature dependent neutron diffraction (ND) data was collected. As the sample is cooled below 100K, peak starts developing at low angles and becomes extremely intense shown in Fig.2. In addition to this peak, there are few other peaks denoted by '*' in Fig.2 which also develop as T is lowered. At the same time some peaks already present and represent crystalline structure also grow in intensity indicating ferromagnetic like order. These features, i.e. appearance of new diffraction peaks and increase intensities of existing peaks reflects presence of antiferromagnetic (AFM) and ferromagnetic (FM) orders simultaneously. This can arise when magnetic structure is not-collinear, then spin components in certain direction are aligned antiparallel giving rise AFM character and aligned parallel in certain other direction giving FM character. The AFM character at low temperature (2K) is so strong that it cannot be suppressed even by 7T magnetic field as seen infield neutron diffraction data at 2K. However, at 50K this AFM peak could be suppressed by 7T field. Specific heat measured as function of temperature at different fields is shown in the inset of Fig.2. Specific heat (Cp) data shows a sharp peak at ~ 52K which is consistent with the corresponding magnetic transition. However, Cp data does not exhibit any noticeable features at other temperatures as seen in ZFC magnetization. This is not surprising as Cp comprises of large non-magnetic electronic and phononic contributions apart from magnetic part. The sharp feature in Cp gets suppressed with external magnetic field (up to 3T). The low temperature zero field C_P data was analyzed in terms of the expression $C_P/T = \gamma + \beta T^2$ to extract the Sommerfeld's coefficient, γ, and Debye Temperature Θ_D from β. The values of γ ~ 71 mJ/mol-K_2 obtained from Cp data for Tb_3Ni is much large than that for isostructural compound of Tb_3Co for which γ ~ 45 mJ/mol-K2.[3] Similarly Debye Temperature Θ_D = 111K is slightly lower than that expect for these type compounds (150 to 200 K). This is because of crystal field effects at very low temperatures makes estimation of accurate Debye temperature difficulty. [4] Magnetic, specific heat and neutron diffraction studies indicate that Tb_3Ni has a dominant AFM order at low temperatures but the magnetic structure is non-collinear type. It exhibits two spin re-orientation transitions at ~3K and ~50K. Strong anisotropy in the compound is reflected in these studies. The moderate value of MCE is quite lower than the isostructural compound Tb3Co that may be because of strong anisotropy present in the compound.[5]

FI-05. Universal magnetic behavior of $Ni_2Mn_{1-x}Fe_xIn$ (x = 0.0 and 0.1) through magnetization, magnetocaloric and magnetoresistnace scaling methods.

A.K. Patel[1], S. Samatham[1] and K. Suresh[1]
1. Department of Physics, Indian Institute of Technology Bombay, Mumbai, India

Introduction Ever since the discovery of Heusler alloys, these have been continuously claiming prominent place in condensed matter research for their rich properties [1, 2]. One of the interesting aspects of these alloys is the giant magnetocaloric effect (MCE), suitable for magnetic refrigeration for room temperature (RT) applications. There have been numerous compounds identified and investigated for the large MCE at RT, based on rare-earth elements [3]. However, Huesler alloys also provide nearly same order of MCE values, but these are more cost effective. The large MCE is due to the first order magneto-structural transition. Therefore, there is an ample scope to search for good MCE materials within the Heusler family with different combinations of 3d and 4d elements. Nevertheless, apart from the technological view point, it is important and crucial to understand the underlying physics of these compounds in terms of magnetic interactions. Although some of these exhibit second order phase transition from paramagnetic to ferromagnetic state, universality class and origin of magnetic interactions are not still clear. Towards this end, we have made an attempt to unravel the spin interaction and universality class of Fe doped Ni_2MnIn compounds with the help of a novel magneto-entropic scaling. Experimental Technique Polycrystalline $Ni_2Mn_{1-x}Fe_xIn$ (x = 0.0 and 0.1) alloys were prepared by arc melting technique with stoichiometric ratios having at least 4N purity of each element. Room temperature X-ray diffraction (XRD) patterns were recorded on the powder specimens of as-prepared alloys using Cu-K_α radiation. Structural details were obtained using Rietveld refinement using FullProf suite. Magnetization as a function of temperature and field was measured using Vibrating Sample Magnetometer. Resistivity was measured using standard four-probe method down to 5 K with the help of Physical Property Measurement System (QD, USA). Results and Discussion Figure 1(a) shows the room temperature XRD of $Ni_2Mn_{1-x}Fe_xIn$ (x = 0.0 and 0.1) along with Rietveld refinement. The compounds are found to be phase pure and crystallize in cubic structure with space group Fm-3m. The estimated lattice parameters are 6.059 and 5.056 Å respectively. Inverse susceptibility is fitted with Curie-Weiss law, $\chi^{-1} = (T-\theta_{CW})/C$ where C is the Curie constant, to estimate the Curie-Weiss temperature (θ_{CW}) and the effective magnetic moment (μ_{eff}). The fits are shown in the Fig. 1(b). θ_{CW} values for x = 0.0 and = 0.1 are 321 and 332 K while μ_{eff} = 5.04 and 5.82 μ_B respectively. For x = 0.0, in order to estimate the magnetocaloric effect in terms of the change in magnetic entropy, isothermal magnetization curves are measured near magnetic transition T_C at a regular temperature interval of 1 K. The estimated magnetic entropy change is shown in the Fig. 2(a). The maximum magnetic entropy change is found to be 4.2 J.Kg^{-1}.K^{-1} at 50 kOe near 312 K. So as to understand the magnetic interactions, the commonly suggested method is to evaluate the critical exponents near transition temperature. The slope of the Arrott's plot (M^2 vs H/M) is used to identify the type (positive for second order and negative for first order) of phase transition [4]. Here, we have implemented magnetocaloric method [5] to evaluate the critical exponents, as shown in the Fig. 2(b) and (c). Thus obtained critical exponents are $\beta \sim$ 0.28, $\gamma \sim 2.24$ and $\delta \sim 8.06$. Primarily, it is understood from the exponents that x = 0.0 does not specifically belong to any common universality class but may be close to the tricritical mean-field universality class (β = 0.25, γ = 1.0 and δ = 5.0) [6] with slightly higher values of γ and δ. Using these critical exponents as initial guess, we will evaluate the more accurate exponents using modified Arrott's plot (MAP), Kouvel Fisher (KF) methods. In addition, we also perform the similar scaling using magnetoresistance (MR). Finally, the universal scaling of the isothermal magnetization curves and magnetic-entropy will be carried out below and above T_C to unravel the normalization of spin interaction, thereby unveiling the type and range (short or long) of magnetic interactions. Conclusion In the full paper, we mainly explore the type and range of spin interactions of $Ni_2Mn_{1-x}Fe_xIn$ (x = 0.0 and 0.1) with the help of MAP, KF, MCE and MR methods. The ambiguity over the association of first order phase transition near T_C will be explored. The universal scaling by various methods will definitely be helpful to understand the spin interactions. Similar methods will be employed for x = 0.1 and the results will be compared with those of x = 0.0.

FI-06. Signature of a Griffiths phase in layered canted antiferromagnet Sr_2IrO_4.

A. Rathi[2], P. Rout[1], S. Perween[2], R. Singh[3], A. Gupta[2], R. Pant[2] and G. Basheed[2]
1. CSIR-National Physical Laboratory (NPL), New Delhi, India, New Delhi, India; 2. AcSIR, CSIR-National Physical Laboratory (NPL) Campus, New Delhi, India; 3. Indian Institute of Science Education and Research (IISER), Bhopal, India

The 5d layered iridate Sr_2IrO_4 has been greatly acknowledged recently, after the pioneering experiments [1] claiming spin-orbital Mott state and isotropic 2D quantum pseudospin-1/2 Heisenberg AFM excitations, despite weak electronic correlations and large spin-orbit interaction, respectively in 5d systems. Nevertheless, these unconventional observations make SIO analogous to the novel 3d layered high-T_C superconducting (HTSC) cuprates. This led to a theoretical prediction of HTSC in doped-Sr_2IrO_4 [2]; however, recent studies introduce new complexities and alternatively suggest Slater gap [3] and anisotropic 2D XY interactions through critical exponent study [4]. Nevertheless, recently observed HTSC signatures in surface-doped Sr_2IrO_4 [5] recommend reinvestigation of the system. More surprisingly, the magnetic correlations between j = ½ spins even persist in paramagnetic (PM) state [6], which suggest the existence of short-range magnetic clusters in a PM matrix, leading to a Griffiths singularity [7]. In this study, we report the signatures of non-analytic Griffiths phase (GP) in 5d Sr_2IrO_4 and further correlate its unconventional insulating nature with GP above T_N. The temperature-dependent dc magnetization, M (T) shows the magnetic ordering at $T_N \sim 221$ K, in close agreement with the earlier study [4]. The Curie-Weiss (CW) fit in high-temperature range unexpectedly give larger $\mu_{eff} = 0.72\ \mu_B$ than the theoretical value of 0.57 μ_B with $J_{eff} = 1/2$ and $g_J = 2/3$. More importantly, the $1/\chi$ (T) is not fully described by CW behavior down to T_N, but shows negative downturn at much higher temperature, $T_G \sim 285$ K [Fig. 1]. These observations suggest the presence of short-range AFM ordering (or equivalently, finite spin-canted clusters sustained by a strong basal-plane anisotropy) in microscopically phase-separated regions much above the expected bulk T_N. This is a signature of Griffiths singularity, which is further supported by power-law behavior of low-field (100 Oe) inverse magnetic susceptibility, $1/\chi$ (T) α $(T/T_N^R - 1)^{1-\lambda}$ [8] with less-than-unit power exponent, $\lambda = 0.24(1)$ above the magnetic ordering temperature T_N when $T_N < T \leq T_G \sim 285$ K [see inset (a) in Figure 1]. The presence of GP has been associated with the partially irregular sequence of IrO6 octahedral rotation in alternate layers in real samples [9], in contrary to clockwise and anticlockwise rotation in an ordered structure. This can lead to the formation of finite size clusters with local distribution of short-range magnetic interactions. Apart from these, another striking feature in Sr_2IrO_4 is the competition between intralayer canted AFM (in ab-plane) and interlayer AFM (along c-axis) interactions which can stabilize and largely enhance Griffiths phase-like effects, as reported in other systems [10]. The non-analytic nature of GP [7] results in unique critical exponent, $\beta = 0.75(1)$ from modified Arrott plot (MAP) method [11] [see inset (b) in Figure 1], in corroboration with magneto-caloric study. More importantly, the Bray model [7] in GP regime yields a reliable critical exponent, $\beta = 0.19$ (1) [see Figure 1], which falls between that expected for 2D Ising and 2D XY interactions [Table-I], and indicates highly anisotropic 2D XY interactions (XYh_4 universality class) [12]. Finally, the GP signatures in Sr_2IrO_4 suggest the onset of gap formation (from short-range AFM ordering) above the expected bulk T_N, which explains the pseudo-gap above T_N, bad metallic behavior in PM state and continuous nature of "Slater" metal-to-insulator (MIT) transition, as observed in earlier studies [3]. FI-07. Modulation of spin dynamics across metal to insulator transitions in hybrid heterostructures.

M. Zhu[1], Z. Zhou[1], W. Ren[1] and M. Liu[1]
1. Xi'an Jiaotong University, Xi'an, China

Novel functionalities can be achieved in nanostructured materials in proximity with other dissimilar materials. An interesting possibility along these composite heterostructures is offered by ferromagnets in proximity to materials that undergo a metal insulator transition (MIT) and structural phase transition (SPT). In this study, the electron spin resonance (ESR) and spin switching behaviors of ferromagnetic films have been modulated by the proximity to the VO_2 films that undergo a metal to insulator transition (MIT), accompanying with structural phase transition and sharp resistance changes. On one hand, in the VO_2/FeCoB/Ta composite heterostructures, the modulation mechanism for the MIT of VO_2 films induced ESR changes in the FeCoB thin films with different thicknesses has been explored, in which the temperature effect and MIT effect may alternately take the leading role as the thickness varying. On the other hand, in the VO_2/Ta/$(Co/Pt)_3$/Pt/Ta composite heterostructures, the perpendicular magnetic anisotropy (PMA) in the $(Co/Pt)_3$ multilayers can be reoriented by temperature driven MIT in the coupled VO_2 films, leading to the magnetic easy axis of multilayers switching from out-of-plane to in-plane direction, as well as the spin reorientation in the $(Co/Pt)_3$ multilayers. This opens up an avenue for the modulation of spin dynamics in the composite heterostructures, and produces more possibilities of novel functionalities for the spintronics devices.

FI-08. Alternating spin chain compound $AgVOAsO_4$ probed by ^{75}As NMR.

N.A. Koodacadavan[1]
1. Physics, Indian Institute of Science Education and Research, Thiruvananthapuram, India

We performed ^{75}As NMR measurements on a polycrystalline sample of spin-1/2 alternating spin chain Heisenberg antiferromagnet $AgVOAsO_4$. Since the ^{75}As nucleus (nuclear spin $I = 3/2$) is coupled to the magnetic spin V^{4+} via hyperfine coupling, we can extract, understand and investigate the low-lying excitations of the V^{4+} spins by measuring ^{75}As NMR spectra, the NMR shift, and the spin-lattice relaxation rate $1/T_1$. From the fit of ^{75}As NMR spectra, the quadrupole frequency was found to be $v_Q = 6.29$ MHz. The spectral shape remains almost intact over the whole measured temperature range, thus ruling out the possibility of any lattice distortion. The temperature-dependent NMR shift *K(T)*, which is a direct measure of the intrinsic spin susceptibility, and hence free from impurity contributions unambiguously establishes the the spin-1/2 alternating-chain nature of $AgVOAsO_4$. When there is random distribution of defect spins (which would result in a paramagnetic upturn at low temperatures in $\chi(T)$), this paramagnetism broadens the NMR line but without contributing to the NMR shift. Thus, one can precisely estimate the magnetic parameters such as the exchange couplings and the spin gap by analyzing *K(T)* instead of $\chi(T)$. From the analysis of *K(T)*, magnetic exchange parameters were estimated as follows: the leading exchange $J/k_B = 38.4$ K and the alternation ratio $\alpha = J'/J = 0.69$. At low temperatures, the exponential decrease in *K(T)* confirms the presence of the spin gap and implies that the Curie-like upturn observed in $\chi(T)$ was extrinsic in nature and possibly arising from defects in the polycrystalline sample. The transferred hyperfine coupling between the ^{75}As nucleus and V^{4+} spins obtained by comparing the NMR shift with the bulk susceptibility amounts to $A_{hf} = 3.3$ Tμ_B. Below 10 K, both *K(T)* and $1/T_1$(T) enter an activated regime. Its detailed analysis reveals the predominance of 3D correlations triggered by sizable interchain couplings. One can also estimate the spin gap by analyzing the temperature-dependent spin-lattice relaxation rate $1/T_1$. The ^{75}As spin-lattice relaxation time T_1 was measured at the field corresponding to the highest peak position. The recovery of the longitudinal magnetization at different temperatures after a group of saturation pulses was fitted by the following double-exponential function. From the $1/T_1$ data, we estimate the first critical field $H_{c1} = 10$ T, in agreement with the magnetization data. The low-temperature part of *K(T)* yields the spin gap of 6K, which is slightly higher than 4.2 K expected at 6.8 T. The effect of interchain couplings on the low-temperature activated behavior of *K(T)* and the spin-lattice relaxation rate $1/T_1$ is identified.

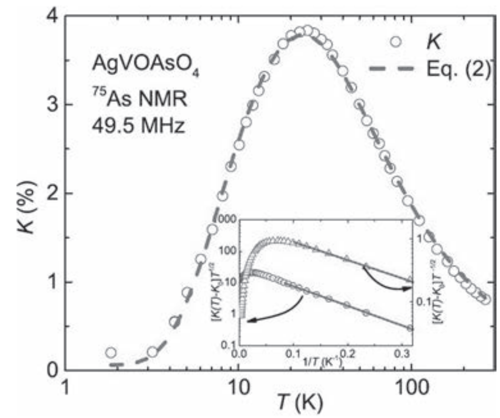

Fig. 1. The temperature dependent ^{75}As NMR shift *K* as a function of temperature *T*. The dashed red line is the fit of *K* by the equation $K(T)=K_0+A_{hf}\,\chi_{spin}(T)/N_A$, $\chi_{spin}(T)$ is the intrinsic spin susceptibility of the spin-1/2 Heisenberg alternating spin chain model. Inset: $(K-K_0)T^{1/2}$ vs $1/T$ and $(K-K_0)T^{-1/2}$ vs $1/T$ along the left and right y axes, respectively. The solid lines indicate the activation laws $(K-K_0)T^{1/2} \propto \exp(-\Delta^{K1D}/T)$ with $\Delta^{K1D}/k_B \approx 14$ K, and $(K-K_0)T^{-1/2} \propto \exp(-\Delta^{K3D}/T)$ with $\Delta^{K3D}/k_B \approx 6$ K, respectively.

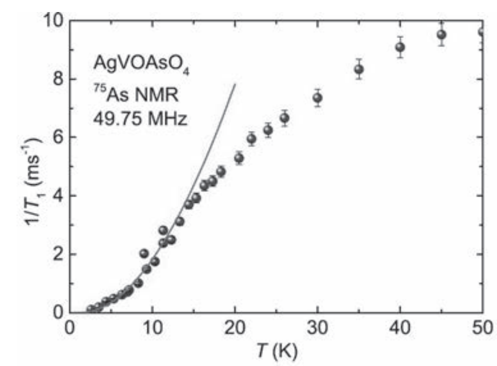

Fig. 2. $1/T_1$ as a function of temperature. The solid line is the fit using the equation $1/T1 \propto T^{\alpha 0}\exp[g\mu_B(H-H_{c1})/k_BT]$. This activated behaviour is due 3D magnon excitations that are gapped below the critical field of gap closing H_{c1}. The exponent α_0 depends on the effective dimension of the magnon dispersion.

INVITED PAPER

4:00

FI-09. Suppression of the double exchange in 4d-5d transition metal compounds. *(Invited)*

S. Streltsov[1] and D. Khomskii[2]
1. Institute of Metal physics, Ekaterinburg, Russian Federation;
2. University of Cologne, Cologne, Germany

The 4d and 5d transition metal compounds attracts nowadays considerable attention due to their specific properties, such as large covalency, strong spin-orbit coupling, the possibility to observe topological effects, etc. Magnetic ordering in these systems often displays strong suppression of magnetic moments, becoming (much) less than the nominal ones. One usually explains this by single-site effects: possible role of spin-orbit interaction, with orbital contribution opposite to the spin one, or by strong hybridization with ligands e.g. oxygens. We show that there exist in such system an intersite mechanism which, in particular, can lead to suppression or at least strong reduction of magnetism: the orbital-selective formation of covalent bonds (molecular orbitals) between metal ions, leading to “exclusion” of corresponding electrons from magnetic subsystem [1]. Especially spectacular are these effects in the situation with noninteger electron occupation, in which case this mechanism leads to suppression of the famous double exchange – the main mechanism of ferromagnetism in transition metals and compounds, including well-known colossal magnetoresistance manganites [2]. We demonstrate this novel mechanism by analytical and numerical model calculations, and show by ab-initio calculation that it explains magnetic behavior of several materials, including Nb2O2F3 and Ba5AlIr2O11[3]. Interplay of covalent bond formation and spin-orbit coupling is also discussed. Special attention will be paid to Ba3CeIr2O9, for which recent neutron and RIXS experiments demonstrates strong reduction of magnetic moments on Ir [4]. Our results thus demonstrate that the strong intersite interaction, typical for 4d and 5d compounds, may invalidate the standard single-site starting point for considering magnetism, and can lead to qualitatively different behavior. More specifically, they also show yet one more unexpected effect in the rich field of orbital physics.

Topological phases have been explored in various fields in condensed matter physics such as semiconductor physics, correlated electron systems, photonics and phononics. This leads to the recent foundation of emerging materials such as topological insulators, topological superconductors/superfluid, topological photonic crystals and topological phononic crystals. In this talk, I review our past works on magnonic analog of integer quantum Hall states (quantum magnon Hall) [1-3,5], where robust spin wave propagation along chiral topological edge modes may enable novel fault-tolerant spintronic devices. I will first introduce the topological integer in the context of the Landau-Lifshitz equation, and argue how the non-zero topological integer guarantees the existence of chiral magnon modes [1,2]. Then I will review material realizations of our ideas with band-calculations results based on a Landau-Lifshitz equation and micromagnetic simulations results [1-3]. I will also discuss a chiral topological exciton in Chern band insulator [4], and localization effect and thermal magnon Hall conductivity in disordered quantum magnon Hall systems [5].

Since the discovery of exchange bias in 1956 the origin of phenomena associated with the effect was unknown until the publication of what is known as the York Model of Exchange Bias in 2010 [1]. This work showed that the key to understanding the effect is the thermal stability of the AF grains in a sputtered film. The orientation of the AF order can be changed via the influence of the exchange field from the F layer when the sample is heated. The analysis of the loop shift via the York Model has enabled both the film thickness and lateral grain size dependence of the loop shift to be determined once the grain size distribution is known to high resolution. The calculated values are shown together with the results for the grain diameter dependence in Figure 1a, and the thickness dependence in Figure 1b. However there is still an ongoing lack of knowledge concerning the behaviour of atoms at the interface between the F and AF layers. At the interface there are competing interactions between AF and F order. However it is known that the interface spins order ferromagnetically because of the setting field dependence of the loop shift during the field annealing process [2]. There is also evidence of interface spin freezing resulting in an enhanced loop shift at low (<50K) temperatures and of the ability in a trilayer F/AF/F stack to order the interfaces independently of the order in the AF layer [1]. The influence of the interfaces on key parameters such as the observed coercivity, defined as the half loop width, and other effects such as training in which the initial measured loop after field annealing and subsequent loops are not identical, has also not been established. It is a conundrum that the coercivity of an exchange bias system can be as high as 1kOe whereas the coercivity of the F layer is typically 100Oe. This coercivity can occur in fields of several kOe. Furthermore if measurements are undertaken at low temperature then the grains in the AF layer will be completely stable against reorientation. Hence the observed coercivity of the F layer is not related to the properties of the F layer, nor can it be attributed to changes in the AF layer. Hence any observed coercivity must come from changes in the orientation of the interface spins. Given that the interface spins can be aligned in fields of the order of 10 to 20kOe, it is clear that these are not single spin effects but rather the behaviour of clusters of spins similar to those which were found to occur in spin glass systems. Hence the coercivity must be associated with irreversibility in the moment orientation of the interface spin clusters as the hysteresis loop is traversed. Hence the origin of the coercivity can thereby be explained. The phenomenon of training must for the same reasons, be an interface effect. In this case there must be a different process that occurs on field cooling to that which occurs after the first reversal of the F layer. This is analogous to the difference between a TRM and an IRM process as was commonly found in the case of spin glass systems [3]. Figure 2 shows the variation of the coercivity (H_C) and the training effect (H_T) with temperature over a range from room temperature to below 2K. The sample structure was Si/Ta (2)/Ru (2)/IrMn (10)/CoFe (5)/Ru (5) (thickness in nm). The results are quite remarkable and unexpected. Figure 2 shows that there must be some entities at the interface that are stable against thermal activation at room temperature. This implies that they must be small particles with a significant anisotropy presumably deriving from coupling to the grains in the AF layer. In all probability they would be of a similar diameter to the AF grains. However given that the variation of the coercivity continues at temperatures down as low as 2K this would indicate that there are also extremely small entities at the interface possibly down to a few or even single spins. Hence this implies that there is a very wide distribution of energy barriers at the interface regardless of its origin. In the presentation the nature of this distribution will be discussed as will the mechanisms by which the distribution gives rise to the observed phenomena.

FP-01. Effect of annealing on magnetic and mechanical behavior of NANOPERM-type alloys.

M. Hasiak[1] and A. Laszcz[1]
1. Wroclaw University of Science and Technology, Wroclaw, Poland

NANOPERM-type metallic glasses [1, 2] are still attractive candidates for variety of practical applications, because of their unique magnetic [3, 4] as well as mechanical properties [5]. Their annealing above crystallization temperature induces partial crystallization that is characterized by formation of α-Fe grains with typical sizes of up to tens of nanometers. Soft magnetic properties and mechanical properties of such nanocrystalline materials can be tailored not only with the aid of their chemical composition, but also by controlling the size the nanocrystalline grains created by heat treatment of amorphous precursor, their morphology, and structural composition. In order to understand magnetic and mechanical properties of NANOPERM-type alloys it is necessary to understand their microstructure and physical consequences of transformation from amorphous to nanocrystaline state. It is well known that structural changes demonstrate themselves also via macroscopic magnetic and mechanical parameters such as temperature dependence of magnetization, Curie temperature, AC and DC hysteresis loops as well as microhardness. We have studied a NANOPERM-type Fe76Mo8Cu1B15 alloy in form of ribbon 0.025 mm thick and 10 mm wide, produced by a rapid quenching method, with emphasis upon its magnetic and mechanical properties. All measurements were performed for the sample in the as-quenched state and after annealing at 837 K for 30 min. (above the primary crystalization temperature i.e. 723 K). Microstructure of the samples was studied by X-ray diffraction and AFM/LFM investigations. Temperature evolution of DC magnetization measured under zero-field cooling conditions using amorphous and nanocrystalline samples with different amounts of nanocrystalline grains was performed in temperature range from 50 K up to 400 K. In addition, DC hysteresis loops were also taken with the help of a VersaLab system (Quantum Design). Room tempertaure AC soft magnetic properties versus frequency and maximum induction were studied for toroidal samples by a hysteresisgraph (AMH-50K-S, Laboratorio ElletroFisico Engineering) at frequency up to 20 kHz. The Steinmetz coefficients for the amorphous and nanocrystaline alloys were calculated in the frequency range 50 Hz - 20 kHz. Mechanical characterization of investigated materials was performed by nanoindentation tests with respect to Oliver-Pharr method for maximum load of 250 mN. Sample of the Fe76Mo8Cu1B15 alloy in the as-quenched state was fully amorphous, which was confirmed by a broad halo in X-ray diffraction pattern and absence of visible precipitates on AFM/LFM images recorded in contact mode. The peaks present in X-ray diffraction pattern confirm two-phase behaviour of annealed material. It was also seen in measurements of microhardnesas for different regions in samples. The average values of hardness obtained for the amorphous matrix and nanocrystalline bcc grains are equal to 1221 HV and 1600 HV, respectively. The magnetic behavior described by DC hysteresis loops for the Fe76Mo8Cu1B15 alloy in the as-quenched state and after annealing at 837 K for 30 min. measured in the temperature range 200-400 K presented in Fig. 1 show a completely different behavior. The Curie temperature of the amorphous alloy equals 313 K, whereas for the annealed sample the higher value of the Curie point due to the nanocrystalline α-Fe phase was observed. For designing process and simulation of inductive elements (e.g. transformers, chokes) the AC magnetic characteristics are very important. Fig. 2 shows core losses as a function of maximum induction for the Fe76Mo8Cu1B15 alloy. It is seen that nanocrystalline material with low core losses in wide range of frequency and Curie point above 400 K (Fig. 1) is excellent candidate for high temperature and frequency soft magnetic material. Moreover, the Steinmetz coefficients K and α [6] calculated for the nanocrystalline Fe76Mo8Cu1B15 alloy increase from 0.0381 to 0.5840 and from 1.71 to 2.42, respectively for with frequency range 500 Hz - 20 kHz.

I. Introduction As key electrical devices, large reactors and converter transformers play an important role in the operation of ultra high voltage direct current (UHVDC) transmission [1]. Meanwhile, the existence of rich harmonics in the exciting current or driving voltage leads to distorted flux densities in the saturated iron core. Consequently the magnetic force due to the leakage flux not only exhibits special spectrum in the frequency domain but also threatens the normal operation of electrical devices e.g. vibration and deformation of windings [2-3]. Therefore it is important to investigate the influence of magnetic force on iron core and windings when electrical devices such as reactors work under harmonic magnetizations. The time-stepping method starting from arbitrary initial value is usually used for the computation of time-periodic nonlinear problems. However, the main drawback is that many periods are required to be stepped through for steady state solution, especially when a much larger time constant exists in the nonlinear system to be analyzed. Numerical methods in time domain and frequency domain have been presented and developed to solve the steady state nonlinear magnetic field efficiently [4-5] by combining the fixed point technique with the finite element method. In this paper, the harmonic-balance system of equations is established first by approximating all time-periodic variables by complex series. Thereupon, decomposition of the system of equations is achieved according to diagonal dominant characteristic of the reluctivity matrix so that harmonic solutions can be decoupled and computed separately and in parallel. This method is used to compute the magnetic force in a gapped-core model under harmonic magnetizations based on the harmonic solutions of magnetic field. II.Decomposition Scheme in Frequency-Domain The two-dimensional nonlinear magnetic field can be formulated as follows by using the magnetic vector potential A, $\nabla\times v\nabla\times A+\sigma\partial A/\partial t=J$(1) where J is the impressed current density, σ and v are the conductivity and reluctivity, respectively. Owing to the time periodicity of the electromagnetic field under harmonic excitations, periodic variables such as current density J, magnetic vector potential A and reluctivity v can be represented by a summation of trigonometric function, $W(\mathrm{t})=\sum W_n e^{jn\omega t}$ (2) $W_f=[W_0,W_{-1},W_{-2},\ldots,W_{-Nh},W_{Nh}]$(3) where W can be replaced by J, A and v. N_h is the total number of harmonics truncated in computation and ω is the angular frequency. W_n is the n-th component in frequency domain. W_f is the spectrum of the periodic variable W. Actually the time-domain multiplication of magnetic vector potential A and reluctivity v in (1) is equivalent to the frequency-domain convolution of the two variables, therefore a new system of equations in the frequency domain can be obtained, as follows, by using the harmonic-balance theory, $M(\sigma,H)A_f+S(D)A_f=K_f$(4) where M is the mass matrix and S the stiffness matrix. H and D are, respectively, the harmonic matrix and the reluctivity matrix. K_f is related to spatial distribution of the impressed current density. A_f is the vector potential in frequency domain. The convolution product term including v_0, which is dc component of reluctivity, is often dominant, therefore the other terms can be assumed as locally constant and moved to the right-hand side. Consequently, a new decomposed harmonic-balance system of equations can be obtained to decouple harmonic solutions, $[\mathrm{j}n\omega M(\sigma)+\mathrm{S}(v_0)]A_{f,n}=F_{f,n}+K_{f,n}$(5) where $A_{f,m}$ and $J_{f,n}$ are the m-th harmonic solution of magnetic vector potential and n-th harmonic vector of impressed current density. $F_{f,n}$ is obtained from the convolution product of reluctivity and vector potential in harmonic domain. The decomposed system of equations can be solved separately and in parallel. Meanwhile only N_h+1 equations in (5) are required to be solved due to the conjugate symmetry of the harmonic solutions. III.Gapped Iron Core and Experiment A gapped-core reactor model made of grain-oriented silicon steel sheet (B30P105) produced by Baosteel is used in experiment for comparison of magnetic forces when the model is magnetized by sinusoidal and harmonic excitation. Fig.1 shows the gapped laminated core and the experimental setup. IV. Computation and Results A gapped-core reactor model is used for the computation of the nonlinear magnetic field and the corresponding magnetic nodal force [6]. A sinusoidal exciting current of 50 Hz is applied to make the model operate in nonlinear region. Variations of reluctivity in nonlinear iteration are shown in Fig. 1. One node on the interface between the iron core and the air gap is selected to compare the calculated magnetic nodal forces (F_y) by the proposed method in this paper and the time-stepping method in MagNet, Infolytica, which is shown in Fig. 2. V.Conclusion An efficient frequency-domain decomposition method is presented to analyze the magnetic force resulted from harmonic magnetizations. Comparison of computed magnetic nodal forces by the proposed method and the time-stepping method shows good consistency, which proves the accuracy of the decomposition method in the frequency domain. FP-03. Investigation into the Effect of Yoke Pressed Structure on Electromagnetic Performance of Transformer.

X. Yan[1], Z. Peng[2], Y. Kang[3], X. Yu[4], Z. Ren[1] and Y. Zhang[1]

1. Shenyang University of Technology, Shenyang, China; 2. Shaoyang University, Shaoyang, China; 3. TEBA Shenyang Transformer Group Co. Ltd., Shenyang, China; 4. Shandong Power Equipment Co. Ltd., Jinan, China

I. Introduction With the increment of transformer capacity, the physical dimension of transformer will be larger and larger. With consideration of transportation limitation, to ensure the transformer capacity, it is feasible to reduce transformer size in large capacity transformer design[1][2]. The yoke-pressed transformer is a kind of special structure, in which widths of widest steel sheets of iron yoke are pressed for height reduction of the transformer. Consequently, the smallest steel sheets are enlarged to keep a constant core cross-section area. The structure variation of transformer core definitely results in variation of electromagnetic performance of transformer. However, the manufacturers still design this type of transformer according to conventional structure. Moreover, it is hard to find researches on electromagnetic performance analysis of transformer resulted from yoke pressed structure. In this paper, four different yoke structures representing different pressing level have been constructed. The corresponding electromagnetic performances have been investigated and discussed through numerical experiments. II. Yoke structures with different pressing levels To research the change of magnetic field distribution in the transformer core in different yoke pressed level, four different yoke structures have been built as shown in Fig.1. Model 1: Normal iron core transformer (no yoke pressed) Model 2: DSP-241000 kVA /500kV transformer product with pressed yoke Model 3: Transformer with yoke further pressed based on model 2 Model 4: Transformer with yoke completely pressed to rectangle Due to symmetry, half transformer configuration has been constructed for finite element analysis for all models. Besides different yoke structures, the configuration and parameters of four transformer models are same. The data of yoke for four models are shown in Table.1. The pressing rate is calculated by dividing the width difference by the width of the widest steel sheet of model 1, in which the width difference is the difference between the width of the widest steel sheet of model 1 and that of other model. III. Electromagnetic performance analysis For the above model transformers, the primary windings are excited with the same rating voltage while the secondary windings are open-circuit. With the field-circuit coupled FEM, the magnetic field in the iron core and excitation current can be obtained. The magnetic circuit of yoke pressed transformer is built to analyze the change of magnetic field in different yoke structures. From Fig.2, it can be seen that even with a same cross-section area and same yoke length for four models, the magnetic field distribution in the iron core have been changed in different level with different pressing rate. The magnetic field distribution in the iron core is not uniform any more once the yoke structure has been reconstructed. The changes in core column and yoke section are opposite, and the changes in the widest and the smallest steel sheets regions are different for core column and yoke. With the enhancing of yoke pressed level, the flux density in the widest sheets region of yoke is increased, while the flux density is decreased in the smallest sheets region of yoke. For the core column, the changes of flux density in corresponding regions are opposite to yoke. The flux density in different regions of four models are shown in Table.2. Furthermore, the magnitude of excitation current is getting bigger and bigger, while the distortion of current waveform becomes worse with the increment of pressing rate. Detailed analysis will be presented in extended paper. IV. Conclusion For the transformer with pressed yoke structure, the widths of steel sheets in different regions of yoke have been modified to keep the cross section area constant in manufacturing process. Generally, it should be no effect on magnetic flux due to same area and length for the magnetic circuit. However, the flux distribution in iron core is not uniform any more once the yoke structure has been reconstructed. The magnetic field distribution in different regions should be researched systematically.

FP-04. A Switched-capacitorless Energy-encrypted Transmitter for Roadway-charging Electric Vehicles.

W. Liu[1], K. Chau[1], C. Lee[2], C. Jiang[1] and W. Han[1]
1. The University of Hong Kong, Hong Kong, Hong Kong; 2. Massachusetts Institute of Technology, Boston, MA, United States

I. INTRODUCTION Due to cleanliness, convenience and high efficiency, wireless power transfer (WPT) technology has been extensively and deeply investigated. In recent years, energy encryption has drawn researchers' attention to satisfy practical requirements of security and reliability in the theme of intelligent transportation and smart city. Especially for roadway-charging electric vehicles (EVs), the use of energy encryption can guarantee the transmitted energy being effectively harvested by the authorized receptors instead of being secretly stolen by the unauthorized ones. Recently, a chaotic encryption strategy based on switched capacitor arrays has been proposed to realize energy security in WPT systems [1, 2]. However, because of the need of discretely adjusting the resonant capacitance and hence the operating frequency, this encryption scheme suffers from the drawbacks of limited energy-transferred channels, high voltage stress across switches and relatively low flexibility. In addition, a generic encryption model based on certificate-less cryptography has been developed to improve the energy security performance for WPT systems [3], but its computational complexity and time involved seriously restrain from dynamically encrypting the operating frequency. Meanwhile, a traditional series-to-series (SS) topology with fixed values of resonant inductance and capacitance has been identified to exhibit a selective characteristic for multiple loads when operating at the selected receptor's resonant frequency [4]. This mechanism can be newly extended to derive an energy-encrypted transmitter without using a switched-capacitor array for multiple energy receptors such as roadway-charging EVs. Consequently, in this paper, a switched-capacitorless energy-encrypted transmitter is proposed for roadway-charging EVs. Moreover, a two-dimension chaotic frequency-and-duration encryption (FDE) algorithm is proposed to improve the security performance while maintaining relatively high efficiency. II.METHODOLOGY The proposed FDE-WPT system without using a switched-capacitor array in the transmitter is shown in Fig. 1(a). The switched-capacitorless transmitter is firstly introduced to the energy-encrypted WPT system, which can offer the definite merit of continuously and flexibly regulating the operating frequency. When the receptors in the *m*-th channel are authorized, no matter the transmitter operates at resonance or not, the corresponding efficiency can be derived out. It indicates that the primary coil inductance and the matched resonant capacitance have no influence on its operating efficiency. Although the primary coil internal resistance leads to extra power loss, because of the enhanced mutual inductance by the ferromagnetic spokes as shown in Fig. 1(b), the power loss in the primary coil can be effectively suppressed and even insignificant. Thus, the proposed system takes the advantage of lower transmitter's power loss over the energy-encrypted SS WPT system with switched-capacitor arrays. Data interaction based on wireless communication facilitates the encryption and decision-making unit to achieve maximum efficiency band trace (MEBT), which provides a secure frequency band to ensure relatively high efficiency in the authorized receptor. Then, a two-dimension chaotic encryption technique is adopted to generate the encrypted frequency and its active duration sequences, namely, the security key. Furthermore, hysteresis control and high-frequency pulse modulation (HFPM) are employed to realize pulse density modulation (PDM). The output voltages of both the authorized and unauthorized receptors and the two-dimension FDE security key are shown in Fig. 2(a). Only the authorized receptor with knowledge of the security key can readily decrypt the encrypted energy, while, due to the lack of security key, the unauthorized ones fail to pick up any energy. Hence, it confirms that the proposed FDE and switched-capacitorless transmitter can effectively enforce the energy security. Additionally, the efficiency and output power versus the operating frequency are plotted in Fig. 2(b). Although the efficiency will decrease when the operating frequency is adjacent to the unauthorized receptors' resonant frequency, the proposed MEBT and FDE can dynamically generate a new sequence of secure energy-transferred channels to guarantee high-efficiency operation, always higher than 90.75%. Finally, an experimental prototype has been constructed and tested to further verify the feasibility of the proposed FDE-WPT system. More experimental results will be given in the full paper. II.CONCLUSION A switched-capacitorless energy-encrypted transmitter, incorporated with two-dimension FDE technology, has been proposed and implemented for roadway-charging EVs. To prevent the energy from being illegally harvested by the unauthorized receptors, the proposed two-dimension chaotic FDE technology generates a well-defended key to improve the security performance while retaining high efficiency. Theoretical analysis, numerical simulation and experimental results will be given to verify the feasibility of the proposed FDE-WPT system. FP-05. Reduction of an Eddy Current Losses in Metallic Support of an Underground Power Cable.

H. Song[1], S. IM[1] and G. Park[1]
1. Department of Electrical and Computer Engineering, Pusan National University, Busan, The Republic of Korea

1. Introduction Underground power cable was adopted for the enhancement of the aesthetic the city, the convenience of the citizens and the development of urbanization. To operate this power cable, a metallic supporting of the power cable is necessary. The metallic supporting structure of the power cable was installed at 1.5 m intervals. This structure supports a three-phase AC power cable running 24 hours a day. This metallic supporting structure of the power cable can be classified into angle, hanger, and cleat. Especially, Cleat is the closest to the power cable and the material of the cleat has both conductivity and permeability. [1]. it has conductivity and generates eddy current. The eddy current loss continues to the thermal loss and may cause metal structure damage [2][3]. In addition, it should be predictable because it can cause heat generation. However, there is not enough research on structure metallic supporting of power cable. This paper analyzes the distribution of eddy currents in power cable supporting structure, and estimate the loss through distribution. Also, a method for reducing the eddy current generated in the metallic structure of the power cable is proposed. The method proposed in this paper is not a method to block the eddy current path, which is a conventional eddy current reduction method. This paper proposes a method to reduce the eddy current by reducing the magnetic field which causes eddy currents. This is applied to the metallic supporting of power cable, and the simulation shows how to reduce the eddy current. 2. Eddy current loss distribution The analytical conditions for the structures supporting underground power cables are the same as the actual operating conditions. Since 3-phase AC is used, it was analyzed at 1.157A, 60Hz. Among the structures, especially the cleats with conductivity and permeability, the material contains Al and has a conductivity of 2.06 and a permeability of 1000. There are two major types of arrays: triangular arrays and horizontal arrays. In Figure 1 (a), It is an array of underground power cable which is operated. but in this paper, the triangular array is analyzed. the triangular array is modeled in three dimensions. In (b), the mesh of the Cleat portion is shown in all models. the loss of the eddy current will mainly deal with the occurrence in Cleat. Eddy current distribution occurs at the cleat portion supporting of power cable. while the three-phase ac current flows. The value of the eddy current increases near the cable where a large amount of current flows. In this part, the loss of the eddy current is remarkably generated in the inside and outside. The reddest point of the cleat is the largest part of the eddy current and its value is 0.41 A/mm2. 3. Reduction of eddy current loss There are two main types of eddy current reduction. First, cut off the path of the eddy current. The eddy current can be reduced by blocking the path of the eddy current. By blocking the direction in which the eddy current flows, it is possible to reduce the eddy current by dispersing the direction in which the eddy current flows in two directions. Second, reduce the size of the magnetic field. The current generates a magnetic field, the magnetic field generates an induced electromotive force, and the induced electromotive force generates an eddy current. At this time, if the magnitude of the magnetic field generated by the current is reduced, the magnitude of the eddy current eventually generated is also reduced. Considering the method of reducing the eddy currents flowing in the cleat in the triangular array, it was predicted that the eddy current loss would be reduced by blocking the path of the largest eddy current. Figure 2 (a) shows the eddy current distribution of the cleat. The eddy current distribution of the cleats was larger than the inside of the cleats, and the patterns of eddy currents occurred inside and outside the cleats, respectively. In Fig. 2 (b), full-slit is applied to the side where the eddy current distribution is large, and the eddy current path is blocked. Comparing Fig. 2 (a) and (b), eddy current distribution is noticeably reduced. However, one side of Cleat was cut out of one structure, so mechanical strength was not considered sufficiently. 4. Comparison of iron loss The distribution of eddy currents in the cleat, which is a metallic structure supporting underground power cable, is analyzed. In addition, a reduction scheme was proposed to reduce the eddy currents generated in the cleats. When the maximum value of the eddy current was compared, about 59.5% eddy current loss was reduced. 5. Conclusion Eddy currents occur because of the conductivity and permeability of metal structures that support 24-hour cables. To prevent such accidents, the eddy currents flowing through the metal structure must be cut off. It is possible to reduce the eddy current by blocking the eddy current path which is a method of blocking the eddy current. There are many ways to cut off the eddy current path, but it is necessary to adopt a method considering mechanical strength and balance among them.

FP-06. Calculation of AC Resistance in a Multi-strand Coil Considering Proximity Effect with Eddy Current Induced Magnetic Fields.

D. Um[1] and G. Park[1]
1. School of Electrical and Computer Engineering, Pusan National University, Busan, The Republic of Korea

I. Introduction Recently, the interest in high-frequency applications such as wireless power transfer(WPT), induction heaters, high speed motors and high-frequency transformers is increasing. At these high frequency systems, the large amount of losses due to the eddy currents occurs, leading to an increase in the equivalent resistance. To prevent this adverse effect, multi-strand coils are used. Moreover, it is important to calculate the exact resistance of multi-strand coils. Therefore, the understanding of effects by the eddy currents should be necessarily conducted. The conventional methods to calculate ac resistance are studied by Dowell, Ferreira and many other authors [1]-[2]. The Dowell's method calculated the resistance by setting the foil conductor equivalent to the high aspect ratio windings [3]. In this method, the exact solution can be calculated when the conductors are closely packed. However, this method increases the error when the aspect ratio is not really high and the coil distance is far apart. Some papers clarify the weakness and limitations of the Dowell's method [4]. The Ferreira's method can be solved by Maxwell's equation in the cylindrical coordinates [5]. The exact solution of round conductors can be provided. Some papers calculate the resistance of multi-strand coils using Ferreira's method [6]. However, this method considering only a single conductor makes error when the conductors are closely packed. In this paper, the Ferreira's method is used to derive a formula for the ac resistance of multi-strand coils. The results suggest a correction factor that describes mutual effects by analyzing analytical considerations on the losses by the eddy currents and using FEA. The final equation can be changed to a closed form formula that can be used by finding local minima for coil optimization. II. Eddy Current Analysis by Using Maxwell's Equation In general circular conductor, the Maxwell's equation in the cylindrical coordinates can be used to obtain the internal and external magnetic fields of the coil and the current density distribution inside the coil as shown in equation (1). $rot(rot\ \mathrm{H})+\mathrm{j}k^2\mathrm{H}=0,\ \mathrm{k}=(\omega\mu_0\sigma)^{1/2}$ (1) The solution of the skin effect can be obtained by solving above equation with the source current and no external magnetic field. The solution of the proximity effect can be represented by considering the external magnetic field [7]. The total loss in equation (2) can be calculated juts by adding these solutions due to the orthogonal relationship. $P=I^2k/(4\pi\sigma r_0)\Psi_1(kr_0)-2\pi k r_0 H^2/\sigma\Psi_2(kr_0)$ (2) where I is the source current, is the conductivity of a conductor, r_0 is a radius of the conductor, H is external magnetic fields, Ψ_1 and Ψ_2 are forms of kelvin function [8]. However, the distributed coil, not a single coil makes the results different. As shown in equation (3), it can be seen that external magnetic field is affected within the effective range due to the magnetic field induced by the eddy currents. $\mathrm{H}^*=\mathrm{H}_0(\mathrm{r}_0/\mathrm{r})^{1/2}\mathrm{J}_2(\mathrm{j}^{3/2}k\mathrm{r}_0)/\mathrm{J}_0(\mathrm{j}^{3/2}k\mathrm{r}_0)$ (3) The magnetic field induced by the eddy currents is represented by the function of distance from a conductor and normalized frequency, which is the ratio of the radius of a strand to conventional skin depth. On the surface of the conductor, the ratio of induced to applied magnetic fields can be only a function of normalized frequency, and it is assumed to reflection factor, F. With putting proper correction factors, the exact resistance calculation can be conducted. The details will be discussed in the next chapter. III. Calculate Correction Factor Using FEA As shown in Fig.1, the analysis of two independent alignments parallel to the magnetic field, and perpendicular to the magnetic field of coils is carried out by using FEA. The magnetic field generated by the eddy currents in parallel alignments shields the applied magnetic field evenly, not locally. In contrast, the magnetic field generated by the eddy currents in perpendicular alignments locally shields the applied magnetic field inside alignments and it leads to the difference of current density distribution among layers. In Fig.2, (a) shows simulation model for parallel alignments by setting boundary conditions. From FEA results, the correction factor of parallel alignments, X is defined as the ratio of losses considering mutual effects to losses of single conductor, shown in equation (4). $\mathrm{X}=1-p(\Delta/\mathrm{r}_0)F(\mathrm{r}_0/\delta)$ (4) where p is a function of the ratio of spacing, Δ to a radius of coils. The correction factor in the perpendicular direction can be obtained in the same method as we put correction factor, Y. Finally, two results are combined by setting weighting values, w in equation (5) and these will be covered in the full paper. $\Delta R_{prox}=(-w\mathrm{X}+(w-1)\mathrm{Y})2\pi k\mathrm{r}_0(H/I)^{1/2}/\sigma\Psi_2(k\mathrm{r}_0)$ (5) IV. Conclusion To find the coil resistance in an alternating magnetic field, the losses in the coil must be calculated accurately. The proximity effect with the conventional single conductor solution does not reflect the shielding effect among the coils, so that the results are overestimated. In this paper, the losses occurring among the coils are analyzed with respect to the magnetic field direction. Finally, two correction factors considering mutual effects are proposed and the results are reflected well by setting proper weight between these two factors.

FP-07. Copper Loss Reduction of Planar Transformer Using Magnetic Cap and Plate.

T. Yamamoto[1], Y. Bu[1] and T. Mizuno[1]
1. Shinshu university, Nagano, Japan

INTRODUCTION A switched mode power supply is used to provide stable DC power to the electrical apparatus. The DC-DC converter in the power supply should have high efficiency and power density. To reduce the size of this converter, it is necessary to increase the switching frequency. However, the power losses in such a converter are observed to increase to an increase in the switching frequency. The losses that are observed in the converters are attributed to the transformer and circuit losses. It is observed that reducing the switching loss of the circuits requires soft switching using SiC and GaN power semiconductors, because SiC and GaN exhibit a considerably lower electrical loss than that exhibited by conventional Si. Moreover, it is necessary to reduce the copper and iron losses to improve the efficiency of the transformers [1]–[3]. The planar transformer uses a rectangular wire as the winding wire for its coil. This type of transformer exhibits a small volume because the space factor of the coil is observed to be high. To reduce the copper loss in a planar transformer, we suggest the production of a transformer based on a novel structure that uses a magnetic cap and plate. This structure can reduce the AC resistance that is caused by the skin and proximity effects. In this study, we additionally investigate an LLC resonant converter using a planar transformer having a magnetic cap and plate. STRUCTURE OF PLANAR TRANSFORMER WITH MAGNETIC CAP AND PLATE Figure 1 shows the structure of a planar transformer with a magnetic cap and plate. This transformer is used in an LLC resonant converter. The magnetic cap cover both the side surfaces of the coil in the core, and the magnetic plate is sandwiched between the primary and secondary side coils. The magnetic cap and plate can reduce the copper loss due to the skin and proximity effects, because these components can reduce the magnetic flux that pass an end of the winding wire. The thicknesses of the magnetic cap and plate were evaluated using finite element method analysis. Magnetic cap and plate is the silicon sheet which is mixed amorphous alloy powder. The mean diameter of the amorphous powder grains is 2.56 μm. The core shape of transformer is EERS, and the core material is metal composite core [4]. IMPEDANCE CHARACTERISTICS OF PLANAR TRANSFORMER WITH MAGNETIC CAP AND PLATE Figure 2 shows the resistance vs. frequency characteristics of the primary side coil when the secondary side coil is short-circuited. The impedance characteristics that are exhibited by a planar transformer for an LLC resonant converter were evaluated using an impedance analyzer (Agilent, 4294A). Further, when the secondary side coil was short-circuited, we measured the resistance to simulate the operating conditions of an LLC converter. When the S1 coil was short-circuited at a frequency of 5 MHz, the resistance of the primary coil was observed to be 177.1 and 189.7 mΩ for a structure with and without a magnetic cap and plate, respectively. Thus, the resistance of a structure with a magnetic cap and plate was observed to be lower that of a structure without a magnetic cap and plate by 6.6%. Further, when the S2 coil was short-circuited, the resistance of the primary coil was observed to be 189.4 and 218.9 mΩ for a structure with and without a magnetic cap and plate, respectively. Thus, the resistance of a structure with a magnetic cap and plate was observed to be lower than that of the structure without a magnetic cap and plate by 13.4%. This reason was the reduction of the resistance due to the skin effect and proximity effect when magnetic cap and plate was applied. LLC RESONANT CONVERTER USING PLANAR TRANSFORMER WITH MAGNETIC CAP AND PLATE The primary side of the LLC resonant converter was the inverter of a half bridge. We used a GaN FET as the switching FET. The secondary side was connected to a rectification circuit. Further, we measured the efficiencies of the input and output powers of the LLC resonant converter. The switching frequency of the converter is 5 MHz. At an output power of 50 W, the efficiencies of the converter were observed to be 82.5% and 81.7%, respectively, while using a planar transformer with and without a magnetic cap and plate. Thus, the efficiency was improved by 0.8% by using magnetic cap and plate. This was attributed to the reduction of resistance owing to the proximity effect when magnetic cap and plate was applied. CONCLUSIONS We investigated an LLC resonant converter using a planar transformer that contained a magnetic cap and plate. At a frequency of 5 MHz, application of a magnetic cap and plate reduced the resistance of a planar transformer by up to 13.4%. Furthermore, in the LLC converter with the output power of 50 W, efficiency was improved by 0.8% by applying the magnetic cap and plate. This was attributed to the reduced resistance owing to the skin and proximity effects when a magnetic cap and plate were incorporated into the structure. From the aforementioned results, it can be inferred that incorporating a magnetic cap and plate into the structure were useful to improve the efficiency of the MHz driving converter that uses a planar transformer. For future studies, we intend to investigate the improvement in efficiency of the MHz driving converter that uses a planar transformer, which is incorporated with a magnetic cap and plate.

FP-08. Determination Approach for the Parameters of Equivalent Circuit Model of Deep Saturated Three-phase Integrative Transformers.

Y. Wang[1], Y. Shangguan[1] and J. Yuan[1]
1. Dept. of Electrical Engineering, Tsinghua University, Beijing, China

Abstract Based on the analysis of the defects of the traditional methods for determining the equivalent circuit parameters of three-phase integrated transformers by single-phase excitation, an expression method of equivalent circuit parameters and their determination approach based on three-phase simultaneous excitation are presented in this paper. The parameters are expressed in terms of the excitation source phase, and the value of parameters is determined by calculating the reluctance of core segments based on the FEM simulations. Then the electric circuit parameters are obtained by converting the magnetic circuit into the electric circuit. This kind of electric circuit model is suitable for analyzing the problems of deep saturation of transformers and the concerning power grid problems. 1. Introduction Each circuit element in the equivalent circuit derived from the magnetic circuit has a definite physical meaning, but the circuit model has a complicated topology and a large number of elements. How to determine the parameters is the difficulty for all researchers [1]. The former scholars only applied the excitation in single phase and used the information of the port measurement to determine the circuit parameters [2]. It is suitable for analyzing the steady state operation of the transformer, but is not suitable to analyze the deep saturation state. The single-phase excitation method did not fully consider the coupling between phases, and it cannot accurately describe the nonlinear parameters. The purpose of this paper is to study the equivalent circuit of saturated transformers based on three-phase simultaneous excitations. 2. Defects in the method of determining parameters by single-phase excitation When the transformer works at a linear state, the influence between the three phases can be neglected [3]. However, when the iron core is deeply saturated, the phase-to-phase coupling becomes significant due to the severe nonlinearity of the core material. Moreover, the saturation degree of the iron core varies greatly at different phase points of three-phase sinusoidal excitation. So it can be predicted that the equivalent circuit parameters of the transformer will vary with the phase of excitation source. The calculated parameters based on single-phase excitation cannot reflect these characteristics. 3. The expression method and determination approach of parameters based on three-phase simultaneous excitation The non-linear inductance parameters are expressed in terms of the excitation source phase. It means that the circuit model will have a set of parameters for each phase of the sinusoidal excitation. The value of parameters is determined by calculating the reluctance of core segments based on the numerical simulations [4]. This kind of determination approach is not limited by the number of parameters, and the equivalent circuit topology can be modeled more complete, as shown in Figure 1. Numerical simulations based on three-phase simultaneous excitations are carried out by using the coupled circuit-FEM method. Symmetrical three-phase voltage excitations are applied to the three windings, and the phase α of the central phase is taken as a control parameter. By observing the electromagnetic field distribution at each phase, we can determine the values of the inductance at this phase. Then, by changing the amplitude of the excitation voltage for each phase, we will obtain a series of inductances and finally the phase-dependent nonlinear inductances can be obtained. 4. Parameter calculation examples and the difference between single-phase and three-phase excitation A 50MVA three-phase transformer is taken as an example to analyze the phase-dependent nonlinear inductances. By increasing the amplitude of the sinusoidal voltage excitation at the transformer winding port, the saturation of the transformer core is gradually aggravated. Table 1 compares the inductance of the central leg determined by single-phase and three-phase excitations when the phase α of the central phase is equal to $\pi/6$. When the excitation voltage is 31.25kV, the flux density in the central leg is about 1.8T and the core is not yet deeply saturated, the difference of the inductance value between the three-phase and the single-phase excitation is very small, it is about 1%. However, as the core is saturated more and more seriously, the difference increases. When the excitation voltage is 62.5kV, the flux density is about 3.26T, and the difference increases to about 12%. Taking into account the closing process and the influence of remanence, the flux density in the transformer core may reach nearly 2.5 times the rated one, and the error caused by single-phase excitation cannot be ignored. In addition, the errors of all the parameters of the equivalent circuit will accumulate, which makes the circuit parameters obtained by single-phase excitation more unreliable. 5. Conclusion The error of equivalent circuit parameters determined by single-phase excitation cannot be ignored when the core operates at deep saturation state. Three-phase simultaneous excitation is required to determine the equivalent circuit parameters. The duality derived complicated equivalent circuit model with phase-dependent nonlinear parameters is more suitable to analyze the deep saturation state of the transformer.

FP-09. Research on Split-Core Reactor Vibration Reduction Method Based on Magnetostrictive Effect.

L. Zhu[1], R. Sha[1], X. Zhang[1], B. Wang[1] and T. Han[1]
1. Key Laboratory of Advanced Electrical En, Tianjin Polytechnic University, Tianjin, China

I. INTRODUCTION The reactor is an important power equipment in the transmission and transmission system, which plays many different roles in the power system. As a typical reactor structure, the split-core reactor can reduce the residual magnetism and effectively control the inductance. In recent years, it has developed rapidly and has been widely used. The vibration noise generated by the power equipment in operation not only affects its normal operation and service life, but also produces audible noise and other environmental problems [1]. How to reduce its vibration noise effectively has become an urgent problem for manufacturers and power departments. Accurate measurement of magnetization and magnetostrictive properties of silicon steel is the basis for the study of reactor noise and vibration. Lieven Vandevelde, a Belgian scholar, puts forward the method of calculating the deformation of an object due to maxwell and magnetostrictive force by means of finite element analysis [2]. GaoYanhui, Japan, Kazyhiro Muramatsu USES the relationship between the node displacement, the magnetostrictive stress of the node and the distance between the node and the center point to calculate the vibration displacement of the iron core of the reactor [3]. In the literature [4], the British scholar Annable Shahaj proposed using magnetic twin chips to control the magnetostriction on the stator teeth of the motor, and the magnetostrictive force components were offset by the magnetostrictive force. Manufacturers often compression core column and base structure, such as the increase of rubber vibration isolator between ontology and body and improve the air gap materials and other methods of reducing the electromagnetic vibration in the reactor from the vibration mechanism of reactor vibration noise research is less. Calculating the magnitude and distribution of electromagnetic vibrations is necessary for designing reactors with lower vibration noise. Based on the measurement results of the magnetization and magnetostrictive properties of orientation silicon steel and non-oriented silicon steel, the model of three-dimensional split-core reactor is established. Based on the inherent magnetostrictive properties of oriented and non-oriented silicon steel sheets, a new type of iron core with alternating core-column structure consisting of oriented silicon steel sheet and non-oriented silicon steel sheet was proposed. Numerical calculation of magnetic field, stress field and vibration displacement of reactor under ordinary structure and new structure, the results show that the method has a certain damping effect. II. EXPERIMENT MEASUREMENT As shown in Fig.1(a), the magnetostrictive measuring device MST500, which is produced by German BROCKHAUS, is used to measure the magnetostriction characteristics of the non-oriented and oriented silicon steel sheet. Fig.1(b) shows the butterfly curves along the rolling direction of a set of 50WW470 non-oriented silicon steel and 30JG130 oriented silicon steel in Fig.1(c) measured at different peak magnetic flux densities. With the increase of magnetic flux density, the area of the magnetostrictive return ring increases, and each ring is symmetric around the origin. The elongation of the samples corresponds to the magnetostriction of the positive value, while the negative magnetostriction means that the sample has undergone a contraction deformation. In short, the “wing” quadrant of the butterfly curve shows the scaling changes of the samples [5]. It can be clearly seen that the non-oriented silicon steel sheet 50WW470 magnetostrictive curve is mainly manifested as the elongation deformation of the silicon steel sheet, and the orientation of the silicon steel sheet 30JG130 magnetostrictive curve is mainly shown as the contraction deformation. III. SIMULATION ANALYSIS When the reactor is running normally, there is a alternating electromagnetic field in the magnetic circuit formed by the core. The differential equations of magnetic field in the core of the reactor can be written as: $B=\mu_0^{-1}\mu_r^{-1}H=\nabla\times A$(1) The mathematical model of magnetostriction is usually described by linear pressure magnetic equations. The elastic deformation of the material and the magnetic strain equation caused by the external magnetic field can be written: $\varepsilon=\sigma/E_y^{H}+dH$ (2) $B=d\sigma+\mu^{\sigma}H$ (3) A single-phase 220V split-core reactor is chosen as the research object. The simulation model of the split-core reactor is shown in Fig.2(a). In analysis and calculation of deformation caused by magnetostriction of split-core reactor, need the magnetostriction model combined with finite element calculation, calculation to simulate reactor actual place state, to fix the bottom of the physical model as constraints. As shown in Fig.2, Simulation of the split-core reactor core structure vibration test point displacement change, under transient conditions, compared with the ordinary reactor structure, the vibration displacement of the split-core reactor test points in the new structure is significantly reduced.

1. Nanjing University of Aeronautics and Astronautics, Nanjing, China

Abstract — This paper considers the core nonlinear material, the weak magnetic effect of core eddy current and the diamagnetic effect of non-measured coil load operation under the condition of high-frequency transformer. A magnetic field model suitable for the calculation of inductance parameters in high-frequency applications such as transformer lightning shock wave process analysis and frequency response analysis is proposed. The influence of the magnetic conductivity of the core on the high-frequency inductance parameters is analyzed under the load condition. The parameters of a three-split transformer were measured and compared with the calculated results to verify the validity of the proposed model. 1.Introduction Power transformers include core, winding and insulating materials. The high frequency characteristic model can be represented by the equivalent circuit of resistance, capacitance, self-inductance and mutual inductance. The transformer winding have their own electrical and magnetic properties for each turn of the winding, line or segment such as loss, inductance and capacitance..The high frequency equivalence model of transformer can be obtained by grouping the basic unit of transformer. For the actual analysis of the issue, the establishment of high-frequency transformer equivalent model is accurate mainly depends on two aspects. Firstly, the calculation of total parameters in the basic unit is accurate:the total parameters include inductance, mutual inductance, capacitance, resistance and so on. The calculation method of capacitance and resistance is mature, but the calculation of inductance and mutual inductance is the most tedious and difficult to calculate accurately. This is mainly due to the non-test coil is short-circuit and other constraints, the physical definition of inductance and mutual inductance is not clear, resulting in a variety of inductance calculation method. Unfortunately, these calculations are not uniform in the inductance calculation. Secondly, the equivalent of the core flux characteristics is reasonable:the equivalent model does not directly reflect the core, but the core permeability nonlinear and frequency-dependent characteristics will affect the internal magnetic field distribution transformer, and makes the equivalent inductance and mutual inductance calculation results in the model are affected. Research now seen in more than 10 kHz frequency can ignore the core permeability. Based on this assumption, the calculation of inductance and mutual inductance is simplified, but at the same time, the frequency response of the equivalent model is not continuous. That is, the model based on characteristics of magnetic conductivity will not be suitable for medium and low frequency operation. In order to study the core nonlinear material and the weak magnetic effect of core eddy current from the mechanism, this paper analyzed the law of the relative permeability of the silicon steel sheet under different frequencies based on the core non-linear eddy current magnetic field model. Based on this, the coupling analysis model of the high-frequency inductance in the load condition is proposed. The inductance and mutual inductance of the unit under different operating frequencies are calculated. The experimental results verify the effectiveness of the proposed model. 2.Analysis model of nonlinear and frequency-dependent characteristics of core Analysis of core equivalent permeability with frequency is shown in Fig.1(a). Select 30Q120 silicon steel sheet and analyze the corresponding variation of relative permeability of silicon steel plate at different frequencies by calculating the nonlinear vortex field of the core (shown in Fig.1(b)). It can be seen that when the relative permeability is above 500 kHz, the magnitude is small, and the corresponding magnetic characteristics of different magnetic working points in high frequency are different. The study also revealed that the inductance of coil inductance affected by magnetic conductivity is associated with both the excitation frequency and the magnitude of the excitation. 3. Calculation model of the inductance of the load conditions Fig.2 shows the magnetic field - circuit coupling analysis model of high frequency inductance calculation under load conditions. Based on the frequency-dependent curves of the magnetic permeability of the core material calculated above, by changing the relative permeability of the core to equalize the frequency of the magnetic field, then the self-inductance and mutual inductance of each coil unit under different frequencies are obtained. Conventional finite element method for computing the inductance Parameter in transformers cannot take into account the diamagnetic effect of non-measured coil load operation. To address this issue, a novel field-circuit coupled calculation method is proposed, in which the electromagnetic field based on the coupled A-Emf formulation and circuit equations are solved simultaneously. The formulation for the new method is derived in detail and the *U*r-*f* curve of the iron core materials are included to consider the effect of iron core frequency dependent. 4.Analysis of the calculation results This paper selects a 2500kVA three-split transformer as an example, and the calculation results of the unit self-inductance and mutual inductance corresponding to different frequencies are analyzed. The detailed calculation method and the influence factors will be seen in the full paper.

I. INTRODUCTION Transformer is one of the most essential equipment in the electric systems, which plays the role of electromagnetic energy conversion and transmission. Statistically, winding deformation produced by huge and dynamical electromagnetic forces under short-circuit fault is one of the most serious problem which may make the transformer fault. In practice, the transformer is like to be a black-box. It is very hard to diagnose the winding deformation accurately by using the present approaches [1], such as the Correlation Coefficient Method (CCM). During the frequency response analysis (FRA) studies, the equivalent circuit model of transformer is usually used to solve the forward problem [2], as shown in Fig.1, but how to determine the increments of equivalent electromagnetic parameters, such as the inductance, capacitance and resistance, is an important inverse problem. The diagnosis of winding deformation for transformer is a typical inverse problem. This paper proposes a novel method for diagnosing winding deformation in transformer more accurately and intuitively, based on Equivalent Circuit Model Updating (ECMU) at a high-frequency range (10Hz ~10MHz). In fact, the ECMUM is an inverse method to determine the electromagnetic parameters states under FRA excitation. It is a challenge to find a unique and accurate solution during inverse updating operation. In our study, thanks to the ECMU and frequency selection, the certainty and qualitative relationship between FRA error data and electromagnetic parameter increments of transformer equivalent circuit model can be determined easily. Also, the maximum approximate unique solution can be obtained exactly. II. Derivation of Inverse Updating equations Similar to the vibrating equations in structural dynamic system [3], the dynamic governing equations in the circuit system can be given as: (1) where, *L*, *R* and *C* are the parameter matrixes of inductance, resistance and capacitance. Under harmonic excitation $u(t)$, the dynamic stiffness matrix of circuit system in frequency domain can be obtained as:(2) where, ω and *j* are the frequency in rad/s and imaginary unit, respectively. In this study, absolute sensitivity of FRF with respect to the *i*th parameter Φ is used and defined as: (3) where, $H(\omega)$ is the frequency response function (FRF). After calculating all the sensitivity at each frequency, the sensitivity matrix can be constructed. Finally, the model updating equation can be obtained as: (4) Here, *S* is the sensitivity matrix; ΔΦ is the updating parameter vector, and ε is the output residual vector. Then, the updating problem in (4) can be solved by [3]: (5) The updated parameters are can be determined iteratively by solving (5), until the residual, ε, becomes sufficiently small. III. Verification and Results Fig. 2 shows the model updating results of FRF error after two iterations. Table I presents the comparison results between the 1st and 2nd updating (*DP* is the updating precision). It can be seen that the updating algorithm has a high efficiency. Also, the parameter increments determined by solving model updated equations iteratively can qualitatively reflect the frequency response errors which are produced by winding faults. According to the parameter increments, we can estimate the transformer winding deformations much more intuitively and accurately. Besides, it is found that the updating precision can be improved by iteratively updating, where the residual of FRF may become sufficiently small.

1 INTRODUCTION The safety of power transformer was seriously impacted by the short-circuit current with the level of power load continuing to rise [1]. Accordingly, the fault current levels may exceed the rated breaking capacities of existing circuit breakers, which will impose a heavy burden on the transformer, even cause unstable operation of the power system [2]. Therefore, it is significant to take effective measures for the purpose of limiting short-circuit current to a reasonable and low level. At present, high-impedance transformer and current-limiting device are most common methods of limiting short-circuit current[3]. However, high leakage reactance of high-impedance transformer will cause the energy loss, volume increase and bus voltage fluctuation under normal circumstances. In addition, the large amount of maintenance and high economic costs are the defects of different fault current limiter. Hence, the integration of high-speed switching current-limiting device and power transformer design is presented in this paper, the impedance of the autonomic regulation, achieve low loss, low voltage loss. The current limiting device, which composed of current-limiting reactor, capacitor and high-speed switch in parallel, is in series with the high-voltage winding of transformer, as shown in Fig 1(a). Variable impedance transformer will be the integration of transformer and current-limiting reactor design, and current-limiting reactor needs to be switched by high-speed switch controlled. Current-limiting reactor is short circuit by high-speed switch in normal working condition, and the loss and impedance of transformer is not increased. Different from normal working condition, the current-limiting reactor is connected with the system while high-speed switch is open when short-circuit fault of power system occurs, to improve the impedance of transformer and limit the short-circuit current. Based on the analysis, the self-regulation of impedance which variable impedance transformer possessing can reduce reactive loss of power system; improve the quality of the power grid. 2 DESIGN OF CURRENT-LIMITING REACTOR To realize the integration of high-speed switching current limiting device and transformer design, the current-limiting reactor is in series with the high-voltage winding of transformer. Taking a transformer rated 110/38.5/10.5kV and 63000kVA as an example, current-limiting reactor is connected to the system, when the three-phase short-circuit fault occurs at the location of the termination of medium-voltage winding. The indicator of short-circuit current is limited to the below 60% of the original short-circuit current. The reactance of current-limiting reactor which is required to limit the fault current can be expressed as follows in governing equation (1) shown in Fig.1(b). Taking magnetic shielding measures to prevent electromagnetic effects of current-limiting reactor from the original transformer, the coils of current-limiting reactor are placed within the aluminum tube. The reactance value of current-limiting coils is reduced considering the effect of eddy current of aluminum tube. In order to weaken the demagnetization effect of aluminum tube while ensuring the shielding effect, determining reasonable the spacing between aluminum tube and coils of reactor is particularly critical. Varying the spacing between aluminum tube and coils, Fig.1 (c) shows the reactance value changing with spacing. Eventually determine the spacing is 100 mm and the reactance value of 14.53 Ω in eddy current field, satisfies the requirement of current limit. 3 THE STRUCTURE AND PERFORMANCE OF VARIABLE IMPEDANCE TRANSFORMER Compared with the conventional transformer, high speed switch and air-core current-limiting reactor is known as rapid current limiting device which is placed in high voltage bushing of transformer, as shown in Fig.1 (d), constituted the so-called variable impedance transformer possessing energy-saving and cost-reducing. The windings of transformer is placed in the transformer tank which is filled with transformer oil and put high speed switch, current-limiting reactor and the module of control and protection in the aluminum tube, filled with SF6 gas. Oil tank and aluminum tube are connected through basin-type insulator of 220 kV. Therefore the benefits in economy and society are remarkable and its extending foreground is roomy. Fig.2 shows the current-limiting ability of variable impedance transformer. The short-circuit current medium-voltage winding is reduced by 42.14% when current-limiting reactor is connected to the system. Therefore the adjustable reactive power, the favorable current limiting effect, easy modification, convenient maintenance and considerably reduce the impact, shown in Fig.3(a) and (b), are the significantly superiority of variable impedance. In addition, the benefits in economy and society are remarkable and its extending foreground is roomy. Reliability analysis and life prediction of variable impedance transformer are also conducted in this paper. Compared with conventional transformers, the variable impedance transformer has higher reliability and longer service life.

FP-13. Analysis of a Novel Three-Coil Wireless Power Transfer System Applied in Biomedical Devices.

X. Zhang[1], L. Wang[2] and X. Zhang[1]
1. Tianjin Normal University, Tianjin, China; 2. Chinese Academy of Medical Science & Peking Union Medical College Institute of Biomedical Engineering, Tianjin, China

Since the concept of wireless power transfer has been proposed and implemented by Tesla over a hundred years ago, it has obtained lots of breakthroughs and applied in many potential fields especially in implantable biomedical devices [1-2]. The implantable biomedical devices are surgically introduces into the human body to rebuild body function, achieve a better quality of life, and expand longevity. With the development of microelectronics, biotechnology, and materials, the industry of implantable biomedical devices grows up quickly. The researches show that in America 8% to 10% of the people have experienced an implantable medical device, while in industrialized countries 5% to 6% of population have consumption demand in implantable medical devices. How to provide a constant power supply, for implantable medical devices, becomes a restricted problem. In order to guarantee the implanted medical devices to work normally, the energy storage or harvesting components should be included in these devices. In the traditional implantable medical devices, there are two ways to provide power for the devices. The common method is the implantable batteries are used to be as a power supply, and the other method is to transfer the power in vitro to the devices with the lead wires through the skin. For implantable batteries, their lifetime, size and toxic composition will lead to potential hazard to the patients. The transcutaneous wires, as well, will bring infection and reliability problems. In order to address above problems, the technology of wireless power transfer is used in the biomedical devices. The system has two parts in which one part including power supply and the transmitter coil is placed outside the patients' body, and the other part including the receiver coil is placed in the patients' body. For this system, the receiver coil should be limited as small as possible and the power transfer efficiency should be as high as possible. Different from the traditional two-coil wireless power transfer system, a novel three-coil system is proposed in this paper. In the novel system, there are two rectangular transmitter coils and one circular receiver coil. To obtain the maximum power transfer efficiency, the system is optimal designed according to the following step as shown in Fig. 1. Firstly, the size and the geometry of the receiver coil are determined. A circular coil with a radius of 10mm is chosen as the receiver coil. Secondly, the distribution of the magnetic field generated by the rectangular coil is analyzed based on the Biot-Savart's law. Then the relationship between the distance and the magnetic field intensity will be obtained and expressed as a formula according to the analysis result. Finally, the above formula is chosen as the optimization constrains and the power transfer efficiency is chosen as the optimization objective function. After the optimal designing, the optimal parameters of the transmitter coils are obtained and verified through the experimental system as shown in Fig. 2. The power transfer distance is about 30cm, and the power received by the receiver coil can achieve about 5W. The detailed results will be given in the full paper.

Reduced magnetic respone of Dy doped $CoFe_2O_4$ nanoparticles Hemaunt Kumar[a,b], R.C. Srivastava[b], Jitendra Pal Singh[c], R. K. Patel[d], Keun Hwa Che[c] [a]Rajkiya Engineering College, Bijnor, Uttar Pradesh, India [b]Department of Physics, Govind Ballabh Pant University of Agriculture and Technology, Pantnagar, Uttarakhand 263145, India [c]Advanced Analysis Canter, Korea Institute of Science and Technology, Seoul 02792, Republic of Korea [d] Department of Physics, Jai Narayan Vyas University, Jodhpur, India Corresponding Author: hvatsal@gmail.com Rare earth ferrites brings tremendous opportunity for researchers to develop a relationship among rare earth concentration and magnetic behaviour. In the present work, effect of Dy doping on the magnetic response is discussed by using Mossbauer spectroscopy and magnetic measurments using vibrating sample magnetometer. Dy doped $CoFe_2O_4$ nanoparticles of crystallite size 22 nm were synthesized using metal nitrates and citic acid by heating precursor at 500^{o}C [1]. X-ray diffraction (XRD) studies reveal presence of pure spinel phase in pure $CoFe_2O_4$ nanoparticles. Crystalline phase do not influenced by the Dy doping, however, onset of poor crystallinity was observed as Dy concentration increases from 0.05 to 0.15. Raman spectroscopic measurments corroborates the results obtained from XRD studies. The values of crystallite size are 22±2, 16±2, 13±1 and 11±1 nm for Dy concentration of 0.0, 0.05, 0.10 and 0.15. Magnetic hysteresis curves measured for these nanoparticles exhbit ferrimagnetic behavior. Saturation magnetization, remanent magnetization, coercivity and anisotropy constant decreases with increases of Dy doping (Table 1). To get insight of underlying mechansim of magnetic response of Dy doped ferrite, measurments to proble local structre are perfromed at room temperature. Mössbauer spectroscopy measurments reveal presence of Fe^{3+} in high spin state as corroborated from isomer shift values. This behavior of Fe ions are furhter confirment by Fe *L*-edge near edge X-ray absorption fine structure measurments. Pre-edge spectral features modifies with Dy doping reflecting the modification of metal-oxygen hybridization as Dy incorpotes into the spinel lattice. With Dy doping cation redistribution occurs among tetrahedral and octahedral stie of spinel lattice. Thus, there two factors which influences magnetic response of ferrite systems- (1) Dy doping induced cation redistribtuion and (2) Dy doping induced reduction of crystallite size. If magnetic moment is calculation on the basis of cation redistribution, magnetic moment remain almost same, however, experimentally magnetic moment reduces almost 50% to its initial value. Another factor which affects the magnetic behavior is crystallite size. Thus, reduction of magnetization with Dy concentration is associated with cation redistribtuion and reduction of particle size.

This paper deals with the characteristic analysis & optimum design criteria of Permanent Magnet Assisted Synchronous Reluctance Motor (PMA-SynRM) for power improvement. The focus of this paper is through torque density and d, q-axis inductance according to flux barrier shape. The proposed procedure allows the definition of the rotor magnet & flux barrier shape, dimensions starting from an existing motor or a preliminary design according to the rated wattage. The performance of a synchronous reluctance motor (SynRM) in terms of torque and power factor depends on the two-axis inductance L_d and L_q of the machine. The large difference of L_d - L_q and L_d / L_q ratio are good for the machine's properties. Therefore, Considerable attention has been paid in the past to improve rotor design of SynRM[1]-[3] as shown in Fig 1. By adding a proper quantity of permanent magnets the torque density and power factor of SynRM can be greatly increased. It is called Permanent Magnet Assisted Synchronous Reluctance Motor (PMA-SynRM). And it is important to select an appropriate combination of design parameters to enhance more torque density than an existing PMA-SynRM. In this paper, finite element analysis for a PMA-SynRM is presented and the d-q axis inductance, torque characteristics analysis are performed. Comparisons are given with inductance and torque characteristics of normal Synchronous reluctance motor and those according to quantity of residual flux density (0T, 0.4T) in PMA-SynRM, respectively. And then, it is confirmed that the PMA-SynRM results in high output power performance through numerical analysis data. The focus of this paper is to find design solutions through the comparison of torque density and d-q axis inductance, especially torque ripple of PMA-SynRM according to the rotor magnet and flux barrier shape, dimensions variations under each rated wattage condition (1HP–7 HP) corresponding to the rotor diameters (66.82, 71.4, 84.95, 92.1, 101, 109.1 mm preliminary design). Coupled finite elements analysis (FEA) and Response surface Methodology (RSM) have been used to evaluate design solutions [4]-[7] as shown in Fig 2. A normal synchronous reluctance motor runs at a somewhat poorer power factor than the induction motor. This problem can be alleviated by inserting permanent magnets between rotor segments. For a PMA-SynRM, the L_d and L_q axis inductances affect performance in terms of torque and power factor; in our case the optimization has been oriented on the maximization of their difference (L_d-L_q) and minimization of torque ripple (objective function) The RSM seeks to find a relationship between design variables and responses through statistical fitting methods, which are based on observed data from a system. The response is generally obtained from either real experimentation or computer simulations. Therefore finite element analysis (FEA) is performed to obtain the data of SynRM in this paper. There are many experimental designs for the creation of response surface. In this paper the central composite design (CCD) is chosen to estimate the interactions of design variables and curvature properties of response surfaces in a number of repeated experiments. A method of optimum design related to the torque density and torque ripple of PMA-SynRM according to the flux barrier number, and especially, rotor diameter has been proposed. For rapid design, an automatic pre-process including an automatic ACAD file drawing and mesh generation with regard to the stator and rotor shape variations has been developed. Starting from an existing design, the best design solution is selected, and it is confirmed repeatedly that the flux barrier number, can be a fixed value related to the rotor diameter, whether PMASynRM or SynRM.

FQ-03. Analytical Method for 3-D Overhang Effect of Surface-Mounted Permanent-Magnet Motor Using Conformal Mapping.

Y. Ko[1], J. Song[1], M. Seo[1], Y. Kim[2] and S. Jung[1]
1. Sungkyunkwan University, Suwon, The Republic of Korea; 2. Chosun University, Gwangju, The Republic of Korea

Introduction: In various industrial applications, the overhang structure is often applied to improve the power density by concentrating the magnetic flux at the end part of the stator. The magnet overhang is usually used for small motors such as engine cooling fan to increase the power density. However, 3-D finite element method(FEM) is requisitely conducted to take the precise overhang effect into account. Although accurate analysis results are provided, the 3-D computation time is inevitably longer than 2-D analysis. Therefore, we propose the well-established analytical method applying conformal mapping(CM), so it is possible to consider the overhang effect and significantly save the computation time. The overhang effect has been reflected through the approximation 2-D FEM by changing the remanence flux density, B_r, of the permanent magnet(PM) according to the overhang length of the 3-D structure [1],[2]. Also, it is essential that 3-D analysis is conducted. Magnetic equivalent circuit(MEC), one of analytical methods, takes into account the overhang effect using the effective air-gap length between the overhang part and stator core [3],[4]. When applying MEC, the radial component of no-load air-gap flux density, B_R, is calculated, but it is difficult to estimate the tangential component of no-load air-gap flux density, B_{th}. Therefore, it is hard to compute the cogging torque, calculated by the combination of B_R and B_{th}. In most papers, considering the overhang effect, the 2-D analysis has been carried out by increasing the average of the air-gap magnetic flux density corresponding to the entire stator length or changing PM B_r corresponding to the overhang length. In this paper, we propose the analytical method for considering 3-D overhang effect using the two type CMs, x-y plane CM and x-z plane CM. The x-y plane CM is based on 2-D no-load magnetic flux density, which is the conventional CM, and the x-z plane CM is related to no-load magnetic flux density of overhang structure along to z-axis. For the validity of the proposed method, the no-load analysis, cogging torque and EMF, is computed via B_R and B_{th} from CMs and the result can be compared with 3-D FEM. Overhang Effect: It is requisite to predict the appropriate overhang length at the motor design stage. As the overhang length increases, the power density is not linearly improved. After the limit overhang length, L_{lim}, the leakage flux of PM occurs. Therefore, as the overhang length increases, it is necessary to estimate the change of the air-gap flux density and calculate the L_{lim}. The overhang effect is greatly related to the end layer of the stator along to the z-axis. Especially, the overhang effect is insufficient in the center layer. The total stator can be divided into two layers, applied layer and non-applied layer, based on the influence of the overhang effect. It is also important to calculate the boundary point between the applied layer and non-applied layer to conduct the exact overhang effect. This point is called as the non-overhang effect length, $L_{non\text{-}OH}$. Fig. 1(a) shows the x-z plane cross-section overhang structure including the leakage magnetic flux part of PM. Fig. 1(b) shows the air-gap flux densities for each points of the layers. The leakage flux part has a long effective air-gap length between the magnet and the stator so the air-gap flux density is small. In this paper, the overhang effect is predicted though the overhang function, f_{OH}, that is derived from the x-z plane CM. No-load Field distribution: The conformal transformation is a significantly useful method for the analytical solution of Laplacian field with boundaries. The x-y plane CM is used to transform the stator slot model into the stator slotless model. After the process, the x-y plane CM result is the complex relative air-gap permeance, λ^*, of the relation between slot model and slotless model. It consists of the real and imaginary components. Based on λ^*, the no-load magnetic flux density of the slot model is written as [5] $B_{slot}=B_{slotless}\ \lambda^*$ (1) where $B_{slotless}$ is the no-load magnetic flux density of the slotless model. The x-y plane CM is calculated without overhang structure. The proposed x-z plane CM transforms the overhang model into the non-overhang model. In this case, the real component of λ^* is contributed to overhang effect. Therefore, f_{OH} is the real component of λ^*. Thanks to the x-y plane CM, the maximum f_{OH}, L_{lit} and L_{non_OH} for each overhang length can be founded. Fig.2 (a) shows x-y plane CM and x-z plane CM configurations. f_{OH} is a function that gradually increases with respect to 1 when moving from the center line to the stator end layer along the z-axis. Fig. 2 (b) shows overhang function along the z-axis. The no-load air-gap magnetic flux density considering overhang effect, $B_{overhang}$, is calculated by the combination of B_{slot} and f_{OH} and is written as $B_{overhang}(z)=B_{slot}f_{OH}(z)$. (2) If the overhang length changes, the $B_{overhang}$ can be obtained by performing only the x-z plane CM associated with f_{OH} again. Without 3-D FEM analysis, no-load cogging torque and EMF can be computed by using no-load air-gap magnetic flux density, consists of radial and tangential components, for each element stack length. The results, air-gap magnetic flux density, cogging torque and EMF, of the proposed method can be verified to compare the 3-D FEM results. Also, the method is applied to other size and pole-slot combination to verify the proposed x-z plane CM.

FQ-04. Investigation of flux adjustment capability in hybrid excited switching flux permanent magnet machines.

X. Liu[1,2], S. Wang[1,2] and D. Dong[1,2]

1. State Key Laboratory of Reliability and Intelligence of Electrical Equipment, Hebei University of Technology, Tianjin, China; 2. School of Electrical Engineering, Hebei University of Technology, Tianjin, China

Permanent magnet (PM) excited machines have been applied in many applications, such as automotive, aerospace, industrial automation and renewable energy. However, due to the poor flux-weakening performance of PM machine, the concept of hybrid excited machines, which employ both dc filed windings and PMs to generate field flux, has been developed. Recently, in order to improve the flux-weakening capability of switching flux permanent magnet (SFPM) machines, the hybrid excited SFPM (HESFPM) machines, which adopt double salient stator and rotor structure, have been developed [1][2]. With the help of dc field windings, the air-gap flux density can be either enhanced or weakened. Fig.1 (a) and (b) show two types of 12/10 hybrid excited SFPM machines, respectively. Compared with the conventional SFPM machine, in HESFPM-1 partial permanent magnets (PMs) are replaced by dc field windings. However, in HESFPM-2, the dc field windings are added on the outside of conventional SFPM machine together with an extra outer ring structure. Compared with HESFPM-1, which has limited space for the dc field windings, much larger slot area can be used for dc field windings in HESFPM-2, which increase the flexibility of dc field windings design. By defining the ratio of dc slot area to ac slot area in Eq. (1), γ_s, the influence of dc slot area on the flux adjustment capability can be investigated. $Y_s=S_{dc}/S_{ac}$ where S_{dc} refers to the stator slot area filled by dc windings, whereas S_{ac} refers to the stator slot area filled by armature windings. The principle of flux regulation of two types 12/10 HESFPM machines is illustrated in Fig.2. In order to evaluate the flux adjustment capability, the coefficient is defined by: $K_f=(\Psi_{max}-\Psi_{min})/\Psi_{pm}=\Delta\Psi/\Psi_{pm}$ where Ψ_{pm}, Ψ_{max}, Ψ_{min} represent the amplitude of PM flux-linkage, enhanced flux-linkage and weakened flux-linkage with maximum positive and negative dc current, respectively. Fig. 3(a) shows the flux adjustment coefficient against the ratio of dc slot area to ac slot area. Due to the much larger γ_s in HESFPM-2, the flux adjustment coefficient can reach to 0.161, which is twice of that in HESFPM-1, whose flux adjustment coefficient is 0.0877. In terms of electromagnetic torque, Fig. 3 (b), compared with HESFPM-1 with optimized γ_s, larger torque adjustment can also be obtained in HESFPM-2. Thus, the flux weakening performance of HESFPM-2 will be better than HESFPM-1. However, with the optimal ratio of dc slot area to ac slot area, HESFPM-1 can produce higher torque than HESFPM-2, as shown in Table I. In the full paper, the flux weakening performance will also be compared between the two types of the hybrid excited machine together with the validation of the prototype machine.

FQ-05. Multi-Objective Design Optimization of A New Cost Effective Axial Flux Permanent Magnet Assisted Eddy Current Brake.

M. Gulec[1] and M. Aydin[1]
1. Mechatronics Engineering, Kocaeli University, Kocaeli, Turkey

Eddy current brakes (ECB) are used in various areas such as electric vehicles, high-speed trains, elevators, gym products and domestic applications [1-2]. ECB have numerous topologies such as radial or axial flux paths and rotational or linear type alternatives [2-4]. The aim of all topologies is to generate retarding force or torque in the moving conductive part. Owing to Faraday's law of induction, altering magnetic fields occurred from windings or permanent magnets (PM) create the circular fields and these fields cause eddy currents. In general, most ECB in the literature and in the market consist of only DC windings. Nowadays, this conventional ECB structures have not been used as frequently as before due to rapid development in the field of ECB and demand in electrical applications. PM assisted ECB are promising area of research future for the future applications due to benefits in control and high-efficiency structure [5-8]. However, accomplishing the optimum design parameters is vital for PM assisted ECB. In this paper, a novel axial flux (AF) PM assisted ECB is designed and optimized by multi-objective particle swarm optimization (MO-PSO) based on a non-linear magnetic reluctance network modeling. The proposed AFPM-ECB has a single-rotor and single-stator configuration. Magnets are placed to slot openings so that closed slot structure is obtained in order to improve the braking torque characteristics. In addition, it can be clearly said that the same braking torque can be achieved by less excitation with the proposed AFPM-ECB compared to traditional ECB. The proposed AFPM-ECB structure is illustrated in Fig. 1. PM magnetizations and excitation coils are also provided in the figure. Before the running the MO-PSO, an accurate analytical model should be developed. In this paper, a non-linear magnetic reluctance network modeling is used to calculate the air gap flux density profile and the magnetic field in the conductive region. Magnetic reluctance network model is illustrated in Fig. 2. The globally convergence Newton-Raphson based on back-tracking method is used in the non-linear magnetic network modelling. The general braking torque equation derived from Lenz Law related to the calculation of the current density in the conductive region is used in the MO-PSO and the flowchart of the non-linear magnetic model is given in Figure 3. In MO-PSO, three cost functions, 'braking torque', 'PM weight' and 'total ampere-turn', are described to determine the 3-dimensional Pareto front curve. The number of 500 populations and repository are used in the MO-PSO and the best design point is selected reference by 3D Pareto front curve (Fig. 4). The results show that total ampere-turns in proposed AFPM-ECB is reduced as half compared to conventional ECB which has same rated braking torque. In addition, 25% of reduction in weight is achieved by proposed AFPM-ECB. Detail explanations of non-linear magnetic modelling and MO-PSO with 3D-FEA validation will be provided in the final version of the paper.

FQ-06. The Influence of Magnetization on Modular Spoke-type Permanent-Magnet Machine for In-Wheel Traction Applications.

H. Zhang[1] and *W. Hua*[1]
1. School of Electrical Engineering, Southeast University, Nanjing, China

Abstract—The main purposes of this paper consist of two parts: Firstly, the geometric topology of novel modular spoke-type permanent-magnet (MSTPM) machines with different magnetization modes are introduced. Secondly, based on magnetic field modulation (MFM) analysis and finite element method (FEM), the influence of magnetization on MSTPM machines are investigated with respect to field harmonic, combination of slots and poles, winding factor, back electromotive force (EMF), inductance, eletromagnetic torque, and so on. A prototype machine is manufactured to verify the MFM and FEM predicted results. I. Introduction and Topology As shown in Fig. 1, modular spoke-type permanent-magnet (MSTPM) machines are inspired from flux-switching permanent-magnet (FSPM) machines by moving the sandwiched structure from the stator to the rotor to solve the space competition in stators. It has been found that MSTPM machines have better over-load capability and higher efficiency than FSPM machines [1], and stronger flux-weakening capability and superior high-speed performance than SPM machines [2]. Hence, the MSTPM machine is certainly a good choice for in-wheel traction applications where low speed and high torque are required. In [3], the operation principle of MSTPM machines is analyzed based on magnetic field modulation (MFM), and the back-EMF of MSTPM machines is discussed in [4]. However, there is no research covering the MSTPM machines under different magnetization modes and the corresponding influences on performances. Hence, this paper will introduce MSTPM machines with different magnetization and investigate the influence of magnetization based on MFM and finite element method (FEM). More details will be given in the full paper. II. Analysis and Verification Two magnetization modes of MSTPM machines are illustrated in Fig. 2. The Mode I (MI) is that two adjacent magnets have the same magnetization direction; the Mode II (MII) is that two adjacent magnets are magnetized in reversal directions. As shown in Fig. 3, MSTPM machines with different magnetization modes have different permanent-magnet magneto motive force (PM-MMF) waveforms. Hence, for MI MSTPM machine, the PM-MMF can be expressed by formula (1). For MII MSTPM machine, the PM-MMF can be expressed by formula (2). The θ_{rt} and θ_{pm} are the arc width of rotor tooth and magnet, respectively, and f_{pm} is PM magnetic potential. According to the PM-MMF function, it is found that the number of magnet N_{pm} in MII MSTPM machines must be an even number. However, this constraint does not exist in MI MSTPM machines. Based on the Fourier analysis of the PM-MMF function, the working fundamental field harmonic of MI MSTPM machines and MII MSTPM machines can be calculated by formula (3) and (4). The h_1 is the filed harmonic which induces the fundamental back-EMF. Formula (3) and (4) is suitable for MI and MII MSTPM machines, respectively. Hence, the field harmonic which induces the *k*-th back-EMF harmonic can be calculated by formula (5). To verify the above analysis, field harmonics of two MI and MII MSTPM machines with 26 pieces of magnets are analyzed and compared based on PM-MMF function and FEM. Fig. 4 shows the field harmonic spectrums of MI and MII MSTPM machines according to analytical and FEM results. It can be found that there is a good agreement between analytical and FE results. The 26th and 13rd field harmonics are the main working harmonic of MI and MII MSTPM machines with 26 pieces of magnets, respectively, according to analytical and FE results. Besides, there is a considerable 39th field harmonic which is related to the 3rd EMF harmonic in MII MSTPM machines with 26 pieces of magnets, and the MI MSTPM machines however do not have such high field harmonic. This phenomenon will lead to the discussion of combination of slot and pole, winding factor, electromagnetic torque, core loss, and so on, which are key indexes of in-wheel traction machine design and will be displayed with details in the full paper. To verify the analytical and FE investigation, a prototyped MI MSTPM machine as shown in Fig. 5 was manufactured and tested, whose key parameters are listed in Table I. In Fig. 6, the predicted and tested phase to phase (line) back-EMF waveforms @480r/min (the rated speed) are illustrated. It can be found that the tested fundamental frequency is the same as the FEM one, which verifies the correctness of analytical and FEM results. More experimental details will be given in the full paper.

FQ-07. Proposal of Maxwell Stress Tensor for Local Force Calculation in Magnetic Body.

M.K. Ghosh[1], Y. Gao[1], H. Dozono[1], K. Muramatsu[1], W. Guan[2], J. Yuan[2], C. Tian[2] and B. Chen[2]
1. Department of Electrical & Electronic Engineering, Saga University, Sagacity, Japan; 2. Department of Electrical & Electronic Engineering, Wuhan University, Wuhan, China

1. Introduction To investigate the noise reduction of an electrical machine, the deformation and vibration of the cores are evaluated by using the coupled magnetic and mechanical analyses [1]. In these analyses, the local force calculated by using the flux distribution obtained from the magnetic field analysis is required in the mechanical analysis. In the local force calculation [2], the Maxwell stress tensor is usually used. The Maxwell stress tensors are often represented by the Minkowski and Chu models with linear and nonlinear energy expressions, respectively. In the nonlinear magnetic field analysis, the volume forces, which move the magnetic bodies, obtained from both models coincide with each other, whereas their local forces, which deform the magnetic bodies, are different. Therefore, more investigation is required to clarify the suitable expression of the Maxwell stress tensor. In this paper, to clarify the proper expression of the Maxwell stress tensor for the local force calculation of a nonlinear magnetic body, the Maxwell stress tensors are derived from the Fleming's left hand rule because the volume current density can be used to determine the magnetization in the nonlinear magnetic body. As a result, a new Maxwell stress tensor is derived. The surface force obtained from the new Maxwell stress tensor is compared with those obtained from the ordinary Minkowski and Chu models, and the equivalent magnetizing current method [3] to show the effectiveness and validity of the proposed Maxwell stress tensor. 2. Derivation of the Proposed Maxwell Stress Tensor The magnetization of the magnetic body can be expressed by using volume current density. So, the local force in the magnetic body can be calculated by using the total current density J_t, which is not only the magnetizing current density J_m but also conductive current density J_c, such as eddy current, in free space with permeability μ_0. In this case, for example, the x component f_x of the force density is calculated by using the Fleming's left hand rule in free space with permeability μ_0 as follows: $f_x=(J_t\times B)_x+(B_x/\mu_0)\ \mathrm{div}B=(1/\mu_0)[\partial\{1/2\ (B_x^2-B_y^2-B_z^2)\}/\partial x+\partial(B_xB_y)/\partial y+\partial(B_xB_z)/\partial z]$ where B is the flux density. The second term, which is zero, in the first equation on the right hand side is added to derive the Maxwell stress tensor. Finally, the following Maxwell stress tensor T^p can be obtained: $T^p_{ij}=(\mu/\mu_0)\{H_iB_j-\delta_{ij}(1/2)H\bullet B)\}$ where i, j denotes x, y, and z components. δ is the Kronecker's delta. H is the magnetic field intensity in the magnetic body defined by $B=\mu H$ (μ: permeability). In the Maxwell stress tensor T^m of the Minkowski model, μ/μ_0 on the right hand side is 1. Moreover, in the Maxwell stress tensor T^c of the Chu model, the nonlinear energy expression is used in the second term on the right hand side. In the volume force calculation, the volume force obtained from T^p coincides with those obtained from T^m and T^c. However, the local forces are different with each other as shown in the next section. 3. Comparison of Maxwell Stress Tensor in Local Force Calculation Various Maxwell stress tensors T^p, T^m, and T^c described in Section 2 are compared by using a simple nonlinear magnetostatic model shown in Fig. 1. The core (JIS C 2552-2014: 35A300), which is infinite in y and z directions, is placed in the air and the uniform flux density B_{ty} of 1T is imposed in y direction. The x-component f_{sx} of the surface force density on surface A-B is calculated by using T^p, T^m, and T^c. To clarify the proper Maxwell stress tensor, the equivalent magnetizing current method [3], in which the uniform magnetization in the magnetic body is replaced by the equivalent magnetizing current on the surface, is also used. The surface forces f_{sx} obtained by using the Maxwell stress tensors and the equivalent magnetizing current method are shown in Table I. The f_{sx} obtained from the proposed Maxwell stress tensor T^p is much different from those obtained from T^m and T^c. Moreover, f_{sx} by T^p coincides with the equivalent magnetizing current method. So, it can be concluded that the Maxwell stress tensor T^p proposed in this paper should be used for the local force calculation of the nonlinear magnetic body.

FQ-08. Coercivity enhancement of Nd-Ce-Fe-B sintered magnets by the grain boundary diffusion process using Nd-Al-Cu alloys.

Q. Zhou[1], R. Tang[1], F. Xiao[1] and Z. Liu[2]
1. GuangDong Research Institute of Rare Metals, Guangzhou, China;
2. School of Materials Science and Engineering, South China University of Technology, Guangzhou, China

1 Introduction Nd-Fe-B based sintered magnets have a wide range of applications in energy efficient technologies such as traction motors of hybrid electric vehicles and wind generators [1]. In general, Nd-Fe-B based sintered magnets have a large amount of rare earth elements, such as Nd, Pr and Dy. From an economic point of view, new type of magnets incorporating light rare earth elements such as La and Ce into Nd-Fe-B based sintered magnets has stimulated considerable research efforts due to the analogous structure recently [2]. However, magnets incorporated with Ce exhibit much deteriorated magnetic properties due to the inferior intrinsic magnetic properties of $Ce_2Fe_{14}B$, which saturation magnetization, ambient anisotropic field and Curie temperature were reported to be 1.17 T, 2.6 T and 152°C, respectively [3]. Many efforts had been paid to improve the performance. One well-known method to increase the coercivity of sintered magnets is to refine the grain boundary (GB) structure and chemistry through grain boundary diffusion (GBD) [4, 5]. Previous investigations have demonstrated that the coercivity of Ce-based magnets is enhanced by diffusion process with minor amounts of $Nd_{70}Cu_{30}$ and $Nd_{80}Ag_{20}$ [6]. In this work, we investigated the microstructure of Nd-Ce-Fe-B sintered magnets and the eutectic grain boundary diffusion process using Nd-Al-Cu in order to comprehend the origin of the coercivity enhancement by the Nd-Al-Cu diffusion process. 2 Experimental As Nd-Ce-Fe-B sintered magnets with a nominal composition of $(Nd, Ce)_{31.5}Fe_{bal}B_1$ (wt. %) were fabricated by the conventional powder metallurgy method. The magnets were cut into a cube shape with an edge of 10 mm and a height of 4 mm. $Nd_{80}Al_{10}Cu_{10}$ alloy ribbons as a diffusion source were prepared by the melt spinning technique using the high vacuum quenching system. In the diffusion process, the Nd-Ce-Fe-B sintered magnets were covered by the $Nd_{80}Al_{10}Cu_{10}$ alloy ribbons. And the subsequent diffusion process was carried out at 800°C for 1h and subsequent 580°C for 5 h in a vacuum furnace. 3 Results and discussion Fig. 1 shows the demagnetization curves at 300 K for Nd-Ce-Fe-B magnets before and after diffusion treatment. After diffusion process, the coercivity is substantially enhanced from ~0.86 T to ~1.27 T, while the remanent magnetization decreased slightly from ~1.03 T to ~1.02 T. The changes in the magnetic properties were usually related with the microstructure evolution. Fig. 2 shows back-scattered electron(BSE) images and mapping images of the diffusion-processed sample with the *c*-axis in the plane for magnets. The selected analysis peaks for the elemental maps are Nd, Ce, Fe, Cu, and Al, respectively. As shown in Fig. 2a, the dark gray region indicates the $Nd_2Fe_{14}B$ matrix phases (matrix phase), and the brightly imaged regions correspond to the so-called "Nd-rich phases". It is obviously shown that the Nd-rich layers become continuous, distinct and smooth after the diffusion process. These Nd-rich phases are believed to be non-ferromagnetic based on the low Fe concentration, which would be beneficial to the exchange decoupling between $Nd_2Fe_{14}B$ grains [7]. The Nd-rich shell in the $Nd_2Fe_{14}B$ phase was selectively formed at certain $Nd_2Fe_{14}B$/Nd-rich phase interfaces, as indicated by arrows in the Fig. 2a. SEM-EDS mapping images of the diffusion-processed sample are shown in Figs. 2b-2f. It is found that most of the intergranular phases are depleted of Fe and enriched with Nd and Ce, which are similar to those of commercial sintered magnets. It is surprising to find that Cu and Al are also enriched in these Nd-rich phases in the diffusion-processed magnet. It claimed that certain Cu addition promotes the formation of the C-Nd_2O_3 phase during annealing, which was attributed to the high coercivity [8]. On the other hand, although the distribution of Al element is inhomogeneous, it indicated that the eutectic decomposition in the intergranular phase into Al-lean regions and the modified wettability of boundary phase through Al is also advantageous for coercivity. This is probably the reason for the enhancement of coercivity of the diffusion-processed magnet. 4 Conclusions In summary, the phase constitution and magnetic properties were investigated in Nd-Ce-Fe-B sintered magnets by the grain boundary diffusion process using Nd-Al-Cu alloys. The coercivity of Nd-Ce-Fe-B sintered magnet was substantially increased from ~0.86 T to ~1.27 T while smaller degradation of remanence. The detailed microstructure characterization has shown the formation of Nd-rich core/shell microstructure and the distribution of intergranular phases. The coercivity enhancement in this work can be attributed to be the microstructure evolution during the Nd-Al-Cu eutectic grain boundary diffusion process. Finally, these investigations could serve as a reference for the grain boundary diffusion on the Ce-based magnets with moderate performances.

I. Introduction Single-phase induction motors (IM), which do not require power electronics switching devices and position sensors, are more economical and higher maintenance than electric motors powered by additional inverters [1]. Therefore, it is generalized to the driving motor for home appliances operated by commercial single phase power grid. However, the motor has vibration due to the unbalanced rotating magnetic field generated by the main winding and the auxiliary winding [2]. It also has problems such as difficulty in improving efficiency due to loss of conductor bar. A line-start permanent magnet (LSPM) has been developed in which a conductor bar and a permanent magnet (PM) are inserted at the same time to compensate the disadvantage of the single-phase induction motor. The LSPM is possible to line-start and can operate at the synchronous speed in steady state by magnetic torque and reluctance torque. Therefore, unlike general PM motor, position sensor for starting and operation is unnecessary. Consequently, LSPM motor provides lower production cost than general PM motors and higher efficiency than general induction motors. However, when the LSPM is started, a large inrush current flows, which can result in irreversible demagnetization in the PM [3]. Generally the irreversible demagnetization of PM is occured by the operating point in B-H or M-H curve of PM when only primary part is excited. The LSPM is started by the magnetic flux generated by the induction current of the secondary conductor. Fortunately, the induction current of the secondary conductor reduces the reactive magnetic field that affects the PM. Therefore, general demagnetization analysis leads to the over estimation of magnetic field acting on PM, and results in excessive PM usage. In this paper, a demagnetization analysis method considering the current of the secondary conductor of the LSPM motor is discussed. II. Analysis Method This paper deals with analysis methods of demagnetization of LSPM motor. Conventional method is general demagnetization analysis method and process of conventional method is shown in Fig. 1 (a). Initially, no-load back EMF is estimated. Then, magneto-static field analysis is conducted with maximum current flowing through primary conductor. At this point, the maximum current value can be found by examining the slip variation. In this method, induced current in the secondary conductor is ignored. When the operating point of PM is below its knee point, the residual flux density of the PM is renewed. Finally, with renewed flux density of the PM elements, no-load back-EMF is calculated. By comparing no-load back-EMF before and after demagnetization field, demagnetization ratio of PM is determined. The proposed irreversible demagnetization analysis method for LSPM is distinguished from conventional analysis method which is only considering primary current. The proposed demagnetization analysis method is shown in Fig. 1 (b). Firstly, the currents of the primary and secondary conductors are obtained through the transient analysis based on the voltage source. Then calculated currents by transient analysis which is flowing through primary and secondary conductors are applied to irreversible demagnetization analysis in every rotor position considering not only nonlinear characteristic of the core but also that of the PM on the B-H curve. In the next, determination whether PM is irreversibly demagnetized or not can be made with identical process of conventional method. III. Results and Discussion Demagnetization analysis and experiments were carried out to verify the proposed analysis method. DC current was applied to the motor to verify the conventional analysis method. On the other hand, in order to verify the proposed analysis method that reflects the actual phenomenon, AC current is applied to the test motor. As shown in Table I, the results of the no-load back EMF analysis before the demagnetization experiment is the same for both analysis methods. On the other hand, as a result of examining the demagnetization ratio of the conventional analysis methods, it has a demagnetization ratio of 7.7 % based on the experimental value. In the conventional analysis method which does not consider the secondary current, the analysis itself is verified through the demagnetization experiment. As a result of the demagnetization analysis using both the primary and secondary currents, the demagnetization ratio was 0%. When the design of the LSPM is performed by using the conventional demagnetization analysis method, it is possible to overestimate the grade or usage of the PM. The proposed analysis method is expected to be useful for the optimization of the grade selection and the usage of the PM in the design of the LSPM motor.

I. Introduction Rare-earth permanent magnet synchronous machines (RE-PMSMs) are widely used in electric vehicles (EVs) due to their characteristics of high efficiency, high torque density and high power factor. While the dramatic price fluctuations of the rare-earth permanent magnets (PMs) have been restricted the application of RE-PMSMs. Hence, the less-rare-earth interior permanent magnet synchronous machines (LRE-IPMSMs), which combine the features of high electromagnetic performance as well as low cost, have attracted increasing attention in recent years [1]. The anti-demagnetization ability of the LRE-IPMSMs is crucial to the machine safety [2]. In [3], the tapered flux barriers are adopted to improve the anti-demagnetization ability of the LRE-IPMSMs. In [4], a practical analytical approach is proposed to express the direct link between the PM thickness and the demagnetization limit. In addition, the PM minimization is also a significant issue for the LRE-IPMSMs as it is crucial to decrease the machine cost. In [5], an analytical procedure is proposed to reduce the PM quantity in the LRE-IPMSMs without affecting the torque versus speed performance. In this paper, the demagnetization equivalent magnetic circuit (EMC) model of the investigated LRE-IPMSM is established and the effects of structure parameters on the PM flux density are investigated. The PM minimization design of the LRE-IPMSMs is obtained on the premise of no side effect on the machine output toque and anti-demagnetization ability. II. Demagnetization EMC Model The rare-earth PM material used in the investigated LRE-IPMSM is N35UH and the demagnetization curve of N35UH at 150 degrees Celsius (with margin) is shown in Figure 1a. When the demagnetization current is fed, the PM demagnetization condition is examined by comparing the knee point flux density (B_k in Figure 1a) and the PM flux density. In the demagnetization EMC model, the bridge is equivalent to be a magnetomotive force (MMF) (F_{Br_Dei}) and a serial-connected reluctance (R_{Br_Dei}) because the magnetization curve of silicon steel is an approximate straight line in saturation area as shown in Figure 1b [5]. The demagnetization EMC model of the investigated LRE-IPMSM is shown in Figure 1c and it is rewritten as Figure 1d shows. In the demagnetization EMC model, R_{g_Dei} and R_{Ba_Dei} are the air gap reluctance and flux barrier reluctance, respectively; Φ_{Dei} is the segmental demagnetization flux that flows through R_{g_Dei}, as shown in Figure 1d; R_δ is the leakage reluctance; F_{S_Dei} is the MMF producing by the stator current; F_{PMi} and R_{PMi} are the equivalent MMF and reluctance of PM, respectively. III. Effects of Structure Parameters on the PM Flux Density The stator current is the rated current (371A) when the effects of structure parameters on the PM flux density are investigated. Figures 2a-2c show the variations of the PM flux density (B_{PMi}) with respect to the PM width (b_{PMi}), which are calculated by the EMC method and finite-element analysis (FEA). As can be seen, when a certain PM is widened, the flux density of this PM decreases. Besides, the flux densities of the other two PMs increase as a certain PM is widened. The effects of the PM thickness, the flux barrier thickness and the flux barrier span angle as well as the bridge width on the PM flux density are also investigated, which will be given in the following full text. IV. PM Minimization Analysis The PM minimization is obtained on the premise of no side effect on the machine output toque and anti-demagnetization ability. The output torque of LRE-IPMSMs is consisted of PM torque and reluctance torque. As a small quantity of the PM is normally employed in the LRE-IPMSMs, hence the effect of the PM shape on the reluctance torque is neglected when the PM minimization is investigated. In other words, the PM quantity is minimized with providing the targeted PM torque, i.e., the targeted no-load flux. The PM minimization design of the LRE-IPMSMs is obtained by the no-load EMC analysis. Then, the performances and parameters (including the reluctance torque, the PM torque, the anti-demagnetization ability and the PM volume, etc.) of the preliminary and PM minimization machine designs are compared and analyzed. The detailed analyses and results will be given in the full text. V. Conclusion In this paper, the demagnetization EMC model of the investigated LRE-IPMSM is established. Then, the effects of structure parameters, such as the PM width, the PM thickness, the flux barrier thickness, the flux barrier span angle and the bridge width, on the PM flux density are investigated, respectively. It can be found that widening the PM can decrease the corresponding PM flux density slightly and thickening the PM can increase the corresponding PM flux density obviously. After that, the PM minimization analysis of the LRE-IPMSMs is studied on the premise of no side effect on the machine output toque and anti-demagnetization ability. Finally, the performances and parameters of the preliminary and PM minimization machine designs are compared and analyzed in detail.

1. Institut Lumière Matière, Villeurbanne, France; 2. Institut Néel CNRS, Grenoble, France; 3. CEA, Grenoble, France

MnBi has attracted much interest within the past decade for its potential use in rare-earth free magnets. When stabilized in the so-called low temperature phase, MnBi exhibits an intriguing magnetic behavior with an unusual positive-dependence of anisotropy constant on temperature, reaching a maximum of 2.2 $MJ.m^{-3}$ at 490 K [1]. However there is a lack of experimental investigation of the thermal stability of single domain MnBi nanomagnets. On the other hand, two magnetic phase nanocomposites, made of a fine mixture of nanosized grains with respectively high magnetization and high anisotropy, are good candidates to build high performance magnets [2]. In the context of limiting the amount of critical elements like heavy lanthanides, using MnBi is an attractive alternative. In this study we put the focus on structural and magnetic properties of MnBi nanosized grains. MnBi nanoclusters, with a mean size of 5 nm, were produced by gas aggregation in a low energy cluster beam deposition system. They were deposited on silicon substrate and protected with an amorphous carbon layer. We investigated their structure in a transmission electron microscope and by X-ray diffraction, and their magnetic response in a superconducting quantum interference device (SQUID) magnetometer. In this study, we focused on the onset of magnetic ordering after annealing at various temperatures, ranging from 250°C to 500°C. In the as-deposited state, MnBi clusters, with nearly equiatomic composition, present a low degree of crystallinity. They show a linear and positive response to an applied magnetic field, with relatively large magnetic moment. The magnetic moment is inversely proportional to temperature, as expected from a Curie law of paramagnetism. This paramagnetic response contrasts with a recent report on as-prepared MnBi 10-nm clusters made by sputtering [3]. This absence of ferromagnetic response at 10 K shows a low degree of MnBi chemical ordering. We found that their magnetism evolves drastically with annealing conditions, as shown by the temperature dependence of the magnetic moment measured under an external field of 10 kOe, displayed on Fig.1. After annealing at the relatively low temperature of 250°C for 20 minutes, the magnetic moment measured under a field of 10 kOe becomes nearly constant between 10 K and 300 K. The onset of ferromagnetic (or ferrimagnetic) ordering in the MnBi nanoclusters would lead to a superparamagnetic response, that follows the Curie law, provided the elementary magnetic moment does not change within the considered temperature range. Therefore, our findings would be consistent with a superparamagnetic state of MnBi nanoclusters only if the magnetic moment increases with temperature. Fitting with a Langevin function the magnetic response suggests that the magnetic moment hold by elementary magnetic volumes increases by a factor of 5 from 10 to 300 K. Interestingly, annealing at a temperature ranging between 300°C and 400°C leads to the formation of a ferromagnetic phase that exhibit relatively large switching fields, up to 25 kOe, but a relatively low thermal stability as the moment drops below 100 K. We will discuss the evolution of structural and magnetic properties upon annealing conditions, notably considering finite size effects.

FQ-12. Novel Permanent Magnet Design and Materials Structures.

Y. Zhang[1] and *K. Gao*[1]
1. Argonne National Laboratory, North Oaks, MN, United States

Permanent magnets (PMs) are one of the earliest functional magnetic materials. Nowadays, they are used in wide and diverse applications. The demand of PMs increases rapidly, in particular for the applications related to hybrid and electric vehicles, direct-drive wind turbines, and many other energy-efficient appliances [1]. The $Nd_2Fe_{14}B$-based magnets, one of the earliest discovered PMs, are well-known for their high magnetic moment and high energy density. The magnetic properties of NdFeB magnets, such as coercivity (H_c) and energy product $(BH)_{max}$, can be further improved by doping heavy rare-earth elements such as Tb and Dy [2]. A number of other permanent magnetic materials, such as SmCo and MnBi, were explored after NdFeB and utilized for the energy related applications [3, 4]. Additional efforts were made to search for new PM materials with reduced consumption of heavy rare-earth elements. It is also desired to have PM materials that work efficiently at elevated temperatures [1, 5]. Recent progress on magnetic materials design, particularly on thin film based magnetic data storage media, demonstrated an exchange-spring mechanism between the relatively hard and soft magnetic layers [6, 7]. This concept was also applied to the development of high energy density PMs [8, 9]. Despite some success in thin film materials, the application of exchange coupling approach to bulk PMs was hindered by a significant technical challenge – a rapid reduction of H_c with the increase of soft phase volume percentage [6, 7], making it difficult to find an optimal design configuration. Micromagnetic simulation indicated that the reduction of H_c was originated from the rotation of the soft phase magnetization, which lowers the energy barrier of magnetization reversal in the exchange-coupled materials (see Fig 1a) [6]. Although there have been tremendous efforts on exploring new PMs and improving PMs energy product, the usage of PMs magnetic flux is not very efficient in many cases. Because most PMs have a high magnetic moment, the surface magnetic charges push the magnetic flux (B) away from the surface normal direction as a result of magnetostatic coupling (see Fig. 2). A rapid decay of the magnetic flux with distance away from a PM surface is often observed ($B \propto 1/d^2$). For applications such as power generation, such drop of magnetic flux density over distance greatly reduces magnets and devices efficiency. Here we propose a PM structure that addresses this issue. Our design can be understood from Fig. 2, where a weakly exchange coupled or exchange decoupled hybrid PM structure is illustrated. The top and bottom sections of the PMs are made from magnetic materials with a high magnetic anisotropy H_k and a relatively smaller magnetization M_s, while the middle section of the PM consists of a relative low H_k and a high M_s magnetic material. The high H_K/M_s ratio of the surface magnetic materials enables a high out of plane component of the surface magnetization, which facilitates a larger magnetic flux out of the hybrid magnet surface. The middle-section of the magnet, due to a smaller demagnetizing field within the magnet body, can be made of magnetic materials with a smaller H_k. In this hybrid PM, the interaction between the surface and body materials is not necessary to be strongly exchange coupled. The thickness of different layers and the exchange coupling between different layers can be varied based on different application needs. Compared to conventional PMs, this hybrid PM structure has many advantages. It has a higher surface magnetic flux density and lower cost. The high grade PMs are only used at surface section of the magnets. The main body of the magnets are made from less expensive PMs. Modeling and calculation indicates that this hybrid structure can improve magnet efficiency by more than 10% without introducing more cost. The other advantage is the flexibility in materials selection. Depending on applications, the choice of materials for the surface and body section of PM can have many options. In high temperature applications the hybrid PM can show a less negative or even positive temperature coefficient with the properly chosen surface and center materials, as illustrated in Fig. 1b. More detailed examples and measurements have been achieved and the results are consistent with the theoretical predictions [6, 7].

FR-02. Reversible Control of Intrinsic Spins by Guest Molecules in a Layered Ferrimagnetic Metal-Organic Framework.

J. Zhang[1], W. Kosaka[1] and H. Miyasaka[1]
1. Institute for Materials Research, Tohoku University, Sendai, Japan

Reversible magnetic change in response to external stimuli is one of the desired functionalities in molecular magnetic materials. It could be more favorable that the magnetic change is induced by changes of intrinsic spins than that only by structural changes, because the magnetic change could become more drastically. In this study, we demonstrate a reversible magnetic change closely associated with electronic state modulations, as well as structural modulations, in the target material, which is achieved by a solvation/desolvation cycle (i.e., sponge behavior) of the material. The compound is a D_2A-type layered magnet, $[\{Ru_2(O_2CPh\text{-}2,3,5\text{-}Cl_3)_4\}_2(TCNQMe_2)]$-4DCM (1; 2,3,5-$Cl_3PhCO_2^-$ = 2,3,5-trichlorobenzoate; $TCNQMe_2$ = 2,5-dimethyl-7,7,8,8-tetracyanoquinodimethane, DCM = dichloromethane), synthesized by the reaction of $[Ru_2(O_2CPh\text{-}2,3,5\text{-}Cl_3)_4]$ ($[Ru_2^{II,II}]$) acting as an electron-donor (D) and $TCNQMe_2$ as an electron-acceptor (A). Compound 1 has a one-electron transferred charge ordered state with a $[\{Ru_2^{II,II}\}$–$TCNQMe_2^-$–$\{Ru_2^{II,III}\}^+]$ (1e-I) formula (inset of Figure 1). Strong intralayer antiferromagnetic couplings between $[Ru_2^{II,II}]$ with $S = 1$ or $[Ru_2^{II,III}]^+$ with $S = 3/2$ and $TCNQMe_2^-$ with $S = 1/2$, as well as ferromagnetic interlayer interactions, induce long-range ferrimagnetic ordering at $T_c = 101$ K (Figure 1). The interstitial DCM molecules are located in void spaces between layers, which are gradually eliminated under vacuum at 80°C to form a solvent-free compound (1-dry) without loss of crystallinity. The electronic state of 1-dry is thermally fluctuated via a fully electron transferred state at high temperatures to eventually be a charge-disproportionate disordered state with a $[\{Ru_2\}^{0.5+}$–$TCNQMe_2^{1.5-}$–$\{Ru_2^{II,III}\}^+]$ (1.5e-I) [1] formula as the ground state (inset of Figure 1). The T_c in 1-dry is 34 K (Figure 1) because of the presence of diamagnetic $TCNQMe_2^{2-}$ that weakens super-exchange coupling over the framework. A large T_c variation with $T_c \approx 70$ K is switchable, which is achieved by charge state modulations accompanied with a subtle structural modification in a solvation/desolvation treatment.

FR-03. Magnetorheology of Core-Shell Structured Mesoporous Fe_3O_4@$mSiO_2$ Nanoparticle Added Carbonyl Iron Dispersion.

W. Han[1] and H. Choi[1]

1. Polymer Science and Engineering, Inha University, Incheon, The Republic of Korea

I. INTRODUCTION Magnetorheological (MR) fluids, which are composed of micron or sub-micron sized soft-magnetic particles and nonmagnetic fluids, possess tunable and reversible ability to be transformed from a liquid-like to a solid-like state under an applied magnetic field [1, 2]. In the absence of an external magnetic field, MR fluids exhibit a free-flowing state, similar to the behavior presented by Newtonian fluids. However, with the application of a magnetic field strength, their rheological properties can instantly be changed as a result of building up chain-like structure of dispersed magnetic particles under a magnetic field due to magnetic polarization interaction, and this phenomenon has great potential in designing diverse high performance engineering products including vehicle shock absorber, active damper system, torque transducer and MR polishing equipment [3, 4]. Generally, high yield stress and low apparent viscosity without magnetic field as well as good stability and durability have become very crucial factors for the MR fluid application. Among the diverse magnetic materials, soft magnetic carbonyl iron (CI) particles have been regarded as the most attractive materials for MR fluids because of their controllable magnetization and high saturation magnetization; however, the density mismatch between CI particles and the surrounding oil could easily cause sedimentation issues. Therefore, numerous methods have been explored to improve these problems [5, 6]. In this study, we synthesized core-shell structured mesoporous Fe_3O_4@$mSiO_2$ nanoparticles by a surfactant-based sol–gel approach, and then adopted them as an additive for the CI based MR fluid to improve both suspension stability and MR performance. Rheological properties of both pure CI and CI/ Fe_3O_4@$mSiO_2$ nanoparticle based MR fluids for various magnetic field strengths were investigated via rational and oscillatory tests using a rotational rheometer. A profile of sedimentation ratio as a function of time was also recorded to evaluate the effect of mesoporous Fe_3O_4@$mSiO_2$ nanoparticles on sedimentation. II. EXPERIMENT Initially, Fe_3O_4 nanoparticles were synthesized by a solvo-thermal method. The mesoporous-silica-coated Fe_3O_4 magnetic nanoparticles were then prepared by a surfactant-based sol–gel approach. Briefly, 1 g of Fe_3O_4 and 5 g of cetyl trimethylammonium bromide were uniformly dispersed in deionized water by ultrasonic treatment for 30 min. Second, the solution prepared in the first step was added into 900 mL of a 1.0 mM sodium hydroxide aqueous solution and subjected to ultrasonication for 20 min. After stirring the resulting mixture at 60 °C for 30 min, a tetraethyl orthosilicate/ethanol (1/4, v/v) solution (25 mL) was added dropwise, followed by stirring for 3 min. The obtained mixture was then kept for 12 h at 60 °C. The Fe_3O_4@CTAB/SiO_2 nanoparticles were collected and washed several times with ethanol and DI water. Finally, the mesoporous SiO_2 shell was formed by calcination at 550 °C for 5 h to remove the CTAB embedded in the silica layer. Soft magnetic CI micro-spherical particles were dispersed in a silicone oil (1000 cSt) to prepare the MR fluid system. Two different MR fluids with and without mesoporous Fe_3O_4@$mSiO_2$ nanoparticles in the CI suspension were fabricated. The two systems have same particle concentration of CI at 50 wt%, while the one was added with the mesoporous Fe_3O_4@$mSiO_2$ additive (0.1 wt% in the MR fluid). The transmission electron microscopy (TEM) (Philips CM200) was employed to observe the surface morphologies of the magnetic particles before and after coating. A vibrating sample magnetometer (VSM, DMS 1660) was used to examine the magnetic characteristics over a broad magnetic field range. The MR behaviors of the prepared MR fluids were conducted by using a rotational rheometer (MCR 300, Anton PAAR, Germany) equipped with a MR device (MRD 180). III. RESULT AND DISCUSSION Figure 1 shows TEM images of the different stages of products. Primarily, nearly monodisperse spheres with a mean diameter of about 230 nm were observed for pure Fe_3O_4 nanoparticles (Fig.1a). As shown in Fig. 1b, the core–shell structure of Fe_3O_4@CTAB/SiO_2 nanoparticles was successfully formed, where a silica shell with a thickness of approximately 22 nm was uniformly coated on the Fe_3O_4 dark core. After the removal of the CTAB template, the silica shell in the mesoporous Fe_3O_4@$mSiO_2$ nanoparticles exhibited a clear mesoporous structure, with a thickness of approximately 15 nm (Fig.1c). As for their MR performance, Fig. 2a and 2b represent shear stresses as a function of shear rate and three different yield stresses for CI based MR fluids with and without Fe_3O_4@$mSiO_2$ nanoparticle additive under various external magnetic field strengths ranging from 0 to 342 kA/m, respectively. The CI/ Fe_3O_4@$mSiO_2$ additive based MR fluid exhibits higher shear stress and yield stresses than those of pure CI based MR fluid. This is thought to come from both novel increased magnetic interactions with magnetic Fe_3O_4@$mSiO_2$ from the increased magnetic property and the typical extra gap-filling additive effect of the Fe_3O_4@$mSiO_2$ nanoparticles, forming a stronger column structure. Sedimentation was also observed to be improved for the additive system.

FR-01. Effect of Fe_3O_4/sepiolite Nanocomposite Additive on Carbonyl Iron Based Magnetorheological Fluid.

Y. Dong[1], S. Piao[1] and H. Choi[1]

1. Polymer Science and Engineering, Inha University, Incheon, The Republic of Korea

I. INTRODUCTION Magnetorheological (MR) fluids are considered to be a kind of intelligent materials, which are suspensions of magnetically particles disperse in non-magnetic carrier liquids, such as, aqueous, silicone oil, mineral oil and so on [1], [2]. Because their rheological behaviors are strongly influenced by the presence of external magnetic field, the shear viscosity and yield stress of MR fluids can be controlled by applied magnetic field with their fast response time of only a few tens of milliseconds. Therefore, controllable MR fluids have been widely developed in many applications, such as, polishing, haptic device, vehicle dynamics and so on [3], [4]. Among the candidates of MR materials, carbonyl iron (CI) particles are considered to be an excellent one owing to its high saturation magnetization, spherical shape and suitable particle size, and have been widely researched. While the high density of CI particles always causes heavy sedimentation problem, which is a particularly adverse factor for industrial application, recently, many researchers have been using magnetic iron oxide particles as additives and it has been proven that they can enhance both the sedimentation stability and MR characteristics of MR fluids [5]. In this work, we synthesized Fe_3O_4/sepiolite magnetic nanocomposites via a chemical co-precipitation method, and introduced these particles as additives of CI MR fluid. We anticipated that the additives can impede the immediate contact of CI particles and then improve the dispersion stability of the pristine CI based MR fluid. Furthermore, the particles also were expected to occupy the interspace of the chain structure of CI particles and then enhance the MR properties of the CI MR fluid. II. EXPERIMENT The Fe_3O_4/sepiolite nanoparticles were synthesized as previously reported [6], in which 3.1 g ferric chloride and 0.5 g sepiolite were added in 50 mL distilled water and sonicated at 40 Celsius for 1 h. The homogeneous suspension was then transferred into a reactor, and the solution with 2.4 g ferrous sulfate heptahydrate dissolved in 50 mL distilled water was added into the reactor and stirred at 60 Celsius for 30min. The 10 mL ammonium hydroxide solution was added dropwise and reaction for 1 h with vigorous stirring. After being aged for 2 h, the product was washed with distilled water, collected via magnetic separation and dried for 12 h. The CI based MR fluid was prepared by dispersing 50 wt% of CI particles in the silicone oil. The CI-Fe_3O_4/sepiolite based MR fluid was prepared with same CI particle concentration of CI MR fluid, while added 0.1 wt% of Fe_3O_4/sepiolite nanoparticles as an additive. The morphology of Fe_3O_4/sepiolite added in CI particles was examined by scanning electron microscopy (SEM) (SU-8010, Hitachi, Japan) and the MR characteristics of both two MR fluids were measured by using a rotational rheometer (Physica MCR 300, Anton Parr, Germany) under various magnetic field strengths. III. RESULTS AND DISCUSSION The SEM images of synthesized Fe_3O_4/sepiolite nanocomposites, CI and CI-Fe_3O_4/sepiolite mixture are shown in Fig. 1 (a), (b) and (c), respectively. In Fig. 1 (a), it is evident that the Fe_3O_4 grows on the surface of nanosized sepiolite. As shown in Fig. 1 (b), CI exhibits spherical shape with a diameter about 4. After adding the Fe_3O_4/sepiolite in CI particles, it can be confirmed that the nanosized Fe_3O_4/sepiolite particles attached on the surface of microsized CI particles and occupy the free spaces between the CI particles (Fig. 1 (c)). Therefore, we could predict that the sedimentation stability and MR characteristics of the CI-Fe_3O_4/sepiolite MR fluid compare with the pure CI MR fluid will be improved. The flow curves of the CI MR fluid and CI-Fe_3O_4/sepiolite MR fluid were investigated with controlled shear rate mode under various magnetic field strengths, ranging from 0 to 342 kA/m. Figure 2 shows the shear stress of two kinds of MR fluid as a function of shear rate via a log-log scale. Both two kinds of MR fluid behave like a Newtonian fluid with the absence of magnetic field, while when the magnetic fields is applied, for each magnetic field strength, they show an obvious yield stress, which exhibits typical Bingham fluid behavior, indicating the formation of chain structures by induced magnetic dipole-dipole interactions between particles [7]. The shear stress shows dramatic increase with increasing magnetic field strength, which because the interactions between particles increases with increasing external magnetic field strength and the stronger magnetic polarization interaction between particles give rise to the stronger particle chains. In addition, at high magnetic field strength, both two MR fluids hold plateau shear stress region in the whole shear rate range, due to the fact that magnetic field induced magnetic force is stronger than the flow induced hydrodynamic force. When the chain structures are disrupted by the shear flow, they will reformed quickly by the strong magnetic force. More importantly, CI-Fe_3O_4/sepiolite MR fluid shows higher shear stress values than pure CI MR fluid at every magnetic field strength, which proves that the presence of additives make chain structures stronger.

FR-04. Synthesis of Organic-inorganic Poly(diphenylamine)/magnetite Composite Particles and Their Magnetorheological Response.

Y. Dong[1] and H. Choi[1]

1. Polymer Science and Engineering, Inha University, Incheon, The Republic of Korea

I. INTRODUCTION Organic-inorganic smart composites have been extensively studied for their ability to integrate the structure and properties of both organic and inorganic components. Recently, poly(diphenylamine) (PDPA) has attracted much attention in many fields because of its good mechanical properties, special electrochemical properties, low density and ease of synthesis [1], [2], while magnetite (Fe_3O_4) has been widely used in magnetorheological (MR) fluid due to its super-paramagnetic properties [3]. MR fluid usually composed of magnetic particles dispersed in non-magnetic carrier medium is considered as a kind of intelligent materials, which can transform quickly (milliseconds) from a liquid-like state to a solid-like state with dramatic increase of shear stress, shear viscosity, and dynamic modulus by applying external magnetic field [4]. On the other hand, when the external electric field is removed, it returns to the fluid-like state again. Because of its regulable rheological properties, MR fluids are thought to have great potential in many industrial fields. However, the large density difference between the particles and the carrier medium often leads to serious sedimentation problems, which limits its development in engineering [5]. In this work, we synthesized the organic-inorganic PDPA/Fe_3O_4 magnetic composites by a simple route, and applied them in the MR fluid. The PDPA/Fe_3O_4 based MR fluid exhibited pronounced MR characteristics, in addition, the sedimentation stability was improved beneficial from the relatively low density of PDPA/Fe_3O_4 particles. II. EXPERIMENT Firstly, the PDPA was prepared by a chemical oxidative polymerization process as suggested [6], in which 6.00 g diphenylamine monomer (99.0% purity, Sigma-Aldrich) was dissolved in 150 mL ethanol (95.0% purity, Samchun Pure Chemical Co.) over a few minutes of intensive magnetic stirring then transformed into the 500 mL three-neck glass reactor and 120 mL of 3 M hydrochloric acid (HCl, Junsei Chemical Co.) aqueous solution was added. The mixture was maintained at 5 °C under continuous stirring. A solution of 3.01 g ammonium persulfate (APS, >98.0% purity, Daejung Chemicals & Metals Co.) dissolved in 15 mL of 3 M HCl was added dropwise to the mixture. After stirring for additional 16 h, the reaction mixture was collected and washed several times with ethanol and water. The precipitate was dried in a vacuum oven at 60 °C overnight. Then, the PDPA/Fe_3O_4 composites were fabricated by as-synthesized PDPA. 1.00 g PDPA powder was dispersed in a 100 mL mixture of ethanol and distilled water with volume fraction of 1:1 and transfered to a 250 mL three-neck glass reactor with intensive stirring. 5.40 g ferric chloride hexahydrate (97.0% purity, Sigma-Aldrich) and 1.39 g ferrous sulfate heptahydrate (99.0% purity, Sigma-Aldrich) were dissolved in 20 mL distilled water respectively and added in the reactor. The reaction mixture was heated to 60 °C. 10 mL ammonia solution (NH_3: 28.0~30.0% (m/m), Junsei chemical Co.) was added dropwise and continued stirring for 2 h. The final black precipitate was collected by magnetic separation and dried at 60 °C for 12 h. The MR fluid based on PDPA/Fe_3O_4 composites was prepared by dispersing PDPA/Fe_3O_4 composites in silicone oil (100 cSt, KF-96, Shin-Etsu, Japan) with particle concentration of 15 vol%. The microstructures of the PDPA and PDPA/Fe_3O_4 were investigated by the transmission electron microscopy (TEM, CM-220, Phillips, U.S.A.) and the MR characteristics of PDPA/Fe_3O_4 based MR fluid were measured by the rotational rheometer (MCR 300, Physica-Paar, Germany) under various magnetic field strengths. III. RESULT AND DISCUSSION Figure 1 shows the TEM images of PDPA (Fig. 1(a), 1(b)) and PDPA/Fe_3O_4 composites (Fig. 1(c), 1(d)). Both PDPA and PDPA/Fe_3O_4 show irregular shapes and the spherical Fe_3O_4 particles with diameter about 10-20 nm can be observed distinctly in the partial enlargement (inset in Fig. 1(d)) of PDPA/Fe_3O_4. Figure 2 shows the shear stress for PDPA/Fe_3O_4 based MR fluid as a function of shear rate ranging from 0.01-200 1/s under various magnetic field strengths (0-274 kA/m) on a log-log scale. The shear stress shows dramatic increase when the external magnetic field is applied and increases with increasing magnetic field strengths, which indicate that as the magnetic field strength increases, the magnetic field-induced attractive interactions between particles increase, resulting in a stronger chain structure. The solid lines in Fig. 2 were drawn for the Herschel-Bulkley (HB) model [7], which can be shown as: $\tau=\tau_y+K\gamma^n$ where τ is the shear stress, τ_y represents the dynamic yield stress, γ is the shear rate, K and n represent the consistency index and power-law exponent, respectively. As shown, the shear stress curves for PDPA/Fe_3O_4 based MR fluid under external magnetic field are in agreement with the HB model. In addition, the yield stress obtained from Fig. 2 was further investigated as a function of input magnetic field strength based on a power-law relationship.

FR-05. Synthesis and Viscoelastic Behavior of Non-stoichiometric Inverse Spinel Ferrite Nanoparticle Suspension with Controlled Morphology and Enhanced Magnetization.

J. Han[1], W. Han[1], C. Gao[1], Y. Dong[1] and *H. Choi*[1]
1. Dept. of Polymer Science and Engineering, Inha UNiversity, Incheon, The Republic of Korea

Magnetorheological (MR) fluid, an active field-responsive colloidal suspension in which magnetic particles are dispersed in an insulating fluid, becomes one of the most promising smart advanced materials. It has a characteristic of reversible and fast phase transition from a liquid-like to a solid-like state depending on the presence or absence of magnetic field [1]. Based on these characteristics, MR fluids are used widely in engineering applications, especially in a mechanical areas such as haptic devices, active dampers, clutches and MR polishing devices [1]. Various spinel ferrite-based magnetic particles, such as magnetite and hematite (γ-Fe_2O_3), have drawn an attention in engineering applications in addition to MR suspensions as an alternative to widely adopted carbonyl iron (CI) microspheres because of their lower density than CI [1]. On the other hand, commonly used spinel ferrites have a relatively low saturation magnetization which strongly affects their MR behavior [2]. Consequently, the ferrite materials generally exhibit poorer MR performance than CI. As a solution, we applied a method of doping non-magnetism metal cations in inverse spinel structure to improve the low magnetization of Fe_3O_4. In the inverse spinel structure, the A^{2+} cations occupy the octahedral site, whereas the half of B^{3+} cations occupy the tetrahedral site, written as $B^{3+}{}_{tetra}[A^{2+}B^{3+}]_{octa}O_4$ [3]. Fe_3O_4 can be expressed by the following structural formula: $Fe^{3+}{}_{tetra}[Fe^{2+}Fe^{3+}]_{octa}O_4$ as inverse spinel structure. In two sites of spinel structure, doping of metal cation changes the cation distribution, and this distribution also affects magnetic property [4]. The metal dopant influences the interaction between tetrahedral site and octahedral site, which finally improves the magnetic property [5]. Among divalent metal cations, Zn^{2+} cation has non-magnetism and prefers to occupy the tetrahedral site. The structural formula of the Zn-doped ferrite can be expressed as $Zn_d{}^{2+}Fe_{1-d}{}^{3+}[Fe_{1-d}{}^{2+}Fe_{1+d}{}^{3+}]O_4$. The addition of Zn^{2+} cation induces a decrease of magnetic moment of tetrahedral site and as a result increase the total magnetic moment [6]. In this study, to improve MR performance through enhanced magnetization and controlled morphology, we synthesized non-stoichiometric $Zn_{0.417}Fe_{2.583}O_4$ nanoparticles via thermal decomposition process and adopted them as for MR fluid expecting more robust chain-like structure than normal ferrites [7]. II. EXPERIMENT Iron acetylacetonate [$Fe(C_5H_7O_2)_3$] (12 mmol) and zinc acetylacetonate hydrate [$Zn(C_5H_7O_2)_2H_2O$] (8 mmol) were initially dissolved in benzyl ether (20 ml). Subsequently, oleic acid (28 mmol) was added to the above solution mixture as a surfactant that controls the morphology and prevents agglomeration between particles. The mixture was heated to 120 degC for 30 min to evaporate the traces of water included in the precursor, and then to 280 degC under reflux using a condenser for 30 min. After that, the reactor was cooled to room temperature and the brown-black precipitates were obtained using filtration and centrifuge. The obtained product was washed three times with hexane, and dried in a vacuum oven at 60 degC for 12 h. To analyze the MR behavior, the MR fluid was fabricated by dispersing the particles (5 vol%) in silicone oil. Morphology of the synthesized particles was tested using transmission electron microscopy (TEM), and rheological characteristics of the MR fluid was inspected using a rotational rheometer in a parallel-plate geometry with an external magneto-cell. III. RESULT AND DISCUSSION Figure 1 presents TEM image exhibiting the polyhedral structure with truncated octahedron-like form with approximately 150 to 200 nm size. MR fluids with non-spherical angulated particles are expected to develop denser chain structure and strengthen the particles packing under magnetic field, because when forming a chain-like structure, a face-to-face contact occurs rather than a point-to-point contact. Dynamic oscillation test was performed to analyse viscoelastic characteristics of MR fluid. The strain amplitude sweep test was performed before the frequency sweep test under presence of magnetic field to confirm linear viscoelastic region of storage (G') and loss modulus (G''), as shown in Fig. 2(a) in a strain amplitude range of 0.001 to 70 % and the fixed frequency at 1 Hz. As the magnetic field strength increased, G' and the difference between G' and G'' increased, demonstrating that the characteristics of solid-like structure with elasticity were revealed more clearly. In addition, we selected strain amplitude value of 0.005 % to apply frequency sweep test in the linear viscoelastic region where the storage modulus became plateau. Fig. 2(b) shows G'(ω) and G''(ω) as a function of angular frequency at constant strain amplitude value of 0.005 %. Without a magnetic field, both moduli show a tendency of increase with angular frequency possessing a liquid-like behavior. On the other hand, with a magnetic field, high and constant moduli were observed in the same frequency range. This shows that the MR fluid was transformed from viscous to elastic characteristic as the magnetic field was applied, confirming that the elasticity increases with the strength of the magnetic field for this MR fluid.

I. INTRODUCTION Magnetorheological (MR) fluids which are smart colloidal suspensions of magnetic particles dispersed in non-magnetic fluids, are capable of being solid-like under applied magnetic fields, while being liquid-like without a magnetic field [1]. Their rheological properties such as yield stress and shear viscosity can reversibly and quickly be changed as a result of dispersed magnetic particles building up a chain-like structure under a magnetic field [2]. Without magnetic field, the MR fluid behaves like a Newtonian fluid, recovering to a free-flowing liquid state [3]. These phenomena of MR fluids imply a huge potentials in designing diverse high-performance engineering products including active damper system, torque transducer, and MR polishing equipment [4]. Among various magnetic materials, carbonyl iron (CI) particles have been adopted as a superior candidate for MR fluids in both scientific investigation and industrial applications, due to their high saturation magnetization, controllable magnetic property, and appropriate particle size. However, the large density mismatch between CI particles and medium oil leads to a serious sedimentation drawback, thus, obstructing smooth operation of the MR devices. Therefore, many strategies have been explored to solve this problem, such as coating polymer layers on CI particles to decrease the particle density. However, as one of the effective and fastest methods, the introduction of additives has been found to improve the dispersion stability by occupying the interspaces between the CI particles. Addition of various additives such as organoclay, magnetic nanoparticles have been reported to enhance the MR properties. In this study, the additive magnetic Fe_3O_4/polystyrene (PS) composites were synthesized via a Shirasu porous glass (SPG) membrane emulsification technique and added to the CI based MR fluids [5]. The SPG method was adopted for achieving a narrow size distribution of the product. Here, we used the composites as an additive not only to increase the MR behaviors but also to improve the stability of MR fluids relative to CI particles based MR fluid. Rheological properties of both pure CI and CI- Fe_3O_4/PS additive based MR fluids were investigated via steady shear tests under different external magnetic field strengths. II. EXPERIMENT Firstly, preparation of hydrophobically coated magnetite nanoparticles, in which the Fe_3O_4 nanoparticles were synthesized through the coprecipitation method. $FeCl_3{\cdot}6H_2O$ and $Fe_2SO_4{\cdot}7H_2O$ were dissolved in de-ionized (Di) water while stirring under a N_2 atmosphere. After heating the solution to 80 °C, $NH_3{\cdot}H_2O$ was added followed by the addition of oleic acid for the hydrophobic modification of Fe_3O_4. The temperature was maintained at 80 °C for 3 h to obtain the ferrofluid. Then, preparation of magnetic miniemulsion and styrene macroemulsion, the ferrofluid was added to an aqueous solution of sodium dodecyl sulfate and the resulting mixture was treated with an ultrasonifier for 15 min in an ice bath. In order to obtain styrene droplets with a uniform size, SPG was employed. Styrene and hexadecane were mixed and loaded into a tank for forming the dispersion phase. SDS was dissolved in DI water for forming the continuous phase and then N_2 pressure (35 kPa) was applied to obtain monodisperse styrene droplets. Subsequently, the synthesis of Fe_3O_4/PS nanocomposites, where both the emulsions were mixed in a three-neck-flask to which KPS was added. The solution was stirred for 30 min at 250 rpm under a N_2 atmosphere. The reactor was heated to 80 C and the reaction was carried out for 24 h. The Fe_3O_4/PS nanoparticles produced were washed with ethanol and were collected by using a magnet. Finally, two systems with and without additives in the MR suspension were prepared, where both pristine CI (50 wt %) with and without Fe_3O_4/PS additive (0.1 wt %) were dispersed in silicone oil (1000 cSt). III. RESULT AND DISCUSSION Figure 1 shows TEM image and DLS data of morphology and size distribution of the Fe_3O_4/PS composite particles. We can confirm that the Fe_3O_4 nanoparticles were successfully embedded into the PS particles by emulsion polymerization, which were suffused uniformly and almost perfectly in the PS particles. The diameter of the particles varied from 40 to 310 nm and had an average value of 127 nm. Figure 2 shows flow curves of MR characteristics of two different systems, CI and CI-Fe_3O_4/PS based MR fluids to examine the effect of additives. Typical MR characteristics of shear stress were measured as a function of applied shear rate in different magnetic field strengths ranging from 0 to 342 kA/m. When the magnetic field is absent, the shear stress linearly increases almost with increasing the shear rate, following a Newtonian fluid-like behavior of a typical dilute suspension. When the external magnetic field is present, both MR fluids exhibited a Bingham behavior, representing the formation of the stable chain structures of the magnetized particles [6]. We found that regardless of the external magnetic field, the MR properties of the CI-Fe_3O_4/PS suspension showed higher shear stress than that of pure CI based MR suspension, being attributed to the magnetic response of the added Fe_3O_4/PS composites with the magnetic field.

I. Introduction In countries where the economy is growing rapidly, many skyscrapers are being built one after another. For such skyscrapers, high-speed and safe elevators are essential as transportation means. Therefore, we have proposed an elevator with magnetorheological fluid (i.e., MRF) dampers to improve the safety of passengers ([1]). For supplying safe elevators, we have to consider various dangerous factors, such as natural disasters, accidents and so on. If a disastrous earthquake occurs, an elevator works an earthquake-sensing system and stops at a nearest floor to evacuate the passengers. However, in reality, it often happens that passengers are shut into the elevator for a few minutes or more. During the earthquake, the passengers feel fear or may be conscious of death. In this paper, we would like to verify whether the proposed MRF damper can absorb strong vibrations of elevator caused by an earthquake, and would like to confirm the effectiveness of MRF damper by using our experimental simulator. II. Structure and Characteristics of Our MRF Damper Fig. 1(a) shows the structure and the specification of the MRF damper. Our MRF damper is composed of a cylinder filled with magneto rheological fluid, a coil winded around the cylinder, and a piston. As for the magnetorheological fluid, Fig. 1(b) shows the states of a change in viscosity depending on whether magnetic field is applied or not. Thus, we can control the equivalent damping coefficient C (Ns/m) of the MRF damper in real time, by regulating the coil current for making magnetic field ([2]). Fig. 1(c) shows the damping coefficient C (Ns/m) of our MRF damper to the coil currents (0 (A) ~ 1.0 (A)), by adopting "temperature" as parameter. As shown in this figure, we have confirmed that the characteristics of MRF damper are linear to the coil current and invariable in the fluid-temperature (10 (°C) ~ 40 (°C)) that is close to "room-temperature". III. Experimental Verification *1) Evaluated variables* We have advanced this study to build the damper system which can absorb strong vibrations of an elevator during earthquake. Fig. 2(a) shows the acceleration of the disastrous earthquake occurred in Kumamoto prefecture. In order to evaluate the effectiveness of our damper system, we evaluate the acceleration of elevator, from two kinds of variables; (i) the root mean squared value a_{rms} (m/s^2) in the earthquake-period having the acceleration value 0.25 (m/s^2) or more and (ii) the vibration-energy-consumptions E_d (J) performed by using our MRF damper. *2) Designing of controller and system formation* The controller of the proposed MRF damper-system is designed by using the nonlinear control theory with Hamilton Jacobi Inequality ([3]). On the other hand, based on the actual seismic wave shown in Fig. 2(a), our experiment-simulator remakes this wave to another one that will be directly input to the elevator. This remade vibration is input to the mass-body in our experiment simulator corresponding to an actual elevator-cage via out MRF damper in real time. *3) Experimental Results* In this chapter, we would like to verify the vibration damping-characteristics of an elevator for three cases, such as a conventional elevator, an elevator with passive MRF damper and an elevator with controlled MRF damper, where "passive MRF damper" means that it has constant damping coefficient with the constant coil current and "controlled MRF damper" means that its damping coefficient is controlled by the coil current as explained in II. Fig. 2(b) shows the acceleration characteristics of the elevator, under the condition of full passengers and 150 (m) long wire for hanging the elevator cage. From Fig.2 (b), we can obtain that a_{rms} (m/s^2) is reduced by 40 (%) in case of the controlled MRF damper and 33 (%) in case of the passive MRF damper, compared to the case of the conventional elevator. In addition, from Fig.2 (c), we can confirm that the vibration-energy consumptions E_d (J) performed by the controlled MRF damper increased by 42 (%) from that performed by the passive MRF damper. IV. Conclusions These experimental results indicate that the proposed MRF damper, especially the controlled MRF damper can absorb strong vibrations. In conclusion, we confirmed by experiments that the proposed elevator has effectiveness at occurrence of an earthquake.

FR-08. Characterization of Output Torque of a Permanent Magnet-based MRF Clutch with a Field Blocking Mechanism.

M.A. Fernández[1], J. Chang[1] and C. Huang[1]
1. Power Mechanical Engineering, National Tsing Hua University, Hsinchu, Taiwan

Introduction Although it is not an impossible task, previous work [1-2] on magnetorheological fluid (MRF) clutches has proved that the prediction of the torque transmission capacity is not a straight forward process. The prior MRF clutch presented in [3] also showed a big discrepancy between expected torque capacity of the clutch and actual measured torque. In this work, a new MRF clutch has been proposed and fabricated, with the expectation that its torque transmission capacity would be larger, as the clutch itself is also larger. This new clutch is a cylinder-based clutch with four MRF layers, which uses permanent magnets, but uses a steel cylinder which vary the magnetic field by covering the magnets. With the use of simulations and mathematical models, study of the MRF clutch is presented in this paper on how accurately the output torque can be modelled. Magnetostatic simulation The clutch with its MRF layers and with the field-blocking steel cylinder at several different positions were simulated using ANSYS Maxwell. Since the datasheet of the used MRF shows that for weaker fields the relation between the magnetic field and the yield stress is nearly linear, the average magnetic field of each layer was used to calculate the yield stress at that particular layer. Mathematical model The mathematical model used in [3] was used again in this paper, except that the torque due to rotational forces was not taken into account. Since the magnetic field was averaged across each layer, the yield stress will be constant across a layer, and the torque equation was reduced to simply multiplying the average yield stress of the layer by its radius and area. This process was repeated for each of the four layers and then the four values summed together. The results from these calculations can be seen in Fig. 1. Fluid simulation Simulations were also performed in ANSYS Fluent in order to confirm the mathematical model. For these simulations, the Herschel-Bulkley viscosity model was used, with $n = 1$ in order for it to represent a Bingham-type fluid. Again, the yield stress for each layer was chosen based on the same procedure as in the mathematical model, using the average magnetic field in each layer. The inner wall of each layer was set to rotate at low angular velocity of 0.1 *rads/s* in order to reduce its effects on the torque transmission. The results from these simulations are seen in Fig. 1. Experimental procedure The first set of tests performed on the new clutch showed a torque transmission capability similar to that of the previous clutch. These test were performed by having a DC motor drive the input of the clutch while the output was static and pressing down on a force gage. The force gage measurements were recorded and used to calculated the torque. Several measurements were carried out with the field blocking cylinder at different positions in order to discover its effect on the output torque. This first set of tests were performed early in the development of the clutch and did not take into account the effect of angular velocity. The second set of tests repeated the measurements made before, but this time the angular velocity of the input stage was set at 2.09 *rad/s*. The third set of tests followed the same procedure as the second set of tests, and in addition some tests were made to test the effects of angular velocity in the torque. Results The first set of test was carried out after the clutch was built and before any simulation. The results from this first set of tests are seen in Figure 1. After the simulations and the calculations based on the mathematical model were performed, big discrepancies between them and the experimental results were found. Since the simulations and the mathematical model agree on their result, it was decided to reevaluate the experimental set up. More MRF was added to the clutch through a screw hole, not originally designed for this purpose. The addition of this extra MRF proved effective in raising the torque transmission capability of the clutch as seen in Fig. 1, where an increase of at least 67% is seen. This value is still lower than the expected value, therefore, it was decided to dissemble the clutch and modify it to make the filling of MRF easier and more effective. After this, the third set of tests were carried out, whose results are seen in Fig. 1. It was found the torque only increased at most by 13%, which indicates that the discrepancy seen before is not completely due to lack of MRF in the clutch. Thus, further refinement of the models and simulations have to be done. As for the effects of angular velocity in the torque transmission capability, the results can be seen in Fig. 2. Here it can be seen that the addition of MRF to the clutch reduces the slope of the angular velocity-torque relationship. The slope after magnets were added back, however, reaches a value similar as when the magnets were not present. Further study of this phenomena will be done.

FR-09. Phenomenological magnetic hysteresis model of a polymer matrix filled with magnetic particles.

Z. Xiang[1], B. Gupta[1], M. Le[1], G. Coativy[1] and *B. Ducharne*[1]
1. INSA LYON, Laboratoire de Génie Electrique et Ferroélectricité, Villeurbanne, France

ABSTRACT Based on experimental results and finite element method (FEM) simulations, a magnetic lump model of a 3D printed polymer matrix filled with magnetic particles is proposed in this article. Due to the intrinsically dielectric nature of the polymer and since the percolation threshold is not reached even for a high percentage of particles the tested sample shows a high resistivity. This property implies a significant limitation of the formation of the so-called "macroscopic" eddy currents. Taking into account this characteristic, the proposed model is limited to microscopic eddy currents (mainly related to the movement of the walls of magnetic domains). This approach is validated by simulation/measurement comparisons over a wide frequency band of excitation. KEYWORDS magnetic polymer matrix, magnetic hysteresis, frequency dependence, electromagnetic modeling. MAIN TEXT The use of 3D printing for rapid tooling and manufacturing is a very promising technique to manufacture components with complex geometries with the help of computer designing. Due to the mechanical properties and limited application of printed pure polymer parts, there is a critical need to develop printable polymer composites with high performance. 3D printing offers many advantages in the fabrication of composites, including high precision, cost effectiveness and customized geometry. 3D printable materials based on polymer matrices filled with magnetic particles, also called composite materials, are of high interest as they can provide solution for many industrial applications: damage sensing and self-healing [1], thermoplastic induction welding [2], magnetic core for inductors or electric transformers [3]. According to the targeted application, the focus can switch from the ability to drive the magnetic flux (electric inductor) to the local distribution of Joule losses, i.e. localized variations of temperature (thermoplastic welding). In ferromagnetic materials, magnetic losses appear as soon as a tested sample is exposed to a time-varying magnetic excitation field. These magnetic losses have two origins: _ The so-called "microscopic" eddy currents originate from the interactions between the walls of the magnetic domains and the microstructure during the magnetization of the sample. The so-called "macroscopic" eddy currents linked to the diffusion equation [4] of the magnetic field and are strongly dependent on the physical properties of the material (conductivity and permeability). The frequency dependence of these two contributions is different. It is legitimate to assume that when a polymer matrix is filled with a significant percentage of ferromagnetic particles, these properties observable in a ferromagnetic materials will continue to exist to some extent. In this study the composite used is PLA – Rustable Magnetic Iron filament (1.75 mm diameter) consisting of a polylactic acid (PLA) polymer matrix and a particulate phase of 40 wt% iron. This percentage of particles issufficiently weak to avoid the percolation threshold and if the particle distribution is homogeneous, each particle will be electrically insulated (this property will be confirmed by microscopic study in the extended version of the article). This electrical insulation will prevent the macroscopic eddy current formation, and consequently the ferromagnetic losses will be limited to the domain wall motions resulting in the microscopic eddy currents. In [4][5] a simple formulation is proposed to consider Joule variations in a ferromagnetic material when the material's electrical conductivity is weak and the dynamic contribution is mainly based on microscopic eddy currents: equation (1) Here, f^{-1}_{static} is the quasi-static contribution of hysteresis, which in a ferromagnetic material can be provided by the classic Preisach or Jiles-Atherton models. ρ.dB/dt is the dynamic contribution (dynamic losses) and ρ, a constant which depends on the geometry and on the nature of the material. For the polymer composite considered in this study, this formulation can still be used but the high percentage of non-ferromagnetic polymer in the composite highly limits the level of induction. Non-linear behavior (saturation) under magnetic excitation for this kind of material is just inconceivable. f^{-1}_{static} is replaced then by a linear function $\mu_0.\mu_r$. A finite element method simulation has been run for the determination of this relative permeability (figure 1). Fig. 1. Magnetic induction distribution in a magnetic polymer composite homogeneously filled with magnetic particles. In the extended version of the article, a detailed experimental set-up will be illustrated used for the validation of the model. Large number of comparison simulations/experimental results will be shown and the influence of the size, the shape and the distribution of the particle will be studied extensively.

FR-10. Magnetically controlled light manipulating properties of biogenic and synthetic guanine crystals.

H. Kashiwagi[1], M. Iwasaka[2], H. Asada[3], T. Koyanagi[3] and K. Kishimoto[3]
1. Graduate School of AdSM, Hiroshima University, Higashihiroshima, Japan; 2. RNBS, Hiroshima University, Higashihiroshima, Japan; 3. Graduate School of Science and Technology for Innovation, Yamaguchi University, Ube, Japan

Ultra structural photonic properties of biogenic crystals derived from various animals have been studied in recent years with an aim toward developing biomedical optical instruments and microelectronic mechanical system (MEMS) elements. These crystals play significant roles as biological reflectors and in forming structural color (i.e. silvery shine, iridescent luster) on skin surface and scales by the effective use of ambient light [1]-[2]. Mainly derived from fish, guanine crystals in particular have specific light reflecting and light concentrating properties [3]-[5], together with very high refractive indices (n = 1.83), and are promising for the future. It has been shown that micro crystals exhibit magnetic orientation along the direction of a magnetic field due to the highly directional dependency of diamagnetic susceptibility [6]-[10]. In an early study we found that biogenic guanine crystals suspended in water display rotational alignment within a few seconds under several hundreds tesla, thus efficiently switching the direction of reflected light. Subsequently we have focused on developing remote control micro manipulation techniques using magnetic fields that noninvasively affect crystal alignment inside a material. As of yet, however, biogenic crystal capabilities (i.e. uniformly generated platelets, highly efficient reflection/refraction, nano/submicron sizing) have not been realized. Recently chemically synthesized guanine crystals have become commercially available. In the present study we sought to compare the diamagnetic, light propagation, reflection and structural color properties of several types of synthetic guanine crystals supplied by different companies (Wako Pure Chemical Industries, Sigma-Aldrich, Tokyo Chemical Industry). Crystals further crushed by mechanical alloy milling (MAM) were also examined. Suspensions were prepared by collecting supernatants after centrifugation for various lengths of time. Suspensions of guanine crystals derived from goldfish (*Carassius auratus*) were also prepared. Prior to centrifugation, single frequency ultrasonic cleaning was performed for various lengths of time up to 18 hrs in order to break down the guanine crystals into smaller pieces. Magnetic response properties and light reflection dependence of the various submicron through several-micron sized crystals obtained were evaluated by real-time microscopy and high-resolution spectroscopic measurement, with and without magnetic field application. Suspensions, a halogen light source, a charge-coupled device (CCD) microscope and the optical fiber of a spectrometer were placed between the electromagnets. The incident light angle was set at 60°. Guanine crystal behavior was observed from directly above under dark field illumination. Light incidence direction, magnetic field, and the observation/detection were orthogonally directed in the experimental equipment. Results of this study indicate that the synthetic guanine crystals supplied by Wako show a more significant increase in reflective properties under magnetic exposure than do the crystals of other suppliers. Centrifugation time proved to be a significant factor in determining optimum conditions for collecting microcrystals with high diamagnetic properties. Synthetic guanine crystals crushed by MAM and fractured biogenic crystals showed a decrease in light reflection compared with intact crystals. Time-series reflection spectrometry analysis quantitatively confirmed the CCD microscope results, and the variations in light reflection under a magnetic field were duplicated in a number of trials. The light condensing efficiency of goldfish-derived crystals increased by approximately 100 % under a magnetic field, and this held true even though the crystals were thoroughly fractured. Synthetic guanine crystals, on the other hand, showed limited increases of up to 30 %. Furthermore, it was noted that reflection was slightly higher for longer wavelengths than for shorter wavelengths in each crystal examined. Diamagnetic anisotropic energy was also estimated for the various synthetic and biogenic crystals under a magnetic field. In conclusion, it was found that microscopic crystals produced by conventional synthetic processes used in chemical engineering do display diamagnetic orientation properties and light reflection abilities such as those seen in biogenic crystals. A more detailed examination of the physical properties of microcrystals may lead to various biomedical applications, such as optical elements and harmless, eco-friendly convectional tracers to replace radioactive isotopes in micro fluidic systems. It is also hopeful that a bio-inspired light condensing device might be applied to highly sensitive biosensors for use in evaluating human cellular activity. This work was supported by JST-CREST "Advanced core technology for creation and practical utilization of innovative properties and functions based upon optics and photonics (Grant number: JPMJCR16N1)."

FR-11. Cr and Fe substitution effects on magnetic properties and phase stabilities in tetragonal Mn_3(Ga,Ge).

H. Okada[1], K. Moriya[1] and M. Doi[1]
1. Tohoku Gakuin University, Tagajo, Japan

Tetragonal Mn-based compounds have attracted much attention due to their functional properties. Among them, Mn_3Ga and Mn_3Ge with $D0_{22}$-type ($TiAl_3$-type) structure have been expected to be candidates for new spintronic and permanent magnet materials [1,2], because these compounds exhibit high uniaxial magnetic anisotropy despite 3d transition metal compounds and high Curie temperature. The compounds show a ferrimagnetic state with a small net magnetization, arising from an antiferromagnetic interaction between magnetic moments on two different crystallographic Mn_I and Mn_{II} sites (2b and 4d sites, respectively). It is known that off-stoichiometric composition stabilizes the $D0_{22}$ structure. The $D0_{22}$ phase of Mn-Ga alloy is synthesized with Mn-deficient composition $Mn_{3-x}Ga$, whereas Mn-rich composition $Mn_{3+x}Ge$ is required for obtaining the $D0_{22}$ single phase of Mn-Ge alloys. Recently, we reported that the $D0_{22}$ structure without the deficient and excess Mn atoms is synthesized in $Mn_3Ga_{1-x}Ge_x$ [3]. Theoretical investigations predicted that the exchange interaction between the two Mn sites is sensitive to the atomic ordering and the off-stoichiometry [4,5]. On the other hand, structural stability and magnetic property of the tetragonal phase in substitution systems strongly depend on a number of the valence electron of the compounds [6]. Therefore, in order to clarify the magnetic properties and phase stabilities of the Mn-based compound with the $D0_{22}$ structure, it is needed to control the number of the valence electron in the samples. In this work, we have investigated the magnetic properties and phase stabilities of the Cr-substituted, Fe-substituted and (Cr,Fe)-substituted $Mn_3Ga_{0.5}Ge_{0.5}$. Polycrystalline samples of $Mn_{3-x}Cr_xGa_{0.5}Ge_{0.5}$, $Mn_{3-x}Fe_xGa_{0.5}Ge_{0.5}$ and $Mn_{3-x}Cr_{x/2}Fe_{x/2}Ga_{0.5}Ge_{0.5}$ were synthesized by arc-melting method. The ingots were annealed at 1073 K for a week, and then heated at 673 K for a week. Structural properties were investigated by powder X-ray diffraction (XRD) experiments at room temperature. Phase stabilities of the $D0_{22}$ phase were determined by differential scanning calorimetric (DSC) measurements. The magnetization measurements were carried out using vibrating sample magnetometer. The hyperfine magnetic structure was characterized on the basis of the conventional ^{57}Fe Mössbauer effect. The single phase of the $D0_{22}$ phase were confirmed up to $x = 0.2$ for $Mn_{3-x}Fe_xGa_{0.5}Ge_{0.5}$ and $Mn_{3-x}Cr_{x/2}Fe_{x/2}Ga_{0.5}Ge_{0.5}$ and up to $x = 0.1$ for $Mn_{3-x}Cr_xGa_{0.5}Ge_{0.5}$, respectively. In the Cr-substituted system, lattice constant *a* increases and lattice constant *c* decreases with increasing the Cr content, resulting in a suppression of tetragonality (*c*/*a*). On the other hand, the Fe substitution leads to a decrease in lattice constant *a* and an increase in the lattice constant *c*. As shown in Fig. 1, a transition temperature T_{22} from the $D0_{22}$ phase to hexagonal $D0_{19}$ phase slightly increases with increasing Cr content, although the T_{22} decreases in the Fe and (Cr,Fe) substitution systems. These results indicate that a thermal stability of the $D0_{22}$ phase is influenced by the structural properties such as lattice parameters and site occupation rather than the number of valence electron. Magnetization of the Cr substitution system increases with increasing Cr content, although that of the Fe substitution system decreases with increasing Fe content. According to previous report of neutron diffraction measurement [7], magnetic moments of Mn atoms are estimated to be -3.07 m_B at the Mn_I site and 2.08 m_B at the Mn_{II} site for Mn_3Ga. Our results of Mössbauer spectroscopy reveal that the Fe atoms occupy the Mn_{II} site with extremely lower hyperfine filed, resulting in the decrease in the magnetization. On the other hand, it seems that the nonmagnetic Cr atoms occupy the Mn_I sites, leading to the increase in the magnetization. Therefore, the site preference of the substitution elements is important role for the magnetic properties of the substitution systems with the $D0_{22}$ structure.

Bio-photonic crystals in fish and so on have attracted much attention due to their unique biological nano-sturcture. Guanine crystals of fish scales are the thin plate having the interesting properties such as high reflection and optical biaxiality. It has been demonstrated that the magnetic field controls the light reflection intensity from the guanine crystal plates[1], [2]. This reflection anisotropy is generated by a diamagnetic orientation of the guanine crystal with the magnetic filed more than 100 mT (goldfish guanine case). From the viewpoint of optical devices application, the reduction of magnetic field amplitude is effective. In this study, we have prepared a hybrid thin film consisting of diamagnetic guanine crystal plates and soft ferromagnetic material, and demonstrated that the hybridization enables to orient the guanine plate with the magnetic field of several mT. A ferromagnetic thin film was developed by sputtering method. After the chamber was evacuated to a pressure below 5×10^{-7} Pa, the sputtering was carried out with DC power of 50 W at sputter gas pressures of 0.53 Pa in an Ar gas atmosphere. A permalloy film with a thickness of 5-30 nm was formed on the dried surface of the stacked biogenic guanine crystal plates considering the typical thickness of guanine plates of goldfish is around 100 nm. Figure 1(a) shows the SEM image of guanine crystal plate after depositing the permalloy film of 5 nm in thickness. The permalloy entirely covers the guanine crystal surface but the edge of guanine plate is clearly seen. Next, the hybrid plate has been detached from the substrate and the dynamic behavior under the magnetic field has been investigated. Figure 1(b)-(d) shows optical microscope images of the hybrid plate having the 5-nm-thick permalloy film under the magnetic field generated by a three-axis Helmholtz coil. The hybrid plate still tends to float in water. When the rotating field of x-y plane is applied, the hybrid plate rotates according to the magnetic field as shown in Fig.1 (b) and (c), and the reflected light from the plate can be confirmed. When z-direction field is applied, hybrid plate easily stands up (see Fig.1 (d)) unlike pure guanine crystal which is oriented so that the long axis of guanine plate takes orthogonal to the magnetic field due to the gravity[2]. In the pure guanine case, it has been reported that more than 2 T magnetic field is needed to make the guanine crystal stand up against the gravity[3]. These hybrid plate motions arise from the strong shape anisotropy of permally film which fixes the magnetization direction parallel to the long axis direction of guanine plate due to the elongated shape. Critical magnetic field amplitudes for controlling the plate motion, which are 0.6 mT for in-plane motion and 3 mT for standing up, drastically decrease compared to the diamagnetic orientation of the pure guanine crystal. This work was supported by JST-CREST "Advanced core technology for creation and practical utilization of innovative properties and functions based upon optics and photonics (Grant number: JPMJCR16N1)".

FR-13. Magnetic Field Analysis and Optimization Design of Magneticrheological Fluid Brake.

N. Yan[1], W. Li[1] and B. Zhang[1]
1. Shenyang University of Technology, Shenyang, China

I.Introduction Magnetorheological fluid braking system utilizes the mechanical and magnetic properties of the magnetorheological fluid to provide accurate and fast braking response and realize the precise braking of the vehicle. The core of the magnetorheological fluid brake system design is to realize braking torque in the shortest possible time, the less braking torque and no residual. The performance is better than one of the conventional vehicle brake.[1] One of the key points of the design of magnetic fluid brake system is the design of magnetic field generator and the design of magnetic field optimization. The viscosity of the magnetorheological fluid under the influence of the external magnetic field is obviously changed. When the magnetic field reaches a certain range, the fluid loses its fluidity and shows obvious resistance to shear. There is no known numerical calculation model of magneto-rheological hydraulic force, which leads to no basis for the optimization of magnetic field for improving brake mechanics characteristics.[2-3] This paper presents the design and optimization process of the magnetic field of magnetic rheological fluid brake. The power law model is introduced, and the relationship between torque and magnetic induction intensity is obtained by the fitting of experimental data. So the optimization of magnetic field can be carried out smoothly. The electromagnetic design scheme of the magnetic field of brake with different structure is given. The finite element method is used to analyze and optimize. Then the magnetic circuit design was made for brake. As much as possible to meet the needs of the car. II.Numerical calculation model of magnetorheological fluid force The viscosity, shear stress and yield stress of magnetic fluid under different magnetic field strength were tested experimentally. The research objects used in the study were MRF-50 magnetic fluid. The test equipment is an Anton Paar rheometer. The viscosity of the liquid under zero magnetic field is small without considering the subsidence of the magnetorheological fluid. The relationship between shear rate and viscosity can be obtained. With the increase of magnetic field, the shear rate and viscosity meet the relationship. A power law model is introduced to characterize the relationship between shear stress and magnetic induction intensity. III.Design and optimization of magnetic field in generator Magnetic field translocation design requires a strong and uniform magnetic field in a limited volume. This part of the work includes, electromagnetic distribution simulation for different structure brakes, optimization brake thickness and magnetic ring thickness, increasing the strength of the surface magnetic field as much as possible, take into account the amount of magnetorheological fluid. Because the permeability of magnetorheological fluid is lower than that of the shell, it is possible to have low magnetic induction strength. Therefore, it is difficult to design the work. IV.Design of magnetic circuit in brake Considering the leakage and magnetic circuit saturation, the brake needs to be designed in a reasonable way. Design assumptions include: axisymmetric structure, ignoring the bearing's influence on the magnetic circuit, nonlinear permeability, ignoring outer shell magnetic leakage. The design steps are: 1) The shear stress is determined by the maximum torque of the car. 2) The induction strength of working face is obtained by substituting power law model. 3) The working face magnetic flux is estimated. 4) The relation between magnetic resistance and structural dimension is deduced. 5) The magnetic circuit model is derived. 6) The coil and brake sizes are optimized. The finite element simulation model of brake is established after the design, and the design torque is verified. V.Conclusion In this paper, a power law model is introduced to simulate the experimental data. The magnetic field analysis method can play a good role in the magnetic field of magnetic fluid transfer and brake design. An example of finite element analysis of magnetic field in generator and the design of magnetic circuit in brake is given.

FR-14. A Permanent Magnet-Excited Magneto-rheological Fluid Brake Manipulated by Mechanical Magnetic Shield.

P. Lee[1] and J. Chang[1]
1. Power Mechanical Engineering, National Tsing Hua University, Hsinchu, Taiwan

In this paper we proposed a magneto-rheological fluid (MRF) brake manipulated by moving magnetic shield in which magnetic field is generated by permanent magnet (PM). With this movable shield mechanism as a switch, the magnetic field and the corresponding braking torque can be controlled continuously within small space. Furthermore, by changing the edge angle of the shield, the toque-displacement response can be modified. The size of the device is 270mm in diameter and 100mm in length. The estimated torque is 300Nm when excited by high strength NdFeB PMs, thus is suitable for rotary table of machining tool. A MRF is a smart material that consists of micro-sized magnetic particles dispersed in a carrier fluid such as oil. Without external magnetic field it appears as normal viscous fluid. With external magnetic field the magnetized particles link as chains that restrict the movement of the fluid, hence make the MRF resistive to shear force. This reaction is reversible and responses in several tens of millisecond [1-2]. Many devices such as damper, brake, etc. employed the MRF effect such that their properties can be controlled by changing magnetic fields [3-5]. In MRF brake/clutch the MRF fills the working gap between the fixed stator and the movable rotor, thus the shear stress formed between them and the resulting braking torque can be manipulated by changing magnetic fields [6]. The major two ways to produce magnetic field are electromagnet (EM) and PM. Excited by EM, relation of braking torque and magnetic field with MRF is explored [7] leading to automobile applications [8]. Although EM is easier for controlling the devices, it requires larger space and continuous electric supplement than PM to provide the same magnetic field strength, worsen by high power consumption leading to heat generation and fail-safe power failure issues. On the other hand, although PM is of high magnetic field and compact in size, and no heat and power consumption, the magnetic field control is much difficult. A PM excited MRF clutch in which the transmitted torque can be switched by moving the magnet is studied in [9-10]. In this paper a MRF brake module with mechanical movable shields as magnetic field switches is proposed. This device is designed for brake module of a rotary table for machining tool system. By moving blocks of ferromagnetism steel as magnetic shields, the magnetic field of PMs can be continuously controlled, similar to magnetic stands in which magnetic flux is confined within an iron case when the knob is turned off and vice versa. In this research we adopted this principle by using steel structure as shields. As shown in Fig.1 a pair of PMs is on the both sides of a typical disk type MRF brake module. Each magnet is encircled by two fixed steel shields and two movable ones. The 2D magnetic field of cross section of the device is simulated by Ansoft with 3D model built by this view revolving about the center axis. When the movable shields are closed, the magnets are encircled and thus no outward magnetic flux. When the shields are opened magnetic flux emits and magnetizes the MRF. Then braking torque is produced gradually in response to the opening displacement of the movable shields. Base on the resulting magnetic field the shear force can be obtain, and the braking torque is then calculated by integrating the shear force about its revolving axis. The outer diameter of the brake module is set to be 270mm for dimension restriction, the inner/outer diameters of PMs are 174/218mm and thickness is 24mm. A shield structure of 5mm in thickness is sufficient for magnetic shield purpose, and a displacement of 7mm between on and off states is enough for magnetic switch function. To separate the movable and fixed shields, an optimal edge angle is expected to alleviate the magnetic force between the movable and fixed shields such that the shields could be slip-out by smaller shear force rather than pull out directly by stronger normal force. Relationship of braking torque vs. displacement of movable shields for different edge angles is studied with results shown in Fig.2. The toque-displacement response varies by angle variation. When the edge angels are 0~45°, the curves increase rapidly and different angles result in similar effects. At angles above 45° the torque response rates decrease and become nearly linear to the displacement at the angle between 75~80° within the designed displacement range. For angles more than 80° the rates further decrease and when close to extreme value 90°, where almost no torque is observed for displacements less than 2mm, thus is not suitable for this design. The results indicated that braking torque can be manipulated by giving shield displacement as input and the torque response can be specified by shield edge angle. For manufacture consideration we adopted 60° for the first prototype. An infinite displacement of the moving shield results in a braking torque of 337.4Nm. When opening to 7mm, the resulting torque is 299.5Nm. This indicates that 90% of torque range can be controlled by moving these shields within 7mm. After proper mechanism designed for controlling the movable shields, the proposed MRF brake module will be manufactured and its performance result will be evaluated.

FR-15. Fe_3O_4@Angelica Sinensis Polysaccharides Nanoparticles for Magnetic Resonance Imaging.

X. Xu[1], K. Wang[1], Y. Li[1], Y. Wang[2], J. Wang[2] and Y. Jiang[1]
1. School of Materials Science and Engineering, University of Science and Technology Beijing, Beijing, China; 2. Department of molecular imaging, Peking Union Medical College Hospital, Chinese Academy of Medical Sciences, Beijing, China

The superparamagnetic Fe_3O_4 nanoparticles (NPs) are potential magnetic resonance imaging (MRI) contrast agents.[1] Unfortunately, the exposed Fe_3O_4 NPs have poor solubility and biocompatibility. Therefore, the surface of the Fe_3O_4 NPs needs to be suitably engineered to acquire improved biocompatibility.[2] Angelica sinensis polysaccharides (ASP) are one of the most important component in the roots of angelica, a common traditional Chinese medicine, and possess good water solubility, biocompatibility and the function of increasing hemoglobin.[3] Therefore, it is reasonable to expect the Fe_3O_4@ASP core-shell nanoparticles to have the function of both MRI contrast agents and increasing hemoglobin. In this work, we report our study on the Fe_3O_4@ASP NPs synthesized using a two step approach involving hydrothermal synthesis and consequence esterification. As shown in the TEM image in Figure 1a, the Fe_3O_4@ASP NPs are dispersed spherical with a diameter of about 12 nm. However, the dynamic light scattering (DLS) (Fig. 1b) results in a mean size of about 24.3 nm. Since the molecular composition of ASP contains C, H, O and N elements, which are light elements and invisible in TEM, the DLS result demonstrates the existence of the ASP shell wrapped on the surface of Fe_3O_4 NPs, supported by the results of saturation magnetization decreasing and the FT-IR spectra changes after ASP wrapping shown in Fig. 1c and 1d. Moreover, the Fe_3O_4@ASP NPs take on a outstanding superparamagnetic property, water solubility and stability even after ASP wrapping. Cytotoxicity assessment in Hela cells proved the good biocompatibility and low toxicity of the Fe_3O_4@ASP NPs. The Fe_3O_4@ASP NPs suspension was characterized by MRI. As shown in Fig. 2a, the T_2* signal intensity decreased significantly with increasing Fe concentration. The transverse relaxivity (r_2*) of the Fe_3O_4@ASP NPs are calculated to be 363 $mM^{-1}s^{-1}$, which indicates the Fe_3O_4@ASP NPs to be a promising contrast agents for MRI applications. Fig. 2c presents the T_2 weighted image of mice, and shows no obvious damage in the observed organs after 30 days intragastric administration, which demonstrates the safety of Fe_3O_4@ASP NPs as MRI contrast agents. The study of Fe_3O_4@ASP NPs presents a possibility to design functional nanocomposites using purified natural component from Chinese medicine for biologic applications.

1. Graduate School of Sci. & Tech. for Innov., Yamaguchi Univesity, Ube, Japan; 2. RNBS, Hiroshima University, Higashihiroshima, Japan

Optical interference, which enhances or reduces intensity of light propagating, is very important for many kinds of shape analysis methods. It will be available to detect a morphology change in micro- to nano-scale by using optical interference when we can obtain a new optical material from the animal kingdom. This paper focused on the light interference in biogenic guanine crystals which is derived from fish skin/scale. So far, it has been reported that two cross-stacked guanine crystals show stripe patterns which are produced by the optical interference between guanine crystals[1]. In this study, we have found that a very clear moiré effect pattern is generated on a single guanine crystal plate combining with the mirror surface substrate. The observation system is consisted with telecentric lens and coaxial vertical illumination using blue LED. Guanine crystals in water are set on a mirror polishing Si substrate. Figure 1(a) shows the optical image of guanine crystal plates in water using our observation system. It can be clearly seen that homogeneous light and shade stripe patterns are observed on the plates when the surface of the guanine plates are parallel to the Si substrate reflecting that their very flat surface morphology. By contrast, when the guanine crystals in water are set on the substrates having the diffused reflection surface such as the black vinyl tape and Teflon plate, the light and shade stripe pattern is not observed on the single guanine crystal but observed on two cross-stacked crystals as reported before (Fig.1(b)). These results suggest that moiré pattern on the guanine crystal plate is perturbed or disappears when the substance or the defect which changes the reflective state of the light exists under the crystal plate. Next, we have investigated the response of guanine crystal to the magnetic field by using the moiré pattern to determine that the guanine plate is parallel to the substrate. Furthermore, it makes possible to estimate the quite small angle between the guanine crystals and substrate surface from the pattern period of moiré stripes measured by optical observation system. The time dependences of the ratio of guanine crystals oriented in the horizontal magnetic field direction are measured by changing the magnetic field amplitude as shown in Fig.2. The experimental procedure is as follows: First, the horizontal magnetic field of 500 mT is applied and guanine crystals are aligned as the long axis of the guanine plate is parallel to the field (step A). Next, the vertical magnetic field of 200 mT is applied in order to align guanine crystals as the long axis of guanine plate is orthogonal to the field and the moiré pattern disappear (step B) [2]. From this state, the horizontal magnetic field which is orthogonal to the first horizontal filed is applied and moiré patterns appear again (step C). As shown in the figure, the guanine crystal plates quickly oriented to the horizontal direction with the magnetic field of 350 mT or more. This suggests that the magnetic field operates moiré pattern switching which is effective to obtain a reference signal. The dependence of orientation time of guanine crystal upon the angle between the long axis of guanine plate and horizontal magnetic field and the tilt angle dependence of reflection brightness from the guanine plate will also be presented. This work was supported by JST-CREST "Advanced core technology for creation and practical utilization of innovative properties and functions based upon optics and photonics (Grant number: JPMJCR16N1)".

FS-01. Structural Dynamic Modeling and Optimization for Vibration Control of a Composite Cantilever with Magnetostrictive Shunt Damper.

J. Zheng[1], S. Cao[1] and R. Pan[1]
1. Hebei University of Technology, Tianjin, China

Structural vibrations can cause excessive noise and damage. Piezoelectric, electromagnetic and magnetostrictive (e.g., Terfenol-D, Galfenol) transducers can convert unwanted vibration into electrical energy, thus they can be used as energy harvesters for powering other devices and as shunt dampers for vibration control. The vibration control method using the dampers with shunt circuits becomes more attractive because such lightweight devices do not cause high load effects and require little or no power supply. To increase broadband damping, it is necessary to establish an accurate structural dynamic model of the dampers and optimize parameters of the shunt circuits, which have been extensively studied in vibration control of piezoelectric and electromagnetic shunt dampers [1]-[4]. Recently, magnetostrictive shunt dampers [5]-[9] begin to receive attention. The experimental results show that the dampers can effectively suppress vibration [5]-[7] and the attenuation of transmissibility of 5–15 dB occurs in the wide frequency range from 400 to 800 Hz [5]. Different expressions and models of the dampers are also presented. The electrical energy loss expressions [8] of a damper with shunt resistance Rs and parallel shunt resistance-capacitance (Rs-Cs) circuits are derived by a purely electrical model. Based on the linear piezomagnetic equations, the storage modulus and loss factor expressions [5] of a damper with negative inductance Ls are derived, a damper's electromechanical linear model [9] is established, and general analytical expressions for storage modulus and loss factor [9] of the damper with Rs, Ls and series Rs-Cs circuits are derived. However, the above expressions and models are limited because they neglect structural dynamic behaviors of the devices. Although a dynamic compliance model [9] of a vibrating structure is presented, the validity of the model is not proven. A structural dynamic linear model [7] of a composite cantilever with magnetostrictive shunt damper is established. However, three key model parameters [7] are not related to conventional magnetostrictive properties, thus have to be experimentally determined. A generalized structural dynamic model and optimization for vibration control using the magnetostrictive shunt damper have not been reported. In this paper, the structural dynamic modeling framework of a composite cantilever with the magnetostrictive shunt damper is studied. Based on the structural dynamic equilibrium theory, the linear piezomagnetic equations, the law of electromagnetic induction and the circuit theory, the actuation and sensing equations are established to describe the dynamic behaviors of the mechanical-magneto-electro coupled system. The transmissibility, the effective mechanical-mechanical-electro coupled coefficient, the effective storage stiffness and the loss factor of the system are derived from the proposed model. The stability for the system with Rs, Cs and series Rs-Cs circuits are analyzed. The optimal tuning ratio fopt, the optimal electrical damping ratio ζeopt (the corresponding optimal resistance Rsopt and optimal capacitance Csopt) of the series Rs-Cs circuit are obtained by using H2 optimization criteria to minimize the RMS value of transmissibility. The results calculated by the proposed model for the damper are shown in Fig.1 and Fig.2. In Fig.1, comparisons between the calculated and measured results show that the proposed model can accurately describe the transmissibility frequency response curves of the system with positive resistance Rs and positive capacitance Cs, and can predict the changing laws of the resonant frequency and the peak transmissibility with Rs and Cs. Fig.2 (a) shows that to ensure a better damping performance, Rs should have a limitation of [–60Ω,100Ω] under the stability condition Rs≥–Rc (Rc =460Ω is the inherent resistance of the damper's coil [7]). In Fig.2(b), we can discuss the effects of different electrical damping rations of the series Rs-Cs circuit on the transmissibility. Fig.2(c) shows the damping ration of the peak transmissibility under the series Rs-Cs circuit with optimal resistance Rsopt =55Ω and optimal capacitance Csopt=10μF reaches 90.89%, which is higher than 70.44% under Cs circuit with optimal capacitance Csopt=5μF, and 53.29% under Rs circuit with optimal resistances Rsopt=[–60Ω,100Ω]. The proposed model has clear physical meaning, and can describe the vibration control behaviors of the magnetostrictive shunt damper, thus has very strong practicability.

Zhejiang Province Key Laboratory of Magnetic Materials and Application Technology, Ningbo Institute of Materials Technology and Engineering, Chinese Academy of Sciences, Ningbo, China

Flexible magnetic device is one of the indispensable flexible devices. However, the deformation of the magnetic devices will change the magnetic anisotropy of magnetic materials,[1-3] which will decrease the performance of the devices. A determination of the stress-coefficient of magnetoelastic anisotropy in a magnetic thin film is crucially important not only to the fundamental understanding of the magnetoelastic anisotropy but also to the design and fabrication of novel flexible magnetic devices.[4,5] Magnetic anisotropic constants can be obtained by ferromagnetic resonance (FMR), rotational magneto-optic Kerr effect (ROT-MOKE) magnetotransport measurements *et al*. Among them, anisotropic magnetoresistance (AMR) measurements have been proven to be a simple and effective probe to determine the anisotropy energies in magnetic films. Here, we determined the stress-coefficient of magnetoelastic anisotropy of CoFeB amorphous film by using AMR. The CoFeB films were deposited on the flexible polyvinylidene fluoride (PVDF) substrate with anisotropic thermal expansion coefficient. The uniaxial stress is applied on the films by changing the temperature of PVDF substrate [Fig. 1(a)], resulting in the changing of the magnetic anisotropy of CoFeB amorphous film [Fig. 1(b)-(d)]. On the basis of AMR curves, the angle between the magnetization and magnetic field, and hence the normalized magnetic torque can be derived [Fig. 2(a)-(b)]. Finally, the magnetic anisotropy constants can be precisely obtained by fitting the normalized magnetic toque curves [Fig. 2(c)]. Then, the stress-coefficient of magnetoelastic anisotropy in the amorphous CoFeB film was obtained by fitting the magnetic anisotropy constants in different stress states [Fig. 2(d)]. Our work suggests that the extremely sensitive AMR can provide the detailed contributions of stress-induced magnetic anisotropy constants in flexible magnetic thin films.[6]

FS-03. Modeling and analysis of bistable Galfenol cantilever energy harvester with dynamic elastic magnifier.

S. Cao[1], L. Liu[1] and J. Zheng[1]
1. Hebei University of Technology, Tianjin, China

The magnetostrictive (e.g., Terfenol-D, Galfenol) [1]-[6] and piezoelectric (PZT)[7]-[10] cantilever energy harvesters (CEHs) can replace batteries, and have wide applications in monitors, wireless sensors, and implantable devices, etc. Galfenol, with low brittleness and high tensile strength, is more suitable for bending-mode energy harvesting than Terfenol-D and PZT. However, the performance prediction of Galfenol CEHs is complicated because the devices exhibits nonlinear mechanical- magnetic-electric coupled (NMMEC) behaviors. Moreover, traditional CEHs have bigger electrical output only at resonance. In order to improve traditional CEHs' output performance, a elastic base [7], a dynamic magnifier [8], a bistable CEH [9] and a bistable CEH with an elastic magnifier [10] are introduced to PZT CEHs. Recently, three configurations of Galfenol bistable CEHs (BCEHs) using magnetic attractive force [4], buckled beam [5] and magnetic repulsion force[6] have been proposed to enhance the CEHs' low-frequency broadband performances. The measured results show that half bandwidth of the BCEH using magnetic attractive force between magnets is 1.2 times larger than the traditional CEH without magnets [4], and the frequency bandwidth of a BCEH can be improved from 1.5 Hz to 10.5 Hz by manually adjusting the buckling force [5]. Moreover, different models for Galfenol CEHs are presented, including lumped parameter uncoupled model [2], lumped parameter coupled model [6], finite element uncoupled model [1], finite element coupled model [5] and distributed parameter coupled model [3]. However, it is difficult to maintain the BCEH oscillation in a high-orbit state because the ambient vibration level cannot provide adequate velocity for BCEHs to overcome the potential well barrier. Thus, the BCEH has a lower net available power density than the traditional CEHs [5], and the BCEH has a lower peak open-circuit root mean square (RMS) voltage than the traditional CEHs [6].The performances of a bistable Galfenol cantilever energy harvester with dynamic elastic magnifier have not been reported. In order to maintain the Galfenol BCEH [6] oscillation in a high-orbit state, a new structure combining the BCEH [6] with an dynamic elastic magnifier (DEM), which is called BCEH+DEM, is studied in this paper. The DEM consisting of a mass, a damper and a spring element is added between the BCEH [6] and the base to magnify the base vibration level or acceleration and provide a high excitation level for BCEH so as to jump from low-energy orbit to high-energy orbit. The whole system is subjected to a base acceleration excitation. Based on the structural dynamic equilibrium theory, the piezomagnetic equations, the law of electromagnetic induction and the circuit theory, a 2-degree-of-freedom (2DOF) nonlinear lumped-parameter dynamic model of the BCEH+DEM configuration is derived to exhibit the large-amplitude oscillation behaviors. Then, we can further get the dimensionless dynamic model and determine the model's parameters. The model can be solved to calculate the time-domain and frequency-domain characteristics of the system. When the base excitation acceleration amplitude is 2g and frequency is 100Hz, the output voltage, displacement, velocity and Pioncare map of the BCEH+DEM are compared with those without an DEM (i.e. BCEH [6]), as shown in Fig.1.In Fig.1(d), the red curve represents the high-energy orbit of BCEH+DEM and it oscillates in a large-amplitude periodic motion with output displacement 2.156mm and velocity 400mm/s. The low-energy orbit of the BCEH is shown with blue curve and it shows that the BCEH oscillates in a low-amplitude periodic motion with output displacement 0.33mm and velocity 144.7mm/s. It is clear from Fig.1(a) that the output open-circuit peak voltage of the BCEH is only 0.038V and the output open-circuit peak voltage of BCEH+DEM reaches 1.246V, which is about 32 times higher than that of the BCEH. It is verified that the validity of the proposed BCEH+DEM.

FS-04. Balancing negative and positive expansion effect in dual-phase $La(Fe,Si)_{13}$/α-Fe composite with improved mechanical property.

J. Wang[1]
1. School of Materials Science and Engineering, Nanjing University of Science and Technology, Nanjing, China

Most materials exhibit a positive coefficient of thermal expansion (CTE), which leads to expanded lattices with temperature increases due to the population of higher energy levels of anharmonic lattice vibrations. However, small amount of materials contract upon heating and this phenomenon is called negative thermal expansion (NTE).Up to the present time, NTE has been observed in the well-known ZrW_2O_8 family of materials [1-3], MnCoGe-based alloys [4,5], $PbTiO_3$-based compounds [6,7], ScF_3-based compounds [8],$(Bi,La)NiO_3$ [9] and antiperovskite manganese nitrides [10-12]. $NaZn_{13}$-type $La(Fe,Si)_{13}$-based alloys are widely known to exhibit large negative thermal expansion during the magnetic transition. However, zero thermal expansion, which is more promising towards the utilization, has been rarely reported. Here, we introduce α-Fe phase naturally to compensate the negative thermal expansion of 1:13 phase, and thus achieve zero thermal expansion in $La(Fe,Si)_{13}$/α-Fe composite. It is notable that the sample with x=0 breaks itself during the magnetic transition for its poor mechanical property. In this case, it cannot be machined into regular shapes for the measurement of thermal expansion. Therefore, the average CTEs of the rest 4 samples are measured in this paper. The curves of ΔL/L are shown in Fig 1. Here, the reference temperature is 300 K and the average CTE is calculated by ΔL/(L×ΔT). NTE is observed in the samples with x=4 and 6. The average CTEs of samples with x=4 and 6 reach -9.54×10-6 K^{-1} (278-304 K) and -6.25×10-6 K^{-1} (270-291 K). With the increase of extra Fe in ingredient, a large amount of α-Fe phase appears and distributes in the 1:13 phase. NTE of 1:13 phase is offset by the PTE of α-Fe phase. An extremely low CTE of -6.55×10^{-7} K^{-1} between 261 K and 282 K is obtained in sample with x=8, leading to the establishment of ZTE. Besides the low CTE, good mechanical property is another crucial prerequisite for ZTE or NTE materials. La(Fe,Si)13-based alloys with main 1:13 phase is typical brittle. In this experiment, the cuboid sample used for thermal expansion and stress-strain measurements are processed by diamond wire-sawing. During the machining process, the sample with x=0 will break itself into some small bulks (right inset of Fig. 2, the small bulks are carefully polished for the microstructure observation on SEM), while the other sample are strong enough to be processed (left inset of Fig. 2). This indirectly proves that the increase of additional α-Fe phase can improve the mechanical property. With increasing x, the values of largest yield compressive stress are sharply enhanced to 864, 900, 970 and 1004 MPa for x=4, 6, 8 and 10, respectively (see Fig. 2). The improved mechanical property is highly related with the existence of α-Fe phase. It is known that most brittle intermetallics display intrinsic weakness of grain boundaries and insufficient number of slip systems [13,14]. Therefore, the applied stress will easily broke the weaker links between grains and leads to intergranular fractures. However, this situation will greatly changes when introducing a secondary ductile phase. In this experiment, the distributed ductile α-Fe phase is helpful to prevent the movement and slipping of dislocation, thus hinder the cracks propagation along the weak grain boundaries and enhance the mechanical property. On the other hand, additional Fe atoms suppress the formation of La-rich phase, which is detrimental to the mechanical and corrosion properties. It also contributes to the improved mechanical property. In summary, we successfully fabricate dual-phase La(Fe,Si)13/α-Fe composite. The microstructures, magnetic properties, thermal expansion and mechanical properties of samples are investigated. With the increase of extra Fe in ingredient, a large amount of α-Fe phase appears and distributes in the 1:13 phase. NTE of 1:13 phase is offset by the PTE of α-Fe phase. An extremely low CTE of -6.55×10-7 K-1 between 261 K and 282 K is obtained in sample with x=8, leading to the establishment of ZTE. Additionally, as a reinforcing factor, α-Fe phase is helpful to prevent the movement and slipping of dislocation, thus enhancing the mechanical property. Based on these improvement, ZTE and improved mechanical property are achieved simultaneously in La(Fe,Si)13/α-Fe composite.

1. engineering, University of Sannio, Benevento, Italy

The requirement of self-powered stand-alone sensors or wireless sensor networks (WSN) with a "fit and forget" paradigm, that is, without the need of batteries, seems to have attracted the interest of technological research in last years. Activity in development of devices, Known as Energy Harvesters, able to transform ambient energy into a kind of usable energy were boosted. Among this quite large set of solutions, those able to transform mechanical vibrations into electric power and referred to as Kinetic Energy Harvesters (KEH) are among the most known and studied, [1]. Such special set of self powered systems found a noteworthy interest in the health monitoring of civil structures or in automotive or railway applications, where, in the latter, the KEH potentialities have been identified for low cost self power sensors in freight railway wagons, [2]. Among them, one solution is represented by the cantilever configuration exploiting magnetostrictive materials, [3], based on Fe-Ga (Galfenol) alloys, showing interesting mechanical and magnetostrictive properties, [4]. Vibrations energy spectrums are complex and usually distributed over a quite large frequency range, while, conversely, cantilever KEH work in a relatively narrow band and this requires both modelling and experimental effort in order to provide an "optimal" system tuning. In this paper as a first step, different configurations employing one or more Fe-Ga strips over an Al substrate have been developed and tested through the analysis of a converted RMS power vs. frequency in order to detect the geometric and physical parameters affecting resonance frequency, bandwidth and converted power by Villari effect, [2]. The selected cantilever is implemented by bonding two single Galfenol strips 120X15X0,3 mm to a 120X15X2 mm Aluminium foil. The latter guarantees a better mechanical resistance to cyclic loads and provides a larger stiffness yielding to a consequent increase of the resonance frequency. The device has been equipped by a 300 turns coil, as it can be observed in Fig. 1. Experimental tests were performed with an electrodynamic shaker (Fig. 2a) in the *50-200 Hz* frequency interval with sinusoidal acceleration in the *1-4 g* amplitude range [5]. The excitation level has been detected by a reference accelerometer, while the beam bending is measured by a strain gauge based system. The effect of a resistive load on the RMS converted power is shown in Fig. 2b) where the power response with different resistive loads and 4g acceleration is shown. The best result of 305mW is achivied with a 9,9 W. The low energy conversion required the design of a suitable magnets set in order to supply a sufficient magnetic bias to the active material with the aim to increase the converted power [6]. In order to increase the flux captured by the coil, two magnets were attached to the structure [7]. The field generated by two magnets was measured spanning from 43 kA/m on the upper strip down to 3 kA/m on the lower strip. In Fig. 2c) the effect of the magnetic bias on the RMS converted power is shown. However, it should be outlined that the applied bias is the result of an optimization procedure since, as known, high magnetic biases pushes the material towards saturation and energy conversion is no longer observed [6]. Considering the importance of the bias, tests were carried out by varying the number of magnets (Fig. 2d). In this case it is important to evaluate the position of the magnet on the beam as it influences the resonance frequency and the magnetoelatic coupling [8]. These results seem quite encouraging, due to the relatively high converted energy (37mW) and the simple device structure. However, a thorough and accurate modelling analysis in connection to the experimental data, in order to quantitatively show the dependence of the converted power on geometric and physical parameters will be discussed in the full paper.

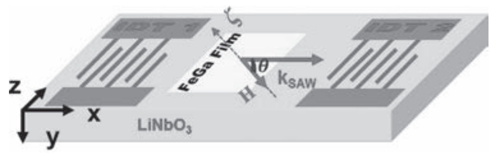
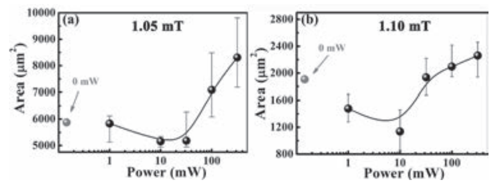
FS-06. Magnetoelastic Coupling Effect on Magnetization in FeGa Film Induced by Surface Acoustic Waves.

C. Zhao[1], L. Pan[1], X. Li[1], Q. Liu[1] and *J. Wang*[1]
1. Key Laboratory for Magnetic and Magnetic Materials of the Ministry of Education, Lanzhou University, Lanzhou 730000, People's Republic of China, Lanzhou University, Lanzhou, China





Surface Acoustic Waves (SAW) devices are attracting increasing interests for their low power consumption, miniaturization, and low-damping to spin wave propagation [1-3]. SAW also can be used to switch magnetization directions in ferromagnetic films by applying a voltage instead of an external magnetic field [4-12], which result in fast magnetization changes in the thin film. In this work, SAW is generated by interdigitated transducers (IDT) on a NbLiO3 piezoelectric substrate, as shown in figure 1. The finger width and a spacing of the IDT was set as 5.5 μm and 5μm, respectively, which is expected to launch SAW with wavelength of 21 μm. Actually, the foundational frequency of SAW has been characterised as about 170 MHz by using VNA with the time domain function. We combine magneto-optical Kerr effect (MOKE) to investigate the propagation of SAW in the magnetic FeGa film, and magnetoelastic coupling effect on magnetization in FeGa film induced by SAW was investigated. In order to confirm the influence of SAW on magnetization process of the FeGa film, MOKE image of magnetic domain was measured and the area of magnetic domain has been calculated to characterize the magnetization process quantificationally, as shown in figure 2. We can find that the input driving power of SAW has an optimal value (about 10 - 15 dBm and with the relationship of Y(dBm)=10lg(X(mW)/1(mW)))), and the magnetization process will be hindered above the optimal value. Image captions Fig. 1 Schematic illustration of the SAW device with 50 nm FeGa rectangle film. There are two IDTs in the device, and the input IDT1 connection to port 1 of VNA is used to generate SAW, and IDT2 connection to port 2 of VNA is used to detect SAW. The LiNbO3 crystalline cut and SAW propagation direction k_{SAW} are along x-axis, which ensure that the maximum strain (stretching strain and compressing strain) amplitude is along the direction of propagation. The effective field due to magnetoelastic coupling effect can be given as,$h_\sigma=(3\lambda_s\sigma)/(\mu_0 M_s)$, where σ is the external stress induced by SAW, is the unit vector in the direction of the external stress. Fig. 2 Area of magnetic domain as a function of driving power *P* at a certain field: (a) H= 1.05 mT, (b) H= 1.10 mT. Before each measurement, the FeGa film is saturated along the axis of ζ at a field of 2.5 mT. After the external field H is reverse and increasing gradually form zero, and the magnetic moments switch from ζ axis to –ζ axis. The area of magnetic domain can be calculated to characterize the magnetization process quantificationally.

FS-07. Mössbauer investigation of magnetostrictive $Fe_{83}Ga_{17}$ with trace rare-earth doping.

P.S. Stamenov[1], Y. He[2], C. Jiang[2] and *M. Coey*[1]
1. School of Physics, Trinity College Dublin, Dublin, Ireland; 2. School of Materials Science and Engineering, Beihang University, Beijing, China

Fe-Ga alloys (Galfenol) are known to exhibit an unusually large magnetostriction, of order 320 ppm, which is attributed to the presence of nanoscale tetragonal Ga-rich $L6_0$ inclusions embedded in the bcc A2 Fe-rich matrix solid solution. The tetragonal axis in a particular nanoinclusion is determined by the orientation of nearest-neighbour Ga-Ga pairs. The distribution of these axes parallel to the three {100} directions means that the maximum magnetostriction can be achieved in a single crystal when the magnetic field is applied parallel to any cube edge. More recently it has been shown that traces of rare-earth atoms, ≈ 0.1 at. %, which can be incorporated into these alloys when they are rapidly cooled, can greatly increase the magnetostriction by a factor of 2 – 3 [1-3]. The mode of action of the trace dopants has yet to be determined. Here we employ Mössbauer spectroscopy in an attempt to gain some insight into the location and mode of action of the trace rare earth dopants. The samples were produced by melt spinning. Precursor ingots of $Fe_{83}Ga_{17}M_x$, with M = La, Nd, Sm, Tb and Tm and x = 0, 0.05 or 0.25 were first prepared from 4N pure Fe and Ga by arc melting under argon four times and annealed at 1000°C in Ar to ensure homogeneity. The ingots were then melt spun on a copper wheel with a surface velocity of 20 ms^{-1}, to obtain ribbons about 50 μm thick, and 5 mm wide. Transverse magnetostriction was measured by the strain gauge method in the direction of the ribbon length, with the field applied perpendicular to the plane of the ribbon. A field of up to 2 T was used to saturate the magnetization. Mössbauer spectra were obtained at room temperature in a conventional constant acceleration spectrometer with a source of ^{57}Co in Rh. The spectrum of undoped $Fe_{83}Ga_{17}$ is shown in Figure 1, together with associated fit to six hyperfine components [3]. It is composed of two main broad overlapping components with hyperfine fields of 31.2 and 26.9 T, associated with iron in the A2 phase with 0 or 1 Ga neighbours [3-5]. They constitute 87 % of the total spectral area, and their ratio is 66:34, compared to a ratio 37:63 expected for a purely random distribution of Ga in the bcc phase. The Ga concentration in A2 on this basis should be 4.8 %, and the remainder is therefore Ga-rich. We identify two minor components with the tetragonal nanoinclusions, which make up 4.8 % of the total volume. One typical example of a doped sample, with 0.5 % La is shown in Figure 2. The sum of the spectra of iron with 0 and I Ga neighbours again represents 87 % of the total area, but the ratio to rises to 68:32, and the amount of iron in the tetragonal nanoinclusions rises to 5.6 % of the total. These are small changes, but they are observed systematically in spectra with five different rare earth dopants. We can therefore conclude that the rare earths serve to increase the volume of nanoinclusions in the sample, and they increase the amount of Ga present in the nanoinclusions. A second conclusion from the data is that there is no significant difference between the 0.05 % and 0.25 % doping, when they are measured for the same dopant. This shows that the solubility limit for the rare earth in these melt-spun ribbons is below 0.05 %. The conclusions are consistent with electron microscopy observations. We consider that the rare-earth dopant is probably initially incorporated into the nanoinclusions and it enhances their tetragonality up to the metastable solubility limit, which is less than 0.05 %. Beyond that, there is no further effect and the rare earth probably precipitates out in a 2:17 or 1:2 phase. In this way we can understand the strong influence of very small amounts of rare earth doping on the magnetostriction of $Fe_{83}Ga_{17}$.

Terfenol-D is a kind of magnetostrictive material that couples magnetic and mechanical energy. It exhibits giant magnetostriction (~1600ppm), giant energy density (25kJ/m^3) and broad bandwidth (~30kHz). It is the core component of giant magnetostrictive transducer (GMT) which has been widely used in the field of ultra-precision machining, precision fluid control and underwater exploration. These applications require GMT to work in a high frequency excitation state. However, when the GMT operates at high frequency magnetic field, hysteresis loss, eddy current loss and Joule's heat energy lead to serious temperature rise. The temperature of Terfenol-D rod can reach above 120°C without a cooling device. The temperature rise of Terfenol-D rod seriously affects the output properties of GMT. So, it is necessary for GMT to analyze vibration model with electromagnetic-mechanical-thermal multi-field coupled effects at high frequency. A time-dependent nonlinear electromagnetic-mechanical-thermal multi-field coupled high frequency vibration model for GMT is established based on Jiles-Atherton model, Armstrong model, Maxwell's equations, Newton's law and Fourier's heat transfer equation. Firstly, the temperature-dependent Terfenol-D dynamic magnetization model is established by a hybrid Jiles-Atherton/Armstrong magnetization model. It includes two parts: numerical integration of the function for anhysteretic magnetization in anisotropic Terfenol-D material; solving of ordinary differential equation for calculating *dM/dH*. The magnetization can be calculated for uniaxial anisotropy Terfenol-D rods when they are subjected to an external magnetic field and stress. The implementation of this algorithm is made in MATLAB. Secondly, a 3-D simulation of the whole GMT working process is programmed using commercial finite element software COMSOL Multiphysics. In order to realize the real-time temperature dependence material properties, the calculated magnetization curve at different temperature of the Terfenol-D is introduced into COMSOL by calling MATLAB files. In this method, the proposed model considers the compositive effect of magnetic, stress and temperature. It also describes the influence of pinning loss, eddy current loss and the magnetocrstalline anisotropy. In order to verify the vibration model, the vibration characteristics of the Terfenol-D rod and the output rod of GMT are measured by means of the test platform, as shown in Fig.1. Combined with the typical application of GMT in underwater acoustic frequency bands, a GMT is designed and fabricated. Its resonant frequency is 6400Hz. The GMT consists of two Terfenol-D rods with 15 mm in diameter and 102 mm in length, two drive coils, disc spring, adjusting nut, output rod, magnetic yoke and shell. Meanwhile, a new temperature control device of high flowing velocity double cavity cooling cycle system is designed. It includes the circulating oil cooler, mass flowmeter and double cooling cavity. The Terfenol-D rod is surrounded by exciting and bias coils. The magnetic circuit is closed through an annular magnetic yoke. Disc spring and adjusting nut allow the Terfenol-D to be placed under a variable prestress. The GMT is cooled by a turbulent cooling medium flow in an internal double cavity cooling channel. The cooling channel is formed between coil skeleton and Terfenol-D rod, coil skeleton and external magnetic yoke where the temperature rise of the transducer is most serious. The cooling medium is dimethyl silicone oil. It is compression refrigeration by circulating oil cooler. Then it flows from the inlet of cooling channel to outlet. The flowing velocity of cooling cycle system can be as high as 20 L/min. The temperature of GMT is controlled to below 22.3 °C. Fig.2a shows the relationship between the amplitude of output displacement and frequency in the conditions of 800 N prestress, 2 A excitation current and 5 A bias current. When f<6400Hz, the amplitude of the output displacement increases with increasing frequencies; When f=6400Hz, the output amplitude reaches the maximum value, the amplitude reaches 49 μm; When f>6400Hz, the amplitude of the output displacement decreases with frequency increases. It can be seen that the measured resonant frequency is 6400 Hz. Therefore, the driving frequency has a great influence on the output displacement. A real-time vibration acceleration of the Terfenol-D rod at 6400 Hz is shown in Fig. 2b. The measured vibration acceleration is 20 m/s^2. The mechanisms of the output acceleration, stress and displacement at the different excitation amplitudes and frequencies have been analyzed. The vibration characteristics of GMT will be tested under conditions of variable temperatures. This research can provide theoretical guidance for design and precise controlling of magnetostrictive devices at high frequency.

FS-09. Concurrent inverse effects of magnetostriction and electrostrictionin magnetoelectric layered structures.

B. Zadov[2], *M. Auslender*[1] and E. Liverts[3]

1. Electrical and Computer Engineering, Ben Gurion University of the Negev, Beer Sheba, Israel; 2. Electrical and Computer Engineering, Ben Gurion University of the Negev, Beer Sheba, Israel; 3. Department of Mechanical Engineering, Ben Gurion University of the Negev, Beer Sheba, Israel

The structures comprising intermittently bonded (laminated or deposited) magnetostrictive and piezoelectric layers attract a keen interest in sensor applications since they exhibit strong strain-mediated magnetoelectric (ME) coupling [1]. The bonding compliance exerts hidden stresses on the structure's layers that cause changes in their properties at *no* mechanical load. We termed such effects in the ME structures concurrent *inverse effects of magnetostriction and electrostriction* (IEME), similarly to inverse effect of magnetostriction in ferromagnetic magnetostrictive materials [2], where it means a change in the magnetic anisotropy, and so the magnetization curve under external stresses. We studied theoretically and experimentally IEME for a laterally wide bi/tri-layer ME structure. Our theory is based on minimization of the total energy including bare elastic [3], magnetic-anisotropy and magneto-elastic energies [4] under the strains matching and zero-mean traction conditions at the layers interfaces and facets, respectively. Unlike the previous theories [4, 5], our theory involves also the *shear* strain and traction. We predicted IEME of the following types: (i) a latent-stress induced magnetic anisotropy unnoted previously [5, 6]; (ii) a decrease of the ME coupling coefficient [5] *below* the values obtained previously [5, 6], which may make a slipping correction factor [6] to be redundant; (iii) a decrease of the dielectric permittivity of the piezoelectric layer(s) larger than in the previous theories [5, 6]. Our materials were Alfa Aesar 99.95% purity polycrystalline Ni foil and APC-844 ceramic lead zinc titanate (PZT). Two 20x20mm^2 area samples with 0.5 mm thick Ni and 0.83 mm thick laminates were used for the magnetostriction measurements, and a pair of 5x2 mm^2 area samples with 0.25 mm thick Ni and 0.58 mm thick laminates, for the magnetization measurements. The magnetostriction was measured with Vishay Micro-Measurements two-axis SR-4 strain gauges. The room temperature magnetization curves were obtained with a Physical Properties Measurement System (PPMS) machine. The type (i) IEME is seen in Figs.1 and 2 which show the magnetization and strain curves of the above Ni layer and the Ni/PZT laminate, respectively. A notable decrease of the initial susceptibility and magnetic saturation lag in the laminate, compared to the bare Ni layer is observed in Fig.1 and similar effects for the magnetostriction in Fig.2. Except reduction of the ME coefficient α, as compared to the Harshe et. results [5], we predicted a shift of the magnetic bias of the α maximum abou twice that predicted from differential magnetostriction of the standalon Ni layer ~ 68 Oe, see in Fig.2, as assumed in previous theories [5, 6]. Our theoretical results on all above noted IEME agree well with the expriment.

FS-10. Experimental and Calculating Analysis of High Frequency Magnetic Energy Losses for Terfenol-D Magnetostrictive Material.

W. Huang[1], C. Gao[1], B. Wang[1] and Y. Li[1]
1. Hebei University of Technology, Tianjin, China

Magnetostrictive terbium-iron-dysprosium alloys (Terfenol-D) exhibit strong coupling between magnetic and mechanical energies. Terfenol-D generates giant magnetostriction (~1600 ppm) combined with a large energy coupling factor (0.75) and fast dynamic response (20 kHz). Hence, Terfenol-D is widely used in dynamic applications such as sonar transducers, ultrasonic devices, linear motors, and micropumps and microvalves[1]. These applications require Terfenol-D working under high frequency excitation conditions. At present, the study of experimental and calculating analysis of high frequency magnetic energy Losses for Terfenol-D magnetostrictive material mainly focuses on low frequency excitation[2-3]. The traditional losses are divided into hysteresis losses and eddy current losses. The currently available core losses calculation formulae do not take the impacts of frequency and flux density on the loss coefficients into account at high frequency and high flux density[4]. These are only suitable for low frequency excitation conditions. Therefore, it is necessary to deduce high frequency magnetic energy losses calculation formulae[5]. In this paper, Several Terfenol-D samples were made into square annular sheets. They were tested with different thickness, different types and different magnetization direction. The values of magnetic energy losses were measured to investigate its variation under different driving magnetic field and different magnetic density. Based on a great deal of experimental data, we proposed an improved losses calculation formula, which can reflect the hysteresis losses, eddy current losses, anomalous losses and losses coefficient. The formula also takes the influence of eddy current skin effect and the dynamic hysteresis loop into consideration. The results show that the losses calculated by the proposed formulae have a good consistency with the measured data. The proposed method can improve the computation accuracy obviously, and reduce the maximum error from 30% to 10%. The results of the calculation and experiments show that: 1. For the Terfenol-D samples, high frequency magnetic energy losses are measured, as shown in Fig. 1. When the frequency is 5kHz, the losses increase from 2.742 to 218.322W / Kg as the flux density varies from 0.01to 0.13T. The losses increase 79.62 times. When the flux density is 0.05T, the losses increase from 8.138 to 319.428W/Kg as the frequency is from 1kHz to 20kHz. The losses increase 39.25 times. The results show that: the losses will increase rapidly with the increasing frequency. Moreover high flux density has great impact on the losses of Terfenol-D. 2. The separation losses are obtained when the flux density is 0.05T according to experimental data and the calculation formula, as shown in Fig. 2. When the frequency increases from 1kHz to 20kHz, the eddy current losses increase from 0.27W/Kg to 117.51W/Kg. More calculating results show that the proportion of hysteresis and eddy current losses are higher, and the anomalous losses are relatively lower. The proportion of hysteresis losses decrease slowly with the increasing of frequency. And the proportions of the eddy current losses increase more quickly than the proportion of anomalous losses. This variation tendency can be explained by the theoretical calculation. Hysteresis losses and eddy current losses are mainly influenced by Bm2, anomalous losses is mainly affected by Bm3/2. The trend of calculating result is consistent with that of the experimental one. Under a given flux density, the eddy current losses change with f 2, and the hysteresis changes with f, meanwhile the anomalous losses are affected by f 3/2. So the eddy current losses change the fastest. The total magnetic losses show the trend of numerical increase and accelerated growth.

FS-11. Magnetoelectric surface acoustic wave characteristics of the ScAlN/FeGa heterostructure with negative Poisson's ratio.

J. Jiang[1] and *F. Bai*[1]
1. State Key Laboratory of Electronic Thin Films and Integrated Devices, University of Electronic Science and Technology of China, Chengdu, China

Magnetoelectric (ME) heterostructures of magnetostrictive/piezoelectric laminates and films contains enormous opportunities in spintronic memory, gyromagnetic-field sensor, transformer, energy harvester, electrical field tunable RF/microwave devices, etc. Recently, the traditional static and dynamic ME effects have been extended to high frequency ME effects,[1] such as electrical field induced ferromagnetic resonance frequency shift and magnetic field induced acoustic resonance frequency shift of surface acoustic wave (SAW) [2] or bulk acoustic wave (BAW) [3]. The former is related to the magnetic anisotropy of the magnetic layer mediated by piezoelectric stress or ferroelectric domain transformation, and has very important applications in tunable RF/microwave devices. The later can be attributed to the piezoelectricity and elastic anisotropy of the piezoelectric layer alternated by magnetoelastic modulus (ΔE) effect, and can be used in ultra sensitive DC magnetic field detection and NEMS antenna. [3-4] In current work, we have investigated the magnetoelectric SAW characteristics of a novel piezoelectric/magnetostrictive heterostructure, i.e. ScAlN/FeGa laminates. Sc doping in AlN can result in more than 400% increase in piezoelectric constant. [5] Galfenol ($Fe_{1-x}Ga_x$ with $12<x<33$) alloys has giant magnetostriction up to 400 ppm under a low driven field between 150 and 250 Oe. Of particular interest is that Galfenol is also auxetic in the <110>{100} direction. A negative Poisson ratio of as low as -0.7 has been reported under either elastic load or magnetic field. [6,7] Fig. 1 (a) and (b) shows the magnetic field dependent modulus of $Fe_{81.7}Ga_{18.3}$ along the <100>{100} direction and <110>{100} direction, measured by a mechanical resonance/antiresonance method. As can be seen in Fig. 1(a), a giant ΔE about 25% and a maximum dE/dH close to 600 MPa/Oe were obtained in the <100>{100} direction. Due to the higher elastic modulus, the ΔE effect along the <110>{100} direction is only ~3%, and the corresponding $(dE/dH)_{max}$ is 80 MPa/Oe (Fig. 1b). Fig.2(a) shows the phase velocity dispersion of the ScAlN/(100) $Fe_{81.7}Ga_{18.3}$ half space calculated by a scattering matrix method.[2] The SAW was designed to propagate along the [110] direction. As can be seen, only the basic Rayleigh mode was found due to the softening of the ScAlN layer by the FeGa substrate with the lower modulus. The phase velocity increases smoothly from 3009 m/s to 3296 m/s with increasing f^*H_{ScAlN} up to 1.58 GHz*μm. But then the curve is broken between 1.58 and 4.6 GHz*μm, indicating that even the basic Rayleigh wave mode cannot be excited. In this sense, there is a cutoff modulus for metallic magnetostrictive substrate, which sets an upper limit on the product of piezoelectric layer thickness and the SAW center frequency. For example, the upper limit of f^*H_{AlN} for AlN/FeSiB heterostructure is only 0.18 GHz*μm, since the lowest Young's modulus of FeSiB is ~60 GPa upon applying magnetic field. This is why the [100] direction was not selected for SAW design, even that the ΔE effect is very large. However, due to the contribution of negative Poisson's ratio, Galfenol alloys with high Ga concentration all have very large f*HScAlN greater than 0.9 GHz*μm, even though the modulus $Fe_{81.7}Ga_{18.3}$ of is as low as 68 GPa, as shown in Fig. 2(b). Note that the modulus and Poisson's ratio data come from Ref. [6]. Finally, we have deposited highly c-axis oriented $Sc_{0.29}Al_{0.71}N$ film on a polished $Fe_{81.7}Ga_{18.3}$ alloy with a 50nm-thickness Ti buffer layer. The full width at half maxiumu of the (002) rocking curve is 3.6°. A one-port SAW resonator was then patterned on the ScAlN surface via a lift-off photolithography techniques. The measured wavelength was 15.76 μm. The characterization of the SAW resonator was performed by measuring S_{11} parameters as a function of frequency using a vector network analyzer (Agilent N5230A) and a microwave micro-prober. It was found that the resonance frequency f_r appeared at 208.87~218.75 MHz, corresponding to a phase velocity in the range of 3292~3448 m/s.

FS-12. Tuning ferromagnetic properties of $LaMnO_3$ thin films by oxygen vacancies and strain.

Y. Liu[1], H. Wong[1], K. Lam[1], C. Mak[1] and *C. Leung*[1]
1. Department of Applied Physics, The Hong Kong Polytechnic University, Hong Kong, Hong Kong

The compound of $LaMnO_3$ (LMO) is an archetypal manganite for investigating the interface coupling when adjoining with other complex oxides [1-3]. Although showing an A-type antiferromagnetic (AFM) insulating ground state in bulk [4], LMO thin films in heterostructures tend to exhibit ferromagnetic (FM) behavior [1-3]. This unexpected FM behavior has gained renewed interests recently [5-8]. In this work, we fabricate a series of LMO thin films on $SrTiO_3$ (STO) substrates with different oxygen pressures (P_{O2}) from 0.2 to 200 mTorr and systematically studied their magnetic properties. LMO/STO films deposited at low P_{O2} (20 mTorr or below) show obvious enhancement of coercive field (HC) that can reach up to 30 times that of LMO film deposited at 200 mTorr (Fig. 1(a)). On the other hand, exchange bias effect is observed in LMO/STO samples with $P_{O2} \leq 20$ mTorr (Fig. 1(b)). H_C and H_{EB} decrease with rising measurement temperature, and H_{EB} vanishes at the blocking temperature (T_B, about 60 K). Fig. 1(c) shows dependence of H_C and H_{EB} on P_{O2}. Obviously, HC and HEB show similar variation with PO2, such that HC and HEB firstly increase with decreasing PO2 and then remain constant. On the other hand, we deposited the LMO films on different substrates [$LaAlO_3$ (LAO), $(LaAlO_3)_{0.3}(Sr_2AlTaO_6)_{0.7}$, STO and $KTaO_3$] at 20 mTorr, to investigate the strain effect in FM properties of LMO film grown on low oxygen pressure. X-ray diffraction measurements indicate LMO films shows epitaxial growth but with strongly tensile, weakly tensile, more weakly tensile, and strongly compressive strains, respectively (Fig. 2(a)). Fig. 2(b) exhibits the field cooling *M-T* curves of LMO films upon cooling field, both the measured and cooled field are 1 kOe. The saturation magnetization of LMO films under strong compressive or tensile strains are much smaller below 100 K, and the magnetization of LMO/LSAT is slight smaller than that of LMO/STO. Fig. 2(c) depicts the hysteresis loops of LMO films on different substrates (hence strain states) at 3 K. All the samples were field cooled in a 2 T external field from 300 K to 3 K. It can be seen that the *M-H* loops of highly-stressed LMO films (with LAO, LSAT and KTO) are much narrower than that deposited on STO, and only in LMO/STO do H_C enhancement and the "kinked" behavior in *M-H* loop prevail. The temperature dependence of magnetization for LMO films deposited at 20 mTorr is consistent with the strain state of LMO films on different substrates. When the LMO film is slightly strained it shows robust ferromagnetic behavior, and the compressive or tensile strain will result in the progressive reduction of magnetization in LMO film. Theoretical investigated on the LMO films also indicated that a large cooperative coupling of Jahn-Teller distortion to oxygen-octahedron rotations has a significant effect on its magnetic property, which can be manipulated by the epitaxial strain [9]. Our results confirm the magnetic properties of LMO thin film are closely related to the deposited oxygen pressure and substrate, and the enhanced coercive field and exchange bias are attributed to the competition between different magnetic phases induced by oxygen vacancies and strain-induced Jahn-Teller effect. 1. Chungnam National University, Daejon, The Republic of Korea

Recently, with the expansion of the DIY industry worldwide, the development of lithium ion battery manufacturing technology has accelerated the trend of lightweight and miniaturized power tools, and the share of portable power tools having special functions is gradually increasing in the electric tool industry. As the market share of such portable power tools has increased and international metal prices have continued to rise sharply, conventional DC motors have been replaced by high-speed permanent magnet motors with high output and efficiency in the power tool industry for mass production. This paper presents the magnetic field analysis of an interior permanent magnet (IPM) motor conducted by the equivalent magnetic circuit (EMC) method and consuming a small amount of computational time. The IPM motor has a specific rotor shape with embedded permanent magnets as shown Fig 1. (a). Magnetic saturation is generated by the permanent magnets and the rotor shape, which affects the magnetic flux density distribution in the air-gap of the IPM motor and its characteristic. The simplified analysis model for the EMC analysis is presented in Fig 1. (b). This study analyzed the magnetic field characteristic of the IPM motor by using an EMC, which was designed with consideration of the magnetic saturation in the bridge region. The EMC is shown in Fig. 1. (c), and the concept for considering the magnetic saturation in the bridge region is shown in Fig 1. (d). The validity of the analysis method was verified through a comparison of the finite-element method (FEM) analysis results. Fig. 2 (a) shows a prototype which was designed and fabricated based on the EMC method considering the bridge region magnetic saturation. The measurement system for the validation of the analysis method is shown in Fig 2(b). The results obtained by measurement, the EMC method, and FEM analysis were compared, and the validity of the analysis method was demonstrated, as shown in Figs 2. (c), (d). The results are discussed in detail in the full paper. This work was supported by the Basic Research Laboratory (BRL) of the National Research Foundation (NRF-2017R1A4A1015744) funded by the Korean government.

Abstract: This paper proposes a coupled finite element analysis of magnetic and thermal fields using object-oriented and adaptive single-mesh methods. A fine mesh is built for both magnetic and thermal analysis to avoid errors of data transfer and mesh reconstruction. An adaptive meshing method based on master-slave definition is employed to simplify the origin mesh into magnetic and thermal mesh according to their field characteristics. Object-oriented method is used for a flexible customization in programming architecture. A permanent magnet machine is introduced to test the proposed coupled analysis method. I. Introduction Recently, requirements of high power density and compact structure have been claimed for electric machines with extensive applications of military, transportation, aeronautics and astronautics, etc. Thermal analysis has become a key factor which affects the system reliability in machine design and optimization process. Lumped parameters, finite element analysis (FEA), and computational fluid dynamics have been widely used for thermal analysis. Normally, losses in machines are calculated by magnetic analysis using FEA and then imported as heat sources into the foregoing thermal analysis models [1-2]. Various researches have proved that FEA can achieve transient reasonable results for magnetic and thermal analysis with an acceptable efficiency using adaptive method, shape optimization, etc. [1-4]. However, there is still lots of problems during coupled analysis using commercial FEA software, such as massive computing effort, customized settings, iron loss calculation under non-sinusoidal magnetization, errors by data transfer and mesh reconstruction, etc. [5-6] According to the characteristics of field distribution, the meshing requirements of magnetic and thermal analysis can be quite different. This paper proposes an adaptive single-mesh method for coupled FEA. Firstly, a relatively fine mesh is built for both magnetic and thermal analysis to avoid errors by data transfer and mesh reconstruction. Then, an adaptive meshing based on master-slave method is employed to reduce matrix order for non-linear transient iterative calculation process. Moreover, object-oriented method is applied to optimize the programming architecture for flexible customization in coupled analysis [7]. Finally, numerical results are obtained using proposed method with low computing effort. II. Coupled FEA Method Finite element variational equations of thermal field based on Galerkin method was employed. During the non-linear transient analysis, cubic spline interpolation was used to describe the non-linear permeability of silicon steels, and Newton iterative method was used to gain approximate solutions of non-linear equations. Object-oriented method was employed to built a programming architecture, including data classes of model data and computing data. The model data consisted of elements, nodes, material properties, boundary conditions, excitations, etc. The computing data was comprised of matrixes and vector results. For the coupled FEA, a fine mesh of triangular elements was built, from which both magnetic mesh and thermal mesh could be converted with some elimination. According to the original mesh, zero order approximate solution of the magnetic field was calculated and posteriori errors was then estimated according to the distribution. An adaptive meshing was applied to simplify the original mesh by eliminating internal nodes which satisfied error verification requirements. A diagram of master-slave definition is illustrated in Fig. 1. Node 5 was defined as a slave node when Eqn. (1) was satisfied. The solution of node 5 could be described as a function of its master nodes 2 and 3 in Eqn. (2). $\mathrm{abs}(A_5-(m_{25}*A_2+m_{35}*A_3))<\xi$ (1) $A_5= m_{25}*A_2+m_{35}*A_3$ (2) where A_i denoted the magnetic vector potential of node i. m_{jk} denoted the influence weight coefficient of node j on node k. ξ denoted the upper limit of specified error. The magnetic mesh was reconstructed from the original mesh by eliminating all salve nodes from the computing matrixes. Based on this magnetic mesh, results of master nodes could be gained and then applied for calculation of slave nodes. Area-weighted losses were gained using loss models in all elements of the original mesh. Similar to the magnetic analysis process, zero order approximate solution of the thermal field based on the original mesh was obtained, followed by a simplified thermal mesh using the master-slave method. Thus, coupled FEA was achieved using an adaptive single-mesh method to avoid errors of data transfer and mesh reconstruction. III. Results and Conclusions A classical permanent magnet machine was introduced to test the proposed coupled FEA method. 2-D analysis was carried out and results were presented in Fig. 2 using software GID. Despite the massive computing efforts of zero order solution based on the original fine mesh, the cost of the non-linear transient process was reduced by 8% using the master-slave method. More results along with more details about the programming architecture and loss models will be presented in the full version of the manuscript.

Abstract :This paper presents an analysis method for a double salient linear machine with transverse flux for high force density. By employing mutually coupled windings, the utilizations of the magnetic and electric circuits are increased as well as the airgap flux density. The effects of tooth pitches of the translator and stator on the force output under a constant volume have been explored based on a rapidly simplified circuitry. Moreover, the electromagnetic features of the proposed machine are simulated and compared with that from 3-D finite element method including the waveforms of magnetic fluxes, inductances, and induced voltages. The correctness of the proposed analysis method is also confirmed by experimental results. I. Introduction The transverse flux machines are comparative candidates with axial flux ones requiring high force density within the restricted space of system[1,2], especially for linear drive industries like rail transportation systems[3], aviation actuator systems[4] and aircraft launch systems[5]. The transverse flux linear machine system gets rid of the intermediately transmission mechanisms and decouples the electrical loading and magnetic loading to obtain a higher force density. In this paper, a double-salient cylindrical linear machine with transverse fluxes (DLMTF) is proposed to enhance the airgap flux by mutually coupled windings in a constant volume of the motor. Based on the 3-D magnetic field distributions, a 2-D analysis approach is proposed to effectively calculate the magnetodynamic performances. Moreover, the design method to maximize the force-density is presented and verified by simulation and experimental results. II. Magnetostatic and magnetodynamic Analysis The structure of the proposed DLMTF is shown in Fig. 1. It has 8 poles in the radial directions and combination of 6/4 poles in the axialdirections. The stator and translator core are double salient and laminated along the axial directions perpendicular to each flux path. Every two phases of integrated coil windings are inserted into the slot of the one united translator block. The two phases of integrated windings in one translator block can maximize the mutual inductance and increase the utilizations of magnetic circuits. Furthermore, the copper loss can be effectively reduced due to the decreases of the end-coil parts. A. Analysis of DLMTF To obtain an accurate electromagnetic analysis of the proposed DLMTF with 3-D magnetic flus paths, a 3-D numerical analysis method should be adopted. However, the 3-D analysis is time consuming in the initial design stage. Therefore, a simplified circuitry shown in Fig. 2 is proposed considering the axial symmetry of the DLMTF machine. In the proposed circuitry, magnetic fluxes from the magnetomotive force of the PM and translator currents flow radially across the airgap, link coils on the translator block and shape complete loops over the aligned or unaligned poles. B. Analysis of DLMTF and drive system To identify the magnetic properties of the DLMTF, the magnetic circuit model combining with the external circuit is given in Fig. 2. Each branch in the asymmetrical half-bridge converter includes the corresponding resistance and inductance. The inductance is calculated from the magnetic circuit model. According to the circuitry, the field distributions, the inductance, induced voltage, flux and force varying with translator positions can be calculated and verified by the 3-D FEM. III. Design improvements of high force density From the proposed circuitry, it can be seen that the field morphology is similar to the transverse switched reluctance machine but much higher airgap flux in a constant volume due to the mutual inductances. As shown in Fig. 1, the translator and stator has available space for teeth extensions in the radial and axial directions under a certain volume of the machine, which lead to increased fluxes for every magnetic loop. However, the increased tooth pitch of the translator and stator will decrease the window area in the axial direction and limit the electrical loading due to the translator current. In addition, the teeth pitch has significant effects on the flux varying with translator positions. Therefore, teeth pitches of the translator and stator have major influences on the power-density. In order to obtain a high force density design, the reluctances of each component in the magnetic circuit in Fig. 2 are expressed by the tooth pitch and the relationship between the force and the teeth pitch is deduced and verified by 3-D FEM. IV. Experiment and discussion To verify the accuracy of the simulated results, a DLMTF prototype is manufactured and the test bench is set up. At different translator positions and saturation conditions, the flux, induced voltage and inductance can be measured and compared with the simulation results. V. Conclusions A transverse flux double salient linear machine is proposed and analyzed by using an accurate and rapid circuitry in this paper. According to the simplified analysis method, tooth pitches of the translator and stator give different force output under a certain volume. And a design with the higher force density is given based on the deduced relationship between the force and tooth pitches. The validity of the proposed analysis method, the properties of a prototype are measured in the laboratory and compared with the simulation results. In full papers, an extended analysis and experimental results will be illustrated in detail.

FT-04. Electromagnetic Analysis of a Balanced Armature Receiver Considering Fringing Flux Effect by Lumped Parameter Method.

D. Xu[1,2], Y. Jiang[2] and S. Hwang[2]

1. School of Mechanical Engineering and Automation, Shanghai University, Shanghai, China; 2. Mechanical Engineering, Pusan National University, Busan, The Republic of Korea

1. Introduction With the increasing market demand for balanced armature (BA) receivers due to their small size and premium performance, an effective analysis method with high accuracy is required to design BA receivers. Jensen et al. [1, 2] investigated the distributions of nonlinear magnetic characteristics, such as the cogging force, force factor, inductance and speedance, by lumped parameters method (LPM) while treating the relative permeability of soft magnetic materials as infinite to disregard the reluctance of soft magnetic materials. Xu et al. [3, 4] improved upon the study of Jensen by considering the reluctance of soft magnetic materials with nonlinear relative permeability of soft magnetic materials, and verified the analysis results by finite element method (FEM). However, both Xu and Jensen only considered the magnetic flux follows the particular intended path in the magnetic circuit, and did not consider the effect of fringing flux, flux leakage and magnetic refraction flux. The comparison of nonlinear magnetic characteristics with Jensen's method, Xu's method and FEM in [3, 4] states that the results of Xu's method are much improved from those of Jensen's research, but there is still a gap needs to be improved in the situation of large current and large vibration displacement, which is caused by the influence of ignored fringing flux, flux leakage and magnetic refraction flux on the saturation of soft magnetic materials. Even though the electromagnetic analysis of Xu et al. [5, 6] by 3D FEM is more accurate, significant time is required in the analysis. The fringing flux [7] is generated in the air gaps in the magnetic circuit of a BA receiver, where the magnetic flux lines repel each other and bulge outward when passing through. Thus, the cross-sectional area and the effective length of air gap are increased, and the total flux in air gap is changed. As a result, the flux linkage passing through the armature calculated by the flux of air gap is also affected. Therefore, the distributions of the nonlinear magnetic characteristics calculated by the flux density of air gap and the flux linkage passing through the armature are influenced by the fringing flux effect. 2. Analysis method In previous research [3, 4], only the reluctances of permanent magnet (PM), air gap, armature and magnet housing are considered, the equivalent 2D modeling of magnetic circuit is shown in Figure 1 (a) and the equivalent magnetic circuit (EMC) is presented as Figure 2. Except for considering the fringing flux effect, two improvements are also completed in this study compared with previous research [3]: one is that one more part of reluctance on the armature arm is added, the other is that two different nonlinear material properties are used for armature and magnet housing. The flux line distribution at equilibrium position without current is depicted in Figure 1 (b), and the Figure 1 (b) depicts that the fringing flux areas generated in the air gaps are different on the right and left side because of the influence of the armature on the left side. Therefore, four reluctances of fringing volume are considered, as shown in Figure 1 (a). The ratio of the mean width of the cross-sectional length to the air gap [7] on the left and right are defined as "a" and "b", and the ratio of the mean MPL of the fringing flux to the air gap [7] on the left and right are defined as "c" and "d". Thus, the mean width and length of fringing flux on each side is shown in Figure 1 (b), and the EMC of the modeling considering fringing flux is added as pink color in Figure 2. Magnetic equations can be obtained by Kirchhoff's current law and Kirchhoff's voltage law with eight nodes and three loops. The flux density and flux can be obtained by solving those equations, and then the total force acting on armature and the induced back EMF can be calculated. Finally, in the same manner as [3, 4], equations of the nonlinear magnetic characteristics can be obtained, and the distributions in variation of vibration position and current can be obtained by iterations with under-relaxed Newton-Raphson method. The distributions obtained by the previous research method [3, 4], the improved method considering fringing flux effect in this study and 2D FEM used to verify the results will be compared and presented in the full paper. It can be predicted that the distributions of nonlinear magnetic characteristics are much more close to those obtained by FEM when considering fringing flux. 3. Conclusion This study presents the effect of fringing flux on the distributions of nonlinear magnetic characteristics of a balanced armature receiver by lumped parameter method. The nonlinear magnetic characteristics can be established by solving the nonlinear equations obtained from the equivalent magnetic circuit. The distributions of the nonlinear magnetic characteristics in variation of vibration position and current could be obtained by iterations with under-relaxed Newton-Raphson method. Compared with the distributions without considering fringing flux, the distributions considering fringing flux will be much more close to those obtained by 2D finite element method. Therefore, the analysis method in this study could provide valuable information with high accuracy and save significant simulation time in electromagnetic analysis of balanced armature receivers.
